# CONTENTS

## PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

	PAGE
I.—The Action of Hydrogen Sulphide on a Neutral Solution of Potassium Permanganate. By HORACE BARRATT DUNNICLIFF and SUKH DAYAL NIJHAWAN . . . . .	1
II.—Preparation of 1-Halogeno-2-nitronaphthalenes and 2-Nitronaphthalene. By HERBERT HENRY HODGSON and ERNEST KILNER . . . . .	7
III.—The Influence of Carbon Rings on the Velocity of Reactions involving their Side Chains. Part I. The Hydrolysis of Cyclic and Open-chain Malonic Esters. By RICHARD GANE and CHRISTOPHER KELK INGOLD. . . . .	10
IV.—Tesla-luminescence Spectra. Part VI. Some Amino-derivatives. By WILLIAM HAMILTON McVICKER, JOSEPH KENNETH MARSH, and ALFRED WALTER STEWART . . . . .	17
V.—The Solubility of Sodium Iodide in Ethyl Alcohol. By FREDERICK ERNEST KING and JAMES RIDDICK PARTINGTON . . . . .	20
VI.—The Structure of the Normal Monosaccharides. Part III. Rhamnose. By EDMUND LANGLEY HIRST and ALEXANDER KILLEN MACBETH . . . . .	22
VII.—The Specific Heats of Hydrocyanic Acid. A Reply. By EDITH HILDA INGOLD . . . . .	26
VIII.—Resolution of <i>dl</i> -Dicentrine. By ROBERT DOWNS HAWORTH, WILLIAM HENRY PERKIN, jun., and JOHN RANKIN . . . . .	29
IX.—Synthetical Experiments in the <i>iso</i> Quinoline Group. Part VI. A Synthesis of Derivatives of Parab erine. By RAY CAMPBELL, ROBERT DOWNS HAWORTH, and WILLIAM HENRY PERKIN, jun. . . . .	32
X.—Keto-enol Isomerism of Ethylenebisacetylacetone. By GILBERT T. MORGAN and CYRIL JAMES ALLAN TAYLOR . . . . .	43
XI.—The Solubilities of Sodium, Potassium, and Calcium Ferrocyanides. Part I. By MONICA FARROW . . . . .	49
XII.—Studies of Valency. Part VII. Surface Polarity and the Reaction of Ethylene and Chlorine—The Effect of the Adsorbed Water Layer. By RONALD GEORGE WREY-FORD NORRISH and GRIFFITH GLYN JONES . . . . .	55

	PAGE
XIII.—The Chemistry of the Caryophyllene Series. Part I. By GEORGE GERALD HENDERSON, JOHN MONTEATH ROBERTSON, and (in part) CARL ALOYSIUS KERR . . .	62
XIV.—The Density of Boric Oxide Glass and the Suspected Variation in the Atomic Weight of Boron. By HENRY VINCENT AIRD BRISCOE, PERCY LUCOCK ROBINSON, and GEORGE EDWARD STEPHENSON . . . . .	70
XV.—Butyl Esters of the Simpler Amino-acids. Part I. By WALTER THOMAS JAMES MORGAN. . . . .	79
XVI.—The Nitration of $\beta$ -Naphthoic Acid and Some New Amino- and Nitro-naphthoic Acids. By HAROLD AINS- WORTH HARRISON and FRANK ALBERT ROYLE . . .	84
XVII.—A Revision of the Structural Formula of Glucose. By WILLIAM CHARLTON, WALTER NORMAN HAWORTH, and STANLEY PEAT . . . . .	89
XVIII.—Studies in Adsorption by an Optical Method. Fix- ation by Dispersoids of Methylene-blue within the Disperse Phase. By ANDOR FODOR and RASSA RIWLIN	102
XIX.—Substituted Dihydropentazines—A New Series of Cyclic Nitrogen Compounds. By FREDERICK DANIEL CHATTAWAY and GEORGE DAVID PARKES . . . . .	113
XX.—Purification of Phosphoric Oxide. By GEORGE INGLE FINCH and REGINALD PERCY FRASER . . . . .	117
XXI.—Production of Arsenic Subsulphide. Reduction of Certain Arsenic Compounds by Sodium Hyposulphite [Hydrosulphite]. By WALTER FARMER and JAMES BRIERLEY FIRTH . . . . .	119
XXII.—Hydrogen Electrode Studies of the Precipitation of Basic Chromates, Borates and Carbonates. By HUBERT THOMAS STANLEY BRITTON. . . . .	125
XXIII.—Chloro-derivatives of <i>m</i> -Hydroxybenzaldehyde. By HERBERT HENRY HODGSON and HERBERT GREENSMITH BEARD . . . . .	147
XXIV.—The Nitration of <i>m</i> -Bromophenol. By HERBERT HENRY HODGSON and FRANCIS HARRY MOORE . . .	155
XXV.—Condensation of 3-Bromo- and 3-Nitro-4-dimethyl- aminobenzaldehyde with Ethyl Acetoacetate and Ammonia. By LEONARD ERIC HINKEL and WILLIAM REES MADEL . . . . .	161
XXVI.—The Oxidation of Certain Sesquiterpenes with Chromyl Chloride and Chromic Acid. By DAVID TEMPLETON GIBSON, JOHN MONTEATH ROBERTSON, and JAMES SWORD . . . . .	164

XXVII.—Action of Hydrogen Fluoride on Compounds of Selenium and Tellurium. Part I. Selenium Dioxide. By EDMUND BRYDGES RUDHALL PRIDEAUX and JOHN O'NEIL MILLOTT . . . . .	167
XXVIII.—The Hydration of Strong Electrolytes, the Viscosity of their Aqueous Solutions, and the Dilution Law. By JAMES NETHERWOOD SUGDEN . . . . .	174
XXIX.—Action of Acetylene Tetrabromide on Organic Bases. By JAMES DAVIDSON FULTON . . . . .	197
XXX.—Heterogeneous Equilibria between the Sulphates and Nitrates of Sodium and Potassium and their Aqueous Solutions. Part I. The Ternary Systems. By MOHAMMED ABDUL HAMID . . . . .	199 ✓
XXXI.—Heterogeneous Equilibria between the Sulphates and Nitrates of Sodium and Potassium and their Aqueous Solutions. Part II. The Quaternary System $H_2O-Na_2SO_4-NaNO_3-K_2SO_4-KNO_3$ . By MOHAMMED ABDUL HAMID . . . . .	206 ✓
XXXII.—Preparation, Hydrolysis, and Reduction of the Fluoro-, Chloro-, and Bromo-benzyl Bromides. By JOHN BALDWIN SHOESMITH and ROBERT HENRY SLATER . . . . .	214
XXXIII.—Cyclic Organo-metallic Compounds. Part I. Compounds of Tellurium. By HARRY DUGALD KEITH DREW . . . . .	223
XXXIV.—The Quaternary Salts of Benzoxazoles. By LESLIE MARSHALL CLARK . . . . .	232
XXXV.—Reactions of the <i>meso</i> -Hydroxyanthrones. By MARCUS AURELIUS MATTHEWS . . . . .	236
XXXVI.— <i>cyclo</i> Hexanespirocyclohexane. By WOODFORD STANLEY GOWAN FLUCKNETT NORRIS . . . . .	245
XXXVII.—The Interaction between Copper and Sulphuric Acid. By CECIL WILLIAM ROGERS . . . . .	254
XXXVIII.—Hydrogen Electrode Studies of the Reactions between Solutions of Salts of Weak Metallic Bases and the Acetate, Oxalate, and Tartrate of Sodium, with a Note on the Effect of Dextrose on Zirconium Chloride Solution. By HUBERT THOMAS STANLEY BRITTON . . . . .	269
XXXIX.—The Absorption of Gases by Colloidal Solutions. By ALOIS GATTERER . . . . .	299
XL.—The Reciprocal Salt Pair (Na, Ba)-(Cl, $NO_3$ ) in Aqueous Solution at 20°. By ALEXANDER FINDLAY and JAMES CRUICKSHANK . . . . .	316
XLI.—The Equilibrium between Ethyl Alcohol and the Alkali and Alkaline-earth Salts. Part I. By DAVID GLYNWYN ROBERT BONNELL and WILLIAM JACOB JONES . . . . .	318

	PAGE
XLII.—The Dissociation Pressures of Alcoholates. Part I. By DAVID GLYNWYN ROBERT BONNELL and WILLIAM JACOB JONES . . . . .	321
XLIII.—The 4- and 4'-Methoxybenzoylbenzoins. By HERBERT GREENE . . . . .	328
XLIV.—The Reaction between Hydroxylamine and Ferric Chloride. By ALEC DUNCAN MITCHELL . . . . .	336
XLV.—The Structure of the Normal Monosaccharides. Part IV. Glucose. By EDMUND LANGLEY HIRST . . . . .	350
XLVI.—3:4- and 2:5-Dimethoxyphenylhydrazine. By WILLIAM HENRY PERKIN, jun., and LEON RUBENSTEIN . . . . .	357*
XLVII.—The System Ferrous Oxide-Phosphoric Acid-Water and Some of its Oxidation Products. By SYDNEY RAYMOND CARTER and NORMAN HOLT HARTSHORNE . . . . .	363
XLVIII.—Condensations involving Reactive Methyl Groups in Heterocyclic Bases. By JAMES ERNEST HUMPHRIES. . . . .	374
XLIX.—The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part I. By JAMES ALLAN and ROBERT ROBINSON . . . . .	376
L.—The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part II. The Nitration of some 2-Benzyloxyanisoles substituted in the Benzyl Group. By ALBERT EDWARD OXFORD and ROBERT ROBINSON . . . . .	383
LI.—The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part III. The Nitration of some <i>p</i> -Alkyloxyanisoles. By ROBERT ROBINSON and JOHN CHARLES SMITH . . . . .	392
LII.—The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part IV. A Discussion of the Observations Recorded in Parts I, II, and III. By JAMES ALLAN, ALBERT EDWARD OXFORD, ROBERT ROBINSON, and JOHN CHARLES SMITH . . . . .	401
LIII.—The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part V. The Nitration of <i>p</i> -Methoxydiphenyl Ether. By THOMAS RUSSELL LEA and ROBERT ROBINSON. . . . .	411
LIV.—The Equilibrium between Methyl Formate and Methyl Alcohol, and Some Related Equilibria. By JENS ANTON CHRISTIANSEN . . . . .	413
LV.—The Equilibria underlying the Soap-boiling Processes. The System Potassium Oleate-Potassium Chloride- Water. By JAMES WILLIAM MCBAIN and WILLIAM JOSEPH ELFORD. . . . .	421

LVI.—Tetrahydroacridine, Octahydroacridine, and their Derivatives. Part II. Resolution of the Octahydroacridines (A) and (B). By WILLIAM HENRY PERKIN, jun., and WILLIAM GREENWELL SEDGWICK . . . . .	438
LVII.—The Conversion of Berberine into $\beta$ -Homochelidonine ( $\alpha$ -alloCryptopine). By ROBERT DOWNS HAWORTH and WILLIAM HENRY PERKIN, jun. . . . .	445
LVIII.—10-Chloro-5 : 10-dihydrophenarsazine and its Derivatives. Part I. The Synthesis, Preparation, and Some Properties of 10-Chloro-5 : 10-dihydrophenarsazine. By HAROLD BURTON and CHARLES STANLEY GIBSON . . . . .	450
LIX.—10-Chloro-5 : 10-dihydrophenarsazine and its Derivatives. Part II. The Action of Primary Chloroarsines on Diphenylamine and its Homologues. By HAROLD BURTON and CHARLES STANLEY GIBSON . . . . .	464
LX.—The Molecular Configurations of Polynuclear Aromatic Compounds. Part V. The Identity of the Nitration Products derived from 2 : 7- and 4 : 5-Dinitrophenanthraquinones. By GEORGE HALLATT CHRISTIE and JAMES KENNER . . . . .	470
LXI.—Orientation Effects in the Diphenyl Series. Part I. By HENRY GEORGE DENNETT and EUSTACE EBENEZER TURNER . . . . .	476
LXII.—The Complex Salts of $\beta\beta'\beta''$ -Triaminotriethylamine with Nickel and Palladium. By FREDERICK GEORGE MANN and (Sir) WILLIAM JACKSON POPE . . . . .	482
LXIII.— $\gamma\gamma'\gamma''$ -Triaminotripropylamine and its Complex Compounds with Nickel. By FREDERICK GEORGE MANN and (Sir) WILLIAM JACKSON POPE . . . . .	489
LXIV.—The Resolution of <i>dl</i> -Alanine and the Formation of <i>trans</i> -2 : 5-Dimethylpiperazine. By FREDERICK BARRY KIPPING and (Sir) WILLIAM JACKSON POPE . . . . .	494
NOTES.—Air Oxidation of Titanous Sulphate Solution. Vanadous Sulphate, a New and Powerful Reducing Agent. By A. S. RUSSELL . . . . .	497
The Effect of Heat on Chloral Hydrate. By JAMES DENIS MOUNFIELD and JOHN KERFOOT WOOD . . . . .	498
Preparation of Ethylene Bromohydrin. By FREDERICK HENRY McDOWALL . . . . .	499
An Automatic Siphonic Gas Circulator. By GEORGE M. GREEN . . . . .	500
LXV.—A Comparison of Some of the Physical Properties of the Alkali Cyanates and Azides. By JOHN ARNOLD CRANSTON and ALEXANDER YOUNG LIVINGSTONE . . . . .	501

	PAGE
✓ LXVI.—Studies on the Dependence of Optical Rotatory Power on Chemical Constitution. Part VI. Rotatory Powers of Phenyl, <i>o</i> -, <i>m</i> -, <i>p</i> -Tolyl and $\beta$ -Naphthyl Derivatives of <i>d</i> -Camphorimide and <i>d</i> -Camphoramic Acid. By BAWA KARTAR SINGH and AMAR NATH PURI	504
LXVII.—Conditions of Formation of Rings Attached to the <i>o</i> -, <i>m</i> -, and <i>p</i> -Positions of the Benzene Nucleus. Part II. The Reduction of <i>m</i> - and <i>p</i> -Phenylenediacetonitrile. By ALAN FRANCIS TITLEY	508
LXVIII.—The Action of Hydrogen Fluoride on Compounds of Selenium and Tellurium. Part II. Tellurium Dioxide. By EDMUND BRYDGES RUDHALL PRIDEAUX and JOHN O'NEIL MILLOTT	520
LXIX.—The Action of Alcoholic Potassium Hydroxide upon Chloronitrobenzene. By DONALD HENRY RICHARDSON.	522
LXX.—Action of Mercurous Nitrate on Chloroauric Acid. By WILLIAM BRANCH POLLARD	529
LXXI.—Halogenation of 2:6-Dimethylbenzbisthiazole and of 3:5-Diphenylimino-2:4-diphenyltetrahydro-1:2:4-thiodiazole. By ROBERT FERGUS HUNTER	533
LXXII.—Bromination of some 5-Substituted 1-Phenylbenzthiazoles. By ROBERT FERGUS HUNTER	537
LXXIII.—Studies in Colour and Constitution. Part I. The Influence of the Methylthiol Group, alone and in Conjunction with the Methoxy-group. By HERBERT HENRY HODGSON and FREDERICK WILLIAM HANDLEY	542
LXXIV.—Iodination in the Carbazole Series. By STANLEY HORWOOD TUCKER	546
LXXV.—Optical Activity and the Polarity of Substituent Groups. Part III. Menthyl Acetophenone- <i>o</i> -carboxylate. By HAROLD GORDON RULE and JOHN SMITH	553
LXXVI.—The Chlorination and Bromination of 4-Aminodiphenyl. By HAROLD ARCHIBALD SCARBOROUGH and WILLIAM ALEXANDER WATERS	557
LXXVII.—The Influence of the Intensity of Illumination on the Velocity of Photochemical Changes. The Determination of the Mean Life of a Hypothetical Catalyst. By FRANK BRIERS, DAVID LEONARD CHAPMAN, and ERNEST WALTERS	562
LXXVIII.—The Action of Alkaline Arsenites on Some Halogenated Organic Compounds. By ISIDORE ELKANAH BALABAN	569
LXXIX.—The Crystal Structure of Catechol. By WILLIAM AUGUSTUS CASPARI	573

LXXX.—Unsymmetrically Substituted Dinitro- and Diamino-derivatives in the Stilbene and Tolane Series. Part I. The Elimination of Hydrogen Chloride from 3:4-Dinitrostilbene Dichloride. By HAROLD AINSWORTH HARRISON and HAROLD WOOD . . . . .	577
LXXXI.—The Budde Effect in Bromine. Part I. The Photoactive Constituent of Wet Bromine. By BERNARD LEWIS and ERIC KEIGHTLEY RIDEAL . . . . .	583
LXXXII.—The Budde Effect in Bromine. Part II. The Kinetics of the Reaction and the Light Absorption of Wet and of Dry Bromine. By BERNARD LEWIS and ERIC KEIGHTLEY RIDEAL . . . . .	596
LXXXIII.—Studies of Valency. Part V. Absorption Spectra of Halogen and Sulphonic Derivatives of Camphor: Origin of the Ketonic Absorption Band. By THOMAS MARTIN LOWRY and GLYN OWEN . . . . .	606
LXXXIV.—Studies of Valency. Part VI. General and Selective Absorption of Halogen Derivatives of Methane. The Origin of General Absorption. By THOMAS MARTIN LOWRY and ROSE RACHEL SASS . . . . .	622
LXXXV.—The Equivalent Conductivity of Solutions of Sodium Hydroxide and the Mobility of the Hydroxyl Ion. By HUMPHREY RIVAZ RAIKES, ALBERT FREDERICK YORKE, and FREDERICK KENNETH EWART . . . . .	630
LXXXVI.—The Mercuration of Aromatic Substances. Part II. <i>o</i> -Nitrotoluene. By SAMUEL COFFEY . . . . .	637
LXXXVII.—Tautomerism in the Thyroxin Molecule. By CEDRIC STANTON HICKS . . . . .	643
LXXXVIII.— <i>N</i> -Alkylated Amidines. By MONMOHAN SEN and JÑANENDRA NATH RÂÛ . . . . .	646
LXXXIX.—Substitution in Vicinal Trisubstituted Benzene Derivatives. Part IV. By LEON RUBENSTEIN . . . . .	648
XC.—The Decomposition of Substituted Carbamyl Chlorides by Hydroxy-compounds. Part II. The Influence of the Hydroxy-compound. By TUDOR WILLIAMS PRICE . . . . .	653
XCI.—Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XXVIII. <i>d</i> - <i>sec</i> .-Butylbenzene. By PHILIP WILLIAM BENSON HARRISON, JOSEPH KENYON, and JOHN ROBERT SHEPHERD . . . . .	658
XCII.—The Chemistry of Polycyclic Structures in Relation to their Homocyclic Unsaturated Isomerides. Part VI. Some Reactions of <i>iso</i> Phorone. By JOHN WILLIAM BAKER . . . . .	663

XCIII.—The Molecular Configurations of Polynuclear Aromatic Compounds. Part VI. $\beta$ -Dinitrodiphenic Acid; its Constitution and Resolution into Optically Active Components. By GEORGE HALLATT CHRISTIE, ALBERT HOLLERNESSE, and JAMES KENNER . . . . .	671
XCIV.—Styrylpyrylium Salts. Part VI. Styryl Derivatives of 9-Methylxanthylum Chloride and 3:6-Dihydroxy-9-methylxanthylum Chloride. By HAROLD ATKINSON and ISIDOR MORRIS HEILBRON . . . . .	676
XCV.—Arylsulphuric Acids. By GEORGE NORMAN BURKHARDT and ARTHUR LAPWORTH [with FRANK ASHWORTH] . . . . .	684
XCVI.—A New Reaction of Certain Diazosulphonates derived from $\beta$ -Naphthol-1-sulphonic Acid. Part I. Preparation of Phthalazine, Phthalazone, and Phthalimidine Derivatives from 4'-Nitrobenzene-2-naphthol-1-diazosulphonate. By FREDERICK MAURICE ROWE, ESTHER LEVIN, ALAN CHAMLEY BURNS, JOHN STANLEY HERBERT DAVIES, and WOLFE TEPPER . . . . .	690
XCVII.—Absorption Spectra and Tautomerism. Part I. Keto-enol Tautomerism. Ethyl Acetoacetate, Acetylacetone, and $\alpha$ -Benzoylcamphor. By RICHARD ALAN MORTON and WILLIAM CHARLES VICTOR ROSNEY . . . . .	706
XCVIII.—Absorption Spectra and Tautomerism. Part II. Ethyl Mesityloxidoxalate, Formylphenylacetate, and Diacetylsuccinate. By RICHARD ALAN MORTON and EDWARD ROGERS . . . . .	713
XCIX.—Absorption Spectra of Mesityl Oxide. By RICHARD ALAN MORTON . . . . .	719
C.—Studies of Dynamic Isomerism. Part XXI. The Velocity of Mutarotation of Tetramethylglucose and of Tetra-acetylglucose in Aqueous Acetone. By GRIFFITH GLYN JONES and THOMAS MARTIN LOWRY . . . . .	720
CI.—Absorption Spectra of Condensed Nuclear Hydrocarbons. By NORMAN STEWART CAPPER and JOSEPH KENNETH MARSH . . . . .	724
CII.—The Interaction of Nitric Oxide and Hydrogen and the Molecular Statistics of Termolecular Gaseous Reactions. By CYRIL NORMAN HINSHELWOOD and THOMAS EDWARD GREEN . . . . .	730
CIII.—Synthetical Work on the <i>iso</i> Quinoline Alkaloids. Part I. Substituted <i>o</i> -Carboxyphenylethylamines. By GEORGE ALFRED EDWARDS . . . . .	740
CIV.—The Electrometric Titration of Halides. By WALTER CLARK . . . . .	749

CV.—The Absorption Spectra of Various Derivatives of Salicylic Acid. By JOHN EDWARD PURVIS . . .	775
CVI.—Elimination of the Amino-group of Tertiary Amino-alcohols. Part III. A New Method for the Preparation of Optically Active Ketones. By ALEX. MCKENZIE, ROBERT ROGER, and GEORGE OGILVIE WILLS . . .	779
CVII.—Experiments on the Variation of the Angles of Crystals during Growth. By ERNEST SYDNEY HEDGES . . .	791
CVIII.—The Nitration of Benzamidines. By ROBERT FORSYTH, VISHVANATH KRISHNA NIMKAR, and FRANK LEE PYMAN . . .	800
CIX.—Derivatives of Tetrahydrocarbazole. Part V. Carboxylic Acids. By WINIFRED MAUDE COLLAR and SYDNEY GLENN PRESTON PLANT . . .	808
CX.—The Oximes of 2:4-Dinitrobenzil and the Beckmann Change. By GERALD BISHOP and OSCAR L. BRADY . . .	810
CXI.—Synthetical Work on the <i>iso</i> Quinoline Alkaloids. Part II. A Method of Opening the Rings of Cyclic Ketones. By GEORGE ALFRED EDWARDS . . .	813
CXII.—Trypanocidal Action and Chemical Constitution. Part IV. Arylamides of Aminohydroxyphenylarsinic Acids. By LESLIE FRANK HEWITT and HAROLD KING . . .	817
CXIII.—Liquid-line Corrosion. By ERNEST SYDNEY HEDGES . . .	831
CXIV.—Observations on Liquid Boundaries and Diffusion Potentials. By SYDNEY RAYMOND CARTER and FREDERICK MEASHAM LEA . . .	834
CXV.—The Hydrolytic Action of Low-pressure Superheated Steam on Salts of the Alkaline-earth Metals. By PERCY LUCKOCK ROBINSON, HAROLD CECIL SMITH, and HENRY VINCENT AIRD BRISCOE . . .	836
CXVI.—Studies with the Microbalance. Part III. The Filtration and Estimation of very small Amounts of Material. By ERNST JOHANNES HARTUNG . . .	840
CXVII.—The Ternary System Sodium Thiosulphate-Sodium Sulphate-Water. By RICHARD RANDOLPH GARRAN . . .	848
CXVIII.—The Ternary System Sodium Sulphide-Sodium Sulphate-Water. By ARTHUR ROBERT HOGG . . .	855
CXIX.—The Constitution of Maltose. By (Sir) JAMES COLQUHOUN IRVINE and IAN MACLEOD ARMSTRONG BLACK . . .	862
CXX.—The Constitution of the Disaccharides. Part X. Maltose. By CONRAD J. ASTLEY COOPER, WALTER NORMAN HAWORTH, and STANLEY PEAT . . .	876

	PAGE
CXXI.—Synthesis of Derivatives of $\gamma$ -Xylose. By WALTER NORMAN HAWORTH and GEORGE CRONE WESTGARTH .	880
CXXII.—Termolecular Reactions. Reduction of Silver Acetate by Sodium Formate. By ALEXANDER COUTIE .	887
CXXIII.—The Relative Concentrations of Various Electrolytes required to salt out Soap Solutions. By JAMES WILLIAM MCBAIN and ALBERT VINCENT PITZER .	893
CXXIV.—Hydrofluozirronic Acid and the Analysis of Zirconium Fluoride. By EDMUND BRYDGES RUDHALL PRIDEAUX and EDWIN CLAXTON ROPER .	898
CXXV.—The Morphine Group. Part III. The Constitution of Neopine. By CONSTANT FREDERIK VAN DUIN, ROBERT ROBINSON, and JOHN CHARLES SMITH. . . . .	903
CXXVI.—The Morphine Group. Part IV. A New Oxidation Product of Codeine. By ROBERT SIDNEY CAHN and ROBERT ROBINSON . . . . .	908
CXXVII.—Researches on Residual Affinity and Co-ordination. Part XXVI. A Quadridentate Group in Combination with Bivalent Metals. By GILBERT T. MORGAN and J. D. MAIN SMITH . . . . .	912
CXXVIII.—Derivatives of 2-Keto-1:2-dihydrobenzisothiazole. By ERNEST WILSON MCCLELLAND and ALBAN JAMES GAIT . . . . .	921
CXXIX.—The Vapour Pressures of Chlorine Dioxide. By FREDERICK ERNEST KING and JAMES RIDDICK PARTINGTON . . . . .	925
CXXX.—The Oxidation Potential of the System Selenium Dioxide-Selenium. By SYDNEY RAYMOND CARTER, JOHN A. V. BUTLER, and FRANK JAMES . . . . .	930
CXXXI.—Applications of Thallium Compounds in Organic Chemistry. Part III. Alkylations. By CHRISTINA MARY FEAR and ROBERT CHARLES MENZIES . . . . .	937
CXXXII.—Determination of the Rate of Hydrolysis of Sparingly Soluble Esters. By R. CHRISTIE SMITH and H. A. PATERSON . . . . .	940
CXXXIII.—Experiments on the Synthesis of Brazilin and Hæmatoxylin and their Derivatives. Part I. Veratrylidene-7-methoxychromanone and an Account of a New Synthesis of some Benzopyrylium Salts. By WILLIAM HENRY PERKIN, jun., JÑANENDRA NATH RÂÿ, and ROBERT ROBINSON . . . . .	941
NOTES.—Acetyl- <i>o</i> -phenylenediamine and Acetyl-1:2:3-benzotriazole. By FRANK BELL and JOSEPH KENYON . . . . .	954

Density of Boric Oxide from a Fractional Crystallisation of Boric Acid. By HENRY VINCENT AIRD BRISCOE, PERCY LUCOCK ROBINSON, and GEORGE EDWARD STEPHENSON .	954
A Synthesis of 1:2-Dihydroquinaldine. A Correction. By FREDERICK ALFRED MASON . . . . .	955
The Reduction of Ethyl Dibenzylacetoacetate. By ELLEN SUSAN HILL . . . . .	956
Synthesis of Naphthathioxins. By REGINALD CHILD and SAMUEL SMILES . . . . .	957
Critical Temperature of Mercury. By LEONARD ALFRED SAYCE and HENRY VINCENT AIRD BRISCOE . . . . .	957
Some Organo-silicon Compounds. By RONALD RUMSEY WIDDOWSON . . . . .	958
Deposition of Metallic Zinc on the Positive Pole of a Simple Voltaic Cell. By SPENCER ROBERT HUMBY and MICHAEL WILLCOX PERRIN . . . . .	959
The System Ammonium Acetate-Acetic Acid-Water. By RUTH SUGDEN . . . . .	960
ANNUAL GENERAL MEETING . . . . .	962
PRESIDENTIAL ADDRESS. . . . .	978
OBITUARY NOTICES . . . . .	993
CXXXIV.—Germanium. Part II. Germanium Tetrachloride and its Ammonia Compounds. By WILLIAM PUGH and JOHN SMEATH THOMAS . . . . .	1051
CXXXV.—The Binary System Barium Iodide-Water. By JOHN PACKER and ALBERT CHERBURY DAVID RIVETT. . . . .	1061
CXXXVI.—The Constitution of Magnesium Acetate Solutions. By ALBERT CHERBURY DAVID RIVETT . . . . .	1063
CXXXVII.—The Nitration of Benzil. By FREDERICK DANIEL CHATTAWAY and EDWARD AUTY COULSON . . . . .	1070
CXXXVIII.—Synthesis of 7-Methoxy-3-(6'-bromohomopiperonyl)-2-methyl-1:4-benzopyrone. By WILSON BAKER . . . . .	1074
CXXXIX.—Preparation and Resolution of <i>dl-cis</i> -2:5-Dimethylpiperazine. By FREDERIC BARRY KIPPING and (Sir) WILLIAM JACKSON POPE . . . . .	1076
CXL.—Interactions of Tellurium Tetrachloride and Aryl Alkyl Ethers. Part II. By GILBERT T. MORGAN and RICHARD EATOUGH KELLETT . . . . .	1080
CXLI.—The Behaviour of Mannose Diacetone on Methylation. By (Sir) JAMES COLQUHOUN IRVINE and ANDREW FORRESTER SKINNER . . . . .	1089

✓ CXLII.—Ethyl Hydrogen Sulphate. Part II. By M. ABDUL HAMID, KIRPAL SINGH, and HORACE BARRATT DUNNICLIFF . . . . .	1098
CXLIII.—The Reactivity of Alkyl Iodides with Sodium Benzyl Oxide. A Criticism. By LEONARD JAMES GOLDSWORTHY . . . . .	1102
CXLIV.—The Rate of Reaction between Formic Acid and Iodine in Aqueous Solution. By DALZIEL LLEWELLYN HAMMICK and MICHAEL ZVEGINTZOV . . . . .	1105
CXLV.—The Complexity of the Solid State. Part III. The Behaviour of Pure Sulphur Trioxide. Part II. By ANDREAS SMITS and PIETER SCHOENMAKER . . . . .	1108
CXLVI.—Preparation of Nickel Membranes for Ultrafiltration. By JOHN MANNING . . . . .	1127
CXLVII.—Ring-chain Tautomerism. Part XV. The Phenol-succineins and -glutareins. By SIKHIBHUSHAN DUTT . . . . .	1132
/ CXLVIII.—Synthesis in the Thianthren Series. Part II. By MONMOHAN SEN and JÑANENDRA NATH RÂY . . . . .	1139
CXLIX.—The Hydrates of Chromic Nitrate. By JAMES RIDDICK PARTINGTON and SIDNEY KEENLYSIDE TWEEDY . . . . .	1142
Hæmoglobin. A Lecture delivered before the Chemical Society on February 11th, 1926. By JOSEPH BARCROFT, C.B.E., M.A., F.R.S. . . . .	1146
✓ CL.—A Theory of Colour on the Basis of Molecular Strain. The Effect of Chromophoric Superposition. By SIKHIBHUSHAN DUTT . . . . .	1171
CLI.—Studies on the Walden Inversion. Part X. The Reaction between Water and the Phenylchloroacetate and Phenylbromoacetate Ions. By ALLAN MILES WARD . . . . .	1184
CLII.—Substituted Cinnamic Amides and Acids. By HAROLD AINSWORTH HARRISON and HAROLD WOOD . . . . .	1195
CLIII.—The Chemistry of the Glutaconic Acids. Part XIX. A Consequence of Mobility. By JOHN PACKER and JOCELYN FIELD THORPE . . . . .	1199
CLIV.—Selective Solvent Action. Part V. Salting in. By ROBERT WRIGHT . . . . .	1203
CLV.—10-Chlorophentharsine, and its Rate of Formation from o-Phenylthiolphenyldichloroarsine. By ELYWYN ROBERTS and EUSTACE EBENEZER TURNER . . . . .	1207

CLVI.—Some Reactions of 1- <i>p</i> -Toluidinocyclopentane-1-carboxylic Acid. A New Carbazole Synthesis. By STEPHEN HELLICAR OAKESHOTT and SYDNEY GLENN PRESTON PLANT . . . . .	1210
CLVII.—The Hydrolysis of Guanidine. By JAMES BELL . . . . .	1213
CLVIII.—Nitrosylsulphuric Acid. Part I. By GEORGE ALBERT ELLIOTT, LESLIE LEONARD KLEIST, FREDERICK JAMES WILKINS, and HARRY WILLIAM WEBB . . . . .	1219
CLIX.—Unsymmetrically Substituted Dinitro- and Diamino-derivatives in the Stilbene and Tolane Series. Part II. The Mode of Addition of Water to 3:4'-Dinitro- and Diamino-tolanes. By HAROLD AINSWORTH HARRISON . . . . .	1232
CLX.—Investigations in the Diphenyl Series. Part I. Migration Reactions. By FRANK BELL, JOSEPH KENYON, and PERCY HARRY ROBINSON . . . . .	1239
CLXI.—The Labile Nature of the Halogen Atom in Organic Compounds. Part XII. Halogen Compounds of Barbituric Acids. By ALEXANDER KILLEN MACBETH, THOMAS HENRY NUNAN, and DAVID TRAILL . . . . .	1248
CLXII.—The Velocities of the Reactions between Ethyl Iodide and the Sodium Salts of Various Substituted Phenols in Ethyl-Alcoholic Solution. By LEONARD JAMES GOLDSWORTHY . . . . .	1254
CLXIII.—Carboxylated $\beta$ -Diketones. By GILBERT T. MORGAN and CHARLES RAYMOND PORTER . . . . .	1256
CLXIV.—A Comparison of the Atomic Weights of Silicon from Different Sources. By PERCY LUCOCK ROBINSON and HAROLD CREIL SMITH . . . . .	1262
CLXV.—The Reactivity of <i>meso</i> -Substituted Anthracenes. Part I. By JAMES WILFRED COOK . . . . .	1282
CLXVI.—The Solubility of Beryllium Oxide in Solutions of its Salts. By NEVIL V. SIDGWICK and NEIL B. LEWIS . . . . .	1287
CLXVII.— $\omega$ -Mono- and Dibromo-derivatives of Quinaldine and Nitroquinaldines and their Products of Hydrolysis. By DALZIEL LLEWELLYN HAMMICK . . . . .	1302
CLXVIII.—The Nature of the Alternating Effect in Carbon Chains. Part IV. Some Abnormal Reactions as Evidence of the Incipient Ionisation of Certain Hydrogen Atoms in Hydrocarbon Radicals. By ERIC LEIGHTON HOLMES and CHRISTOPHER KELK INGOLD . . . . .	1305

CLXIX.—The Nature of the Alternating Effect in Carbon Chains. Part V. A Discussion of Aromatic Substitution with Special Reference to the Respective Rôles of Polar and Non-polar Dissociation; and a further Study of the Relative Directive Efficiencies of Oxygen and Nitrogen. By CHRISTOPHER KELK INGOLD and EDITH HILDA INGOLD . . . . .	1310
CLXX.—The Nature of the Alternating Effect in Carbon Chains. Part VI. A Study of the Relative Directive Efficiencies of Oxygen and Fluorine in Aromatic Substitution. By ERIC LEIGHTON HOLMES and CHRISTOPHER KELK INGOLD . . . . .	1328
CLXXI.—A Method for Determining the Solubility of Sparingly Soluble Substances. By STOTHERD MITCHELL . . . . .	1333
CLXXII.—The Inhibition of the Glow of Phosphorus. By HARRY JULIUS EMELÉUS . . . . .	1336
CLXXIII.—An Improved Hydrogen Sulphide Generator. By HENRY GEORGE DENHAM and JOHN PACKER . . . . .	1344
CLXXIV.—The Doubtful Existence of Aurous Oxide. By WILLIAM BRANCH POLLARD . . . . .	1347
CLXXV.—Studies with the Microbalance. Part IV. The Photochemical Decomposition of Silver Iodide. By ERNST JOHANNES HARTUNG . . . . .	1349
CLXXVI.—Trypanocidal Action and Chemical Constitution. Part V. Arylsulphonamides of some Phenylarsinic Acids. By LESLIE FRANK HEWITT, HAROLD KING, and WILLIAM OWEN MURCH . . . . .	1355
CLXXVII.—The Action of Phosphorus on Salts of Silver and Other Metals. By OSWALD JAMES WALKER . . . . .	1370
CLXXVIII.—Experiments on the Formation of Mother-of-Pearl. By PHANI BHUSAN GANGULY . . . . .	1381
CLXXIX.—Aminobenzthiazoles. Part III. The Tautomerism and Unsaturation of the Aminothiazole System. By ROBERT FERGUS HUNTER . . . . .	1385
CLXXX.—Aminobenzthiazoles. Part IV. The Stability of the Bromides of the 1-Xylidinodimethylbenzthiazoles. By ROBERT FERGUS HUNTER . . . . .	1401
CLXXXI.—The Direct Synthesis of Nitrous Oxide. By DAVID LEONARD CHAPMAN, RICHARD ALLEN GOODMAN, and RODNEY THOMAS SHEPHERD . . . . .	1404
CLXXXII.—Resins in Coal. Studies in the Composition of Coal. By WILFRID FRANCIS and RICHARD VERNON WHEELER . . . . .	1410

CLXXXIII.—A Study of the Rule of the Conservation of the Type of Substitution in Aromatic Substances. Part I. Chlorination of 2-Chloro-4-nitrotoluene. By WILLIAM DAVIES and GEOFFREY WINTHROP LEEPER . . . . .	1413
CLXXXIV.—The Boiling Points of Some Higher Aliphatic <i>n</i> -Hydrocarbons. By FRANCIS FRANCIS and NORMAN EDWARD WOOD . . . . .	1420
CLXXXV.—The Monochloro-derivatives of <i>m</i> -Cresol. By GEORGE PHILIP GIBSON . . . . .	1424
CLXXXVI.—The Action of Thionyl Chloride on Hydroxy-anthraquinones. Part II. Quinizarin. By ALBERT GREEN . . . . .	1428
CLXXXVII.—The Heat of Combustion of Salicylic Acid. (A Reply to E. Berner.) By PIETER EDUARD VERKADE and JAN COOPS . . . . .	1437
CLXXXVIII.— <i>As</i> -Chlorotetrahydroarsinoline and Some Quaternary Arsonium Compounds. By ELWYN ROBERTS, EUSTACE EBENEZER TURNER, and (in part) FRANK WARD BURY . . . . .	1443
CLXXXIX.—The Resin of <i>Hevea</i> Rubber. By GEORGE STAFFORD WHITBY, JACOB DOLID, and FREDERIC HARRISON YORSTON . . . . .	1448
CXC.—Some Fatty Acid Derivatives. By GEORGE STAFFORD WHITBY . . . . .	1458
CXCI.—The Conditions underlying the Formation of Unsaturated and Cyclic Compounds from Halogenated Open-chain Derivatives. Part VIII. Products derived from Pimelic Acid. An Application of Bischoff's Dynamic Hypothesis. By ALBERT HASSELL and CHRISTOPHER KELK INGOLD . . . . .	1465
CXCII.—The Conditions underlying the Formation of Unsaturated and Cyclic Compounds from Halogenated Open-chain Derivatives. Part IX. Products derived from Suberic and Azelaic Acids. By FRANK ROBERT GOSS and CHRISTOPHER KELK INGOLD . . . . .	1471
CXCIII.—The Mechanism of Tautomeric Interchange and the Effect of Structure on Mobility and Equilibrium. Part I. The Three-carbon System. By CHRISTOPHER KELK INGOLD, CHARLES WILLIAM SHOPPER, and JOCELYN FIELD THORPE . . . . .	1477
CXCIV.—The Constitution of Polysaccharides. Part IX. The Degradation of Cellulose to an Anhydrotrisaccharide. By (Sir) JAMES COLQUHOUN IRVINE and GEORGE JAMES ROBERTSON . . . . .	1488

CXCV.—The Constitution of Polysaccharides. Part X. The Molecular Unit of Starch. By (Sir) JAMES COLQUHOUN IRVINE and JOHN MACDONALD . . . . .	1502
CXCVI.—The Ultra-violet Spectra of Praseodymium, Neo- dymium, Samarium, Europium, and Erbium. By JAMES HENRY GARDINER . . . . .	1518
CXCVII.—Extinction of Methane Flames by Diluent Gases. By HUBERT FRANK COWARD and FRANCIS JOHN HART- WELL . . . . .	1522
CXCVIII.—Periodic Phenomena at Anodes of Copper and Silver. By ERNEST SYDNEY HEDGES . . . . .	1533
CXCIX.—The Existence of the Suboxides of Lead and Thallium. By FREDERICK AUFENAST and HENRY TERREY . . . . .	1546
CC.—The Precipitation of Cadmium Sulphide from Aqueous Solutions of Cadmium Chloride in the Presence of Hydrochloric Acid and Other Chlorides. By SUBRA- MONIA KRISHNAMURTI . . . . .	1549
CCI.—The Interaction of Hydrogen and Nitrous Oxide on the Surface of Gold. By WILLIAM KENNETH HUTCHISON and CYRIL NORMAN HINSHELWOOD . . . . .	1556
CCII.—The Specific Heats of Hydrogen Cyanide. A Reply. By JAMES RIDDICK PARTINGTON . . . . .	1559
CCIII.—The Laws of Aromatic Substitution. Part V. The Directing Effect of Electrolytically Dissociated Groups. By BERNHARD FLÜRSCHHEIM and ERIC LEIGHTON HOLMES . . . . .	1562
CCIV.—Properties of Conjugated Compounds. Part I. Conjugative Associations in Extended "Conjugated" Systems. By ERNEST HAROLD FARMER and JOHN ROSS . . . . .	1570
CCV.—The Isomerism of the Styryl Alkyl Ketones. Part III. Methoxy-2- and -4-hydroxystyryl Alkyl Ketones. By ALEXANDER MCGOOKIN and DONALD JAMES SINCLAIR . . . . .	1578
CCVI.—The Halogenation of Phenols. By FREDERICK GEORGE SOPER and GILBERT FREEMAN SMITH . . . . .	1582
CCVII.—Compounds of Tervalent Molybdenum. Part IV. Bromides. By WILLIAM WARDLAW and ARTHUR JACOB IMMINS HARDING . . . . .	1592
CCVIII.—The Dehydration of Glycols derived from $\alpha$ -Naphthylglycollic Acid. By ALEX. MCKENZIE and WALTER SAMUEL DENNLER . . . . .	1596

CCIX.—The Complexity of the Solid State. Part IV. The Behaviour of Pure Sulphur Trioxide. Part III. By ANDREAS SMITS and PIETER SCHOENMAKER . . .	1603
CCX.—The Photolysis of Acetaldehyde and of Acetone. By EDMUND JOHN BOWEN and HAROLD GARFIT WATTS . . .	1607
CCXI.—The Constitution of the Condensation Product of $\beta$ -Phenylhydroxylamine and Acetone. By FRANCIS HARROLD BANFIELD and JOSEPH KENYON . . .	1612
CCXII.—The Classification of the Sugars. By JOHN GWILLIAM MALTBY . . . . .	1629
CCXIII.—The Unsaponifiable Matter from the Oils of Elas- mobranch Fish. Part I. A Contribution to the Study of the Constitution of Squalene (Spinacene). By ISIDOR MORRIS HEILBRON, EDWARD DAVID KAMM, and WILLIAM MORGAN OWENS . . . . .	1630
CCXIV.—Synthesis of Iodine Compounds of the Salvarsan Group. By ALEXANDER DOUGLAS MACALLUM . . .	1645
CCXV.—The Introduction of the Selenocyano-group into Aromatic Compounds. By FREDERICK CHALLENGER, ARNOLD THORNTON PETERS, and JACOB HALÉVY . . .	1648
CCXVI.—The Orienting Influence of Free and Bound Ionic Charges on Attached Simple or Conjugated Unsaturated Systems. Part I. The Nitration of Some Derivatives of Benzylamine. By HARRY RAYMOND ING and ROBERT ROBINSON . . . . .	1655
CCXVII.—Copper Hydride and its Crystal Structure. By HEINZ MÜLLER and ALBERT JAMES BRADLEY . . .	1669
CCXVIII.—The Relationship between the Optical Rotatory Powers and the Relative Configurations of Optically Active Compounds. Part III. By GEORGE WILLIAM CLOUGH . . . . .	1674
CCXIX.—The Reactivity of <i>meso</i> -Substituted Anthracenes. Part II. By JAMES WILFRED COOK . . . . .	1677
CCXX.—The Nature of the Alternating Effect in Carbon Chains. Part VII. A Study of the Relative Directive Efficiencies of Oxygen and Sulphur in Aromatic Sub- stitution. By ERIC LEIGHTON HOLMES, CHRISTOPHER KELK INGOLD, and EDITH HILDA INGOLD . . .	1684
CCXXI.—The Action of Light on Concentrated Aqueous Solutions of Ammonium Thiocyanate. By MARSHALL HOLMES . . . . .	1690
CCXXII.—The Catalytic Decomposition of Solutions of Sodium Hypochlorite by Finely Divided Metallic Oxides. By EUGEN CHIRNOAGA . . . . .	1693

CCXXIII.—Studies of Equilibria in Systems of the Type Lead Halide-Potassium Halide-Water. By LESLIE JAMES BURRAGE . . . . .	1703
CCXXIV.—The Catalytic Decomposition of Nitric Oxide at the Surface of Platinum. By THOMAS EDWARD GREEN and CYRIL NORMAN HINSHELWOOD . . . . .	1709
CCXXV.—Experiments on the Synthesis of Anthocyanins. Part I. By ALEXANDER ROBERTSON and ROBERT ROBINSON . . . . .	1713
CCXXVI.—The Transformation of Monomethyl Fructose into Derivatives of $\gamma$ -Fructose. By CHARLES FREDERICK ALLPRESS . . . . .	1720
CCXXVII.—A Method of inserting the Thio-aryl Group. By LESLIE GEORGE SCOTT BROOKER and SAMUEL SMILES . . . . .	1723
CCXXVIII.—Aminopropyl-1:2:4-triazoles. By JOSEPH REILLY and PETER J. DRUMM . . . . .	1729
CCXXIX.—The Constitution of Sucrose. Part I. Oxid- ation of Tetramethyl $\gamma$ -Fructose. By GEORGE McOWAN . . . . .	1737
CCXXX.—The Constitution of Sucrose. Part II. Evidence contributed by the Oxidation of <i>d</i> -Arabinose. By GEORGE McOWAN . . . . .	1747
CCXXXI.—Sugar Carbonates. Part II. Derivatives of Arabinose and Xylose. By WALTER NORMAN HAWORTH and WILLIAM MAW . . . . .	1751
CCXXXII.—Studies in the Diphenyl Series. Part I. The Isomeric 4:4'-Dichloro-3:3'(2:3'?)- and 3:5'-dinitro- diphenyls. By HERBERT HENRY HODGSON and (in part) FAQIR CHAND GOROWARA . . . . .	1754
CCXXXIII.—Orientation Effects in the Diphenyl Series. Part II. The Constitution of Bandrowski's Dinitro- benzidine. By RAYMOND JAMES WOOD LE FÈVRE and EUSTACE EBENEZER TURNER . . . . .	1759
CCXXXIV.—The Preparation of 3:4-Methylenedioxyhomo- phthalic Acid. By ROBERT DOWNS HAWORTH, WILLIAM HENRY PERKIN, jun., and THOMAS STEVENS STEVENS . . . . .	1764
CCXXXV.—Synthesis of Cryptopine and Protopine. By ROBERT DOWNS HAWORTH and WILLIAM HENRY PERKIN, jun. . . . .	1769
CCXXXVI.—The Adsorption of Water Vapour on a Plane Fused Quartz Surface. The Isosteric Heats of Adsorp- tion of Water on Silica and on Platinum. By SAM LENHER . . . . .	1785

CCXXXVII.—The Chemistry of the Three-carbon System. Part V. The Alkylation of Unsaturated Ketones. By GEORGE ARMAND ROBERT KON . . . . .	1792
CCXXXVIII.—Mercuration of <i>o</i> -Nitrotoluene. By HAROLD BURTON, FREDERICK HAMMOND, and JAMES KENNER . . . . .	1802
CCXXXIX.—On Active Nitrogen. Part I. Its Nature and Heat of Formation. By ERIC JOHN BAXTER WILLEY and ERIC KEIGHTLEY RIDEAL . . . . .	1804
CCXL.—Low Temperature Oxidation at Charcoal Surfaces. Part II. The Behaviour of Charcoal in the Presence of Promoters. By ERIC KEIGHTLEY RIDEAL and WINIFRED MARY WRIGHT . . . . .	1813
CCXLI.— <i>ortho</i> -Dithiolbenzene. By WILLIAM ROBERT HARDY HURTLEY and SAMUEL SMILES . . . . .	1821
CCXLII.—The Isomerism of the Dihydroxystearic Acids produced by Oxidation of Acids of the Oleic and Elaidic Series. By THOMAS PERCY HILDITCH . . . . .	1828
CCXLIII.—The Chemistry of Polycyclic Structures in Relation to their Homocyclic Unsaturated Isomerides. Part VII. Tautomerism Corresponding with that of Nitrosophenol and Quinoneoxime in the <i>bicyclo</i> Pentane Series. By ALBERT HASSELL and CHRISTOPHER KELK INGOLD . . . . .	1836
CCXLIV.—Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XXX. The Resolution of Methylcyclohexylcarbinol. By ALLAN DOMLEO and JOSEPH KENYON . . . . .	1841
CCXLV.—A Study of the Basic Copper Sulphates. By GEORGE FOWLES . . . . .	1845
CCXLVI.—The Structure of Fructose, $\gamma$ -Fructose, and Sucrose. By WALTER NORMAN HAWORTH and EDMUND LANGLEY HIRST . . . . .	1858
CCXLVII.—The Correlation of Additive Reactions with Tautomeric Change. Part V. The Structural Con- ditions affecting Mobility and Equilibrium in Additive Reactions. By KENNETH ERNEST COOPER, CHRIS- TOPHER KELK INGOLD, and EDITH HILDA INGOLD . . . . .	1868
CCXLVIII.—The Order of Removal of Manganese, Chromium, Iron, Cobalt, and Nickel from Amalgams. By ALEXANDER SMITH RUSSELL, DEREK CURTIS EVANS, and SYDNEY WILLIAM ROWELL . . . . .	1872
CCXLIX.—The Positions of Tungsten and Molybdenum in the Normal Potential Series. By ALEXANDER SMITH RUSSELL and SYDNEY WILLIAM ROWELL . . . . .	1881

### I.—*The Action of Hydrogen Sulphide on a Neutral Solution of Potassium Permanganate.*

By HORACE BARRATT DUNNICLIFF and SUKH DAYAL NIJHAWAN.

WHEN a slow current of hydrogen sulphide is passed through a 1% solution of potassium permanganate, the purple solution becomes brown and a white deposit of sulphur appears round the delivery tube. After a short time, a greyish-brown solid separates without appreciable rise in temperature; this slowly changes first to a yellow mixture of hydrated manganese dioxide, manganese sulphide, and sulphur and finally to a pink precipitate of manganese sulphide containing much sulphur, the temperature rising rather more than  $10^{\circ}$ .

The course of the reaction was investigated in stages.

When a solution of potassium permanganate was shaken with hydrogen sulphide solution, a brownish-black precipitate of hydrated manganese dioxide and sulphur formed immediately; the faintly alkaline filtrate contained unchanged permanganate. The precipitate was well washed by decantation with air-free water, and the manganese dioxide in it was estimated by determining the amount of chlorine it liberated from hydrochloric acid. The liquid left over from this estimation was treated with sodium carbonate, and the total manganese weighed as  $Mn_3O_4$ . Three estimations gave values of 1:3.8, 1:3.1, and 1:2.7 for the molecular ratio  $MnO:MnO_2$ , showing that the manganese is only partly precipitated as hydrated dioxide.

Through solutions of potassium permanganate of various concentrations hydrogen sulphide was passed until the whole of the manganese was converted into sulphide. The precipitate was filtered off, and the manganese present in it as sulphide was estimated by two methods: (1) The sulphide was extracted with dilute hydrochloric acid, the solution filtered, and the manganese precipitated

as carbonate and weighed as  $\text{Mn}_3\text{O}_4$ . Recovery = 99.8% of theory. (2) The sulphide containing free sulphur was ignited and so converted into  $\text{Mn}_3\text{O}_4$ . Recovery = 99.9% of theory.

The yellow filtrate, which contained colloidal sulphur and was faintly alkaline to phenolphthalein, was freed from hydrogen sulphide by shaking under reduced pressure, and kept in a vacuum desiccator. The sulphur deposited was filtered off and the liquor, now colourless, was left in a vacuum desiccator over a dehydrating agent for some days. Needle-shaped crystals of potassium thiosulphate and rhombic crystals of potassium sulphate grew in it as it became concentrated. The filtrate did not contain polythionates, sulphide, or sulphite. To test for polythionates, the filtrate was examined qualitatively by the tests given by Takamatsu and Smith (J., 1880, 37, 592), Bassett and Durrant (J., 1923, 123, 1279), Gutmann (*Ber.*, 1905, 38, 3277; 1907, 40, 3614), Sander (*Z. angew. Chem.*, 1915, 28, 9; 1916, 29, 11, 16), and Riesenfeld and Feld (*Z. anorg. Chem.*, 1921, 119, 225) in comparison with control thionate solutions of known concentrations.

It was shown that hydrogen sulphide has no action on thiosulphates by passing the gas through standard solutions of sodium thiosulphate at various temperatures; the excess was removed under diminished pressure, and the solutions were titrated against iodine solution. The absence of colloidal sulphur was demonstrated by negative results on the addition of electrolytes and with the cataphoresis test.

*Estimation of the Compounds produced at Various Stages in the Action of Hydrogen Sulphide on Potassium Permanganate.*

In all cases, the excess of hydrogen sulphide was removed by means of a suction pump or by the addition of lead carbonate.

(1) *Estimation of the Products of the Complete Reaction.*—The manganese is quantitatively precipitated as sulphide (see above).

The sulphate in the filtrate was estimated as barium sulphate, the precautions advised by Taylor (*J. Soc. Chem. Ind.*, 1923, 42, 294r) being taken but acetic acid being used instead of hydrochloric acid as suggested by Müller (*Bull. Soc. chim.*, 1916, 19, 8) when sulphates are being estimated in presence of thiosulphates. The thiosulphate in the filtrate was estimated iodometrically, the solution being first acidified with acetic acid (Müller, *loc. cit.*). The mean of several results gave 61.86% of potassium recovered as potassium sulphate and 38.16% as potassium thiosulphate. The sum of these values, 100.02, shows that the whole of the potassium is eventually recovered in these two forms. Practically the same values were obtained from experiments at temperatures ranging from  $-3^\circ$  to

+76°. The values approximate to three molecules of potassium sulphate to two of potassium thiosulphate, and the result, when the reaction is complete, can be summed up in the equation

At the end of the reaction the solution is alkaline and, if it is not acidified before the titration with iodine, the values for the thio-sulphate are always high. Control experiments showed that the lead carbonate used to remove the excess of hydrogen sulphide from the solution has no action on the thiosulphate. The thiosulphate found in a solution (4.170 g. per litre) which had been treated with hydrogen sulphide, shaken with lead carbonate, filtered, and then titrated against iodine was 4.164; 4.167; 4.170; and 4.165 g. per litre.

(2) *Investigation of the Mechanism of the Reaction by a Study of Two Intermediate Stages.*—Hydrogen sulphide was passed through the solution until the hydrated manganese dioxide was converted into a dirty yellow, granular mass. The values then found for potassium recovered as sulphate and as thiosulphate were 59.61, 58.54% and 34.32, 32.45%, respectively, of the total potassium. Since the sum of these values (93.93, 90.99) does not account for all the potassium present, it appears that some other sulphur compound of potassium is first formed which is subsequently decomposed by hydrogen sulphide into potassium sulphate and thiosulphate; the average final values for potassium recovered as sulphate and as thiosulphate were 61.66% and 38.27%, respectively (sum, 99.93). This compound may be one (or more) of the polythionates, for penta-, tetra-, and tri-thionates are known to be thus decomposed by hydrogen sulphide (Debus, J., 1888, 53, 328) and the authors have shown that dithionates slowly undergo a similar change in presence of this gas.

*Identification of the Compounds formed in Solution when the Manganese is precipitated as Hydrated Manganese Dioxide.*

A solution of potassium permanganate was shaken with successive small quantities of half-saturated aqueous hydrogen sulphide until the brown colour just disappeared. (When this was done carefully with standard solutions, it was not possible to obtain a definite end-point.) The filtered liquid, which was faintly alkaline, contained sulphate, thiosulphate, and dithionate, but no sulphide, sulphite, penta-, tetra-, tri-thionate, colloidal sulphur or manganese. In view of the difficulty of testing for thionates in presence of one another, the tests given (p. 2) were performed both on the filtrate and on control solutions of thionates of known concentrations.

The distinction between thiosulphate, dithionate, and trithionate was made as follows : The solution decolorised iodine solution and gave a black precipitate with silver nitrate. (The solution gave no precipitate when warmed with hydrochloric acid. This was due to the low concentration of the thiosulphate.) Dilute aqueous potassium permanganate added to the solution was first bleached (thiosulphate), then a blood-red coloration developed, and brown hydrated manganese dioxide was slowly precipitated. This suggested the presence of tri- or di-thionate. The filtrate from the precipitation of the sulphate by barium chloride was warmed with dilute hydrochloric acid; sulphur dioxide was detected, but sulphur was not deposited. Sulphate was detected in the solution (distinction from thiosulphate). Trithionates give sulphur dioxide, sulphate, and sulphur. Dithionates give sulphur dioxide and sulphate only. In dilute solutions the sulphur may not be precipitated. Mercuric chloride gives a yellow precipitate with trithionates, but does not react with dithionates. With this reagent, the filtrate gave a white turbidity. This is given by thiosulphates in very dilute solution. This suggests the absence of trithionates and the presence of thiosulphate. Ammoniacal silver nitrate had no action on the filtrate. A trithionate would have given a brown coloration.

*Action of Hydrogen Sulphide on Hydrated Manganese Dioxide.*

The blackish-brown precipitate of hydrated manganese dioxide obtained by the action of dilute aqueous sodium hypochlorite on a solution of manganous chloride, after being thoroughly washed with water, was free from alkali, chloride, and hypochlorite. It was suspended in water, through which scrubbed hydrogen sulphide was then bubbled for some time. A large proportion of the dioxide was converted into manganese sulphide contaminated with sulphur, and the solution, which was neutral to phenolphthalein, contained manganese as sulphate and thiosulphate. Ordinary dry A.R. manganese dioxide, when suspended in water and treated with hydrogen sulphide, gave the same results, and so also did hydrated manganese dioxide formed by the action of hydrogen sulphide on potassium permanganate and washed free from sulphate and thiosulphate and until the washings gave no indication of alkalinity with phenolphthalein. The presence of dithionate was not definitely proved, but independent experiments showed that manganese dithionate is decomposed by hydrogen sulphide into the sulphate and thiosulphate.

If neutral potassium sulphate was added to the water in which the hydrated manganese dioxide was suspended, the solution, in which manganese could not be detected, became alkaline to phenol-

phthalein and, when hydrogen sulphide was passed into it, the manganese was completely converted into manganous sulphide. The alkalinity was probably due to the adsorption of sulphate ions of the potassium sulphate. This would also account for the alkalinity of the solution in the reaction under investigation.

*Quantitative Estimation of Intermediate Products in the Filtrate.*

A dilute solution of potassium permanganate was treated with half-saturated aqueous hydrogen sulphide in the way described on p. 3, the precipitate was well washed, and the washings and the filtrate were made up to a definite volume. Care was taken that the solution contained no free hydrogen sulphide. In aliquot portions, the sulphate and thiosulphate were estimated as described on p. 2, and the dithionate by Szentpaly-Peyfuss's method (*Z. anorg. Chem.*, 1924, **131**, 203).

TABLE I.

*Estimation of Sulphate, Thiosulphate, and Dithionate in the Filtrate.*

Percentage of the potassium recovered as			Total
sulphate	thiosulphate	dithionate.	recovered.
69.70 (79.72)	4.84 (19.98)	25.06	99.60
79.87 (83.67)	10.27 (15.98)	9.51	99.65
68.08 (78.82)	4.65 (20.76)	26.84	99.57

The potassium is quantitatively accounted for as sulphate, thiosulphate, and dithionate, but the results show variations in the proportions in which the components are present. If it is assumed that the dithionate decomposes quantitatively into sulphate and thiosulphate, the values given in brackets would be obtained for potassium as sulphate and thiosulphate.

The results can be reconciled with the average values of 61.66 and 38.27% found for the potassium recovered as sulphate and thiosulphate, respectively, in the completed reaction (p. 3) as follows. When a large excess of hydrogen sulphide is passed, air is practically excluded from the reaction. Possibly, also, any oxidising action of the hydrated manganese dioxide is confined to the hydrogen sulphide, because dithionates are not oxidised by manganese dioxide. It is suggested, therefore, that the first products of the reaction are potassium sulphate, potassium dithionate, hydrated manganese dioxide, and sulphur; all attempts to stop the action at this stage, however, have failed. The stoichiometric proportions in which the potassium sulphate and thiosulphate are found at the end of the reaction preclude the possibility of potassium dithionate being the only potassium salt first formed. The

second stage of the action may be represented by the equations

and hence the final result is potassium sulphate and thiosulphate in solution and a precipitate of manganous sulphide and sulphur. When the dilute solution is shaken with hydrogen sulphide, air dissolves freely and a part of the dithionate is directly oxidised to sulphate at the expense of the thiosulphate which would otherwise have been formed from the dithionate in the presence of excess of hydrogen sulphide. Excess of hydrogen sulphide thus does the double duty of reducing the dithionate to sulphate and thiosulphate and protecting it from oxidation by dissolved air. In support of this argument, attention is directed to the results on p. 3. These represent a stage intermediate between those for the final values ( $\text{K}_2\text{SO}_4$ , 61.66% ;  $\text{K}_2\text{S}_2\text{O}_3$ , 38.27%) and those given in Table I, i.e., a stage in which the "protecting" action of the hydrogen sulphide has been fully exerted but in which its reducing action has been stopped before completing its work. Assuming the decomposition of the dithionate into sulphate and thiosulphate in the sense of equation (1), the values on p. 3, calculated for the final product, become  $59.61 + (0.4 \times 6.07) = 62.04$  and  $58.54 + (0.4 \times 9.01) = 62.14$  for the percentage of potassium present in solution as sulphate and  $34.32 + (0.6 \times 6.07) = 37.96$  and  $32.45 + (0.6 \times 9.01) = 37.86$  for the percentage of potassium present as thiosulphate.

These results support the argument that the hydrogen sulphide has a protecting and reducing action, since, in the completed reaction, it was used in excess of that required for the first stage and air could have taken little or no part in the reaction.

### *Summary.*

The first products of the reaction between hydrogen sulphide and potassium permanganate in dilute solution appear to be colloidal hydrated manganese dioxide, which quickly coagulates to a gelatinous precipitate; sulphur; and potassium sulphate and potassium dithionate in solution.

When excess of hydrogen sulphide is passed through the solution, the hydrated manganese dioxide is converted into manganous sulphide with the separation of sulphur. The manganous sulphide is first formed as a colloid, which quickly coagulates to pink manganous sulphide. Excess of hydrogen sulphide decomposes the potassium dithionate into potassium sulphate and thiosulphate with the simultaneous formation of sulphur. A portion of the

sulphur is precipitated; the rest is in colloidal solution and is completely precipitated on standing.

The solution is alkaline throughout. This is probably due to the adsorption of the anions of the potassium salts by the hydrated manganese dioxide or manganous sulphide.

## II.—Preparation of 1-Halogeno-2-nitronaphthalenes and 2-Nitronaphthalene.

By HERBERT HENRY HODGSON and ERNEST KILNER.

2-NITRO-1-NAPHTHYLAMINE is readily obtained from 2-nitro-1-naphthol, which is itself best prepared by the oxidation of 2-nitroso-1-naphthol (Hodgson and Kilner, J., 1924, **125**, 807). For the preparation of large quantities of 4-nitro-1-naphthylamine Morgan and Micklethwait's modification (J., 1905, **87**, 928) of Lellmann and Remy's method is serviceable.

Hydrolysis of aceto-1-nitro- $\beta$ -naphthalide proceeds better with acid than with alcoholic potassium hydroxide (Liebermann and Jacobson, *Annalen*, 1882, **211**, 44), which produces a substantial quantity of 1-nitro-2-naphthol.

By very slow decomposition in the cold in presence of cuprous chloride and concentrated hydrochloric acid, diazotised 2-nitro-1-naphthylamine gives a good yield of 1-chloro-2-nitronaphthalene. Under similar conditions, only poor yields of the corresponding bromo- and iodo-compounds are obtained, which may be due to the preferential formation of naphthalene-1-diazo-2-oxide (compare Friedländer, *Ber*, 1895, **28**, 1951; Morgan and Evens, J., 1919, **115**, 1126). Vesely's electrolytic method (*Ber.*, 1905, **38**, 136) proved unsuitable for the preparation of 1-chloro-2-nitronaphthalene.

These substances all have an extremely irritating action on the skin.

### EXPERIMENTAL.

**2-Nitro-1-naphthylamine.**—A finely powdered mixture of 2-nitro-1-naphthol (5 g.) and ammonium carbonate (3 g.) is made into a paste with concentrated ammonia (10 c.c.) and water (6 c.c.), and heated in a sealed tube at 120–130° for 6 hours. The product when cold is pulverised, and boiled with 200 c.c. of water, aqueous ammonia being occasionally added. The solution, containing the ammonium salt of unchanged 2-nitro-1-naphthol (0.31 g.), is filtered and the solid is dried and extracted with boiling alcohol (150 c.c.).

The extract on evaporation leaves 2-nitro-1-naphthylamine (3.8 g.), which melts at 141°, and at 144° after recrystallisation from alcohol (Lellmann and Remy, *Ber.*, 1886, **19**, 797; 1887, **20**, 872, give m. p. 144°). The substance insoluble in alcohol (about 0.52 g.) does not melt at a high temperature and is probably 2 : 2'-dinitrodinaphthylamine (Found: N, 12.0.  $C_{20}H_{13}O_4N_2$  requires N, 11.7%). An experiment made in an autoclave produced 16 g. of 2-nitro-1-naphthylamine and 1.3 g. of insoluble material from 20 g. of 2-nitro-1-naphthol, 1.8 g. of which were recovered.

**4-Nitro-1-naphthylamine.**—Experiments similar to the above carried out with 4-nitro-1-naphthol indicated an optimum reaction temperature between 140° and 160°. The quantities of 4-nitro-1-naphthylamine, material insoluble in alcohol, and recovered 4-nitro-1-naphthol, respectively, were: (at 120–130°) 0.5 g., —, and 6.8 g. from 8 g.; (at 140°) 2.82 g., 0.24 g., and 1.73 g. from 5 g.; (at 160–165°) 2.94 g., 1.43 g., and 0.2 g. from 5 g. of 4-nitro-1-naphthol. The nitronaphthylamine obtained at 140° melted at 182°, and at 191° after crystallising once from alcohol.

**1-Nitro-2-naphthylamine.**—A mixture of  $\beta$ -naphthylamine\* (1 part), 50% acetic acid (5 parts), and acetic anhydride (1 part) is boiled under reflux for 1 hour; on cooling, aceto- $\beta$ -naphthalide separates in flaky crystals. This product (200 g.) is added in four equal portions to cold glacial acetic acid (250 c.c.), into which, after each of the first three additions, 70% nitric acid (15 c.c.) is run during 1 hour, the temperature being kept at 8–10°. This procedure obviates the stiffening of the reaction mixture which renders Liebermann and Jacobson's process (*loc. cit.*) almost unworkable. After the last addition of aceto- $\beta$ -naphthalide, 25 c.c. of nitric acid are added to the mixture, which is then kept for 2 days. The orange-yellow aceto-1-nitro- $\beta$ -naphthalide that has separated is filtered off and washed with ether (yield 170 g.).

Hydrolysis is effected by boiling a solution of the product (125 g.) in alcohol (500 c.c.) with concentrated hydrochloric acid (125 c.c.) for 4 hours; the treatment is repeated if necessary. The mixture is then poured into 4 litres of cold water and the crude 1-nitro-2-naphthylamine filtered off, dried, and recrystallised from twice its weight of hot alcohol; m. p. 122° (Atterberg gives m. p. 124–125°, and Meldola, 126–127°) (Found: N, 15.0. Calc., 14.9%).

**1-Chloro-2-nitronaphthalene.**—Five grams of sieved 2-nitro-1-naphthylamine are warmed with 30 c.c. of a mixture of 98% sulphuric acid (3 vols.) and water (1 vol.) (*i.e.*,  $H_2SO_4, H_2O$ ). The solution thus obtained is cooled to 0°, stirred, and solid sodium

\* Pinnow's directions (*Ber.*, 1900, **33**, 417) for acetylating  $\alpha$ -naphthylamine give an unsatisfactory result in the case of  $\beta$ -naphthylamine.

nitrite (3—4 g.) gradually added, the temperature being kept below 5°. The diazo-solution is added carefully to a cooled solution of cuprous chloride (5 g.) in concentrated hydrochloric acid (40 c.c.). After 12 hours, the solid is filtered off, dried, and extracted with hot alcohol (50 c.c.). The extract is poured into 1% aqueous sodium hydroxide (100 c.c.), which dissolves any 2-nitro-1-naphthol present. The precipitate is filtered off, washed, and distilled with superheated steam. The solid (2.5 g.) in the distillate, after two crystallisations from alcohol, forms long, pale yellow needles, m. p. 76° (Found: N, 7.1; Cl, 16.7.  $C_{10}H_6O_2NCl$  requires N, 6.7; Cl, 17.1%). 1-Chloro-2-nitronaphthalene does not depress the melting point of 2-nitro-1-naphthol.

*1-Bromo-2-nitronaphthalene.*—The above procedure was repeated, except that the Sandmeyer reaction was carried out in a cooled mixture of crystallised copper sulphate (5.4 g.), copper bronze (1.4 g.), sodium bromide (15 g.), and water (40 g.). The solid obtained (0.95 g.) crystallised from alcohol in stout, bright yellow needles, m. p. 97° (Found: N, 5.8; Br, 31.5.  $C_{10}H_6O_2NBr$  requires N, 5.55; Br, 31.7%).

*1-Iodo-2-nitronaphthalene.*—The Sandmeyer reagent in this case was potassium iodide (6 g.) in water (50 c.c.). The solid product was treated with sodium bisulphite solution to remove iodine, and crystallised from alcohol in pale yellow plates, m. p. 111° (yield 1.9 g.) (Found: I, 42.7.  $C_{10}H_6O_2NI$  requires I, 42.4%).

*2-Chloro-1-nitronaphthalene.*—1-Nitro-2-naphthylamine (5 g.) was diazotised according to Friedländer and Littner (*Ber.*, 1915, 48, 330), and from the resulting solution 1 g. of 2-chloro-1-nitronaphthalene was obtained.

*2-Nitronaphthalene.*—A mixture of 2-nitro-1-naphthylamine (4.2 g.), alcohol (12 c.c.), and concentrated sulphuric acid (3 c.c.) was cooled to 0°, 3.4 c.c. of aqueous sodium nitrite (50 g. in 100 c.c. of solution) were added during 30 minutes, and the whole was kept in the cold for 4 hours. It was then gradually heated to the boiling point during 5 hours, boiled for 2 hours, poured into cold water (300 c.c.), 20% aqueous sodium hydroxide (20 c.c.) was added, and the mixture was steam-distilled. The pure 2-nitronaphthalene in the distillate solidified in yellow crystals (1.24 g.) with a cinnamon-like odour, m. p. 79° (Found: N, 8.2. Calc., N, 8.1%).

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals used in this investigation.

III.—*The Influence of Carbon Rings on the Velocity of Reactions involving their Side Chains. Part I. The Hydrolysis of Cyclic and Open-chain Malonic Esters.*

By RICHARD GANE and CHRISTOPHER KELK INGOLD.

It has been shown during the last 10 years that the angle between two of the valencies of a carbon atom may be materially affected by structural conditions relating to the other two valencies, such as, for instance, their inclusion in a ring (Beesley, Ingold, and Thorpe, J., 1915, 107, 1080, and later papers) or their attachment to groups of larger or smaller molecular volume (Ingold, J., 1921, 119, 305, and later). Thus, on passing through the series (I) to (IV) an increasing

tendency towards the interaction of groups attached to carbon atoms (a) and (b) proves that these two carbon atoms are brought together by the widening of the angle between the remaining two valencies of the central carbon atom.

The opposite sequence would be expected if we were to examine, not the *interaction* of groups attached to carbon atoms (a) and (b), but their *independent* action on some external reagent. Evidently the proximity of the carbon atoms would now be, not an accelerating, but a retarding influence, and a *decreasing* tendency to reaction should be observed on passing through the series (I) to (IV).

We have been induced to examine this inference, not only for its own interest, but also because the large choice of replacement and addition reactions available renders it possible to select reactions capable of more exact study than the violent ring-forming processes employed in the investigations referred to above. This paper contains a record of experiments on the relative rates of hydrolysis by alkalis of a series of cyclic malonic esters of type (V), certain open-chain malonic esters (type VI) being included for comparison.

The remarkable effect of different carbon rings in promoting or retarding reactions in which only their side-chains and not the rings themselves are involved was first impressed on us when comparing

the experiences of Fischer and Diltthey (*Ber.*, 1902, **35**, 844) with those of Ingold, Sako, and Thorpe (*J.*, 1922, **121**, 1177) when studying the formation of amides from malonic esters by the aid of aqueous ammonia. This case appears to have special analogies with results recorded in this paper, and must briefly be considered.

The most rational view of amide formation from esters appears to be that it is the result of two consecutive reversible addition reactions, the first of the aldehyde-ammonia, and the second of the ketone-alcoholate (semi-acetal) type :

Fischer and Diltthey, however, were influenced by the fact that, whilst ethyl malonate and ethyl methylmalonate (VII and VIII) readily yield amides with aqueous ammonia, ethyl dimethylmalonate (IX) refuses to do so, and they therefore formulated the reaction, not as a direct attack by ammonia upon the carbethoxyl groups, but as a complex process involving a tautomeric hydrogen atom (\*), the presence of which in (VII) and (VIII) enables a salt of type (X) to be formed as an intermediate product.

Ingold, Sako, and Thorpe (*loc. cit.*), and at about the same time Dox and Yoder independently (*J. Amer. Chem. Soc.*, 1921, **43**, 2097), prepared without difficulty amides from the cyclic malonic esters (XI) and (XII) which, however, are devoid of a malonyl hydrogen atom.

These observations appear to some extent to rehabilitate the reversible addition mechanism, and to suggest a spatial explanation of the differences noticed. When it is reflected also that amide-formation occurred more easily with the *cyclopropane* than with the *cyclobutane* ester, it seems clear that at least a part of the observed differences is to be accounted for on stereochemical grounds. The special mechanism suggested by Fischer and Diltthey cannot be positively excluded from participation in the cases to which it applies; it must, however, be regarded, not as the general mechanism of amide formation, but only as a possible auxiliary process by means of which amide formation may be facilitated when enolisation of the ester can occur.

Bearing these points in mind, we have examined the velocity of hydrolysis not only of cyclic and disubstituted malonic esters such as (IX), (XI), (XII), and (XIII), but also of a series of malonic esters

FIG. 1.

FIG. 2.

possessing a mobile hydrogen atom. The results of some of these determinations, carried out under strictly comparable conditions, are displayed in Figs. 1 and 2.

Attempts to calculate coefficients and construct such curves

theoretically led to considerable mathematical difficulties, principally owing to the distortion which experimental errors underwent in the process of evaluating coefficients. In its simplest aspect, and neglecting all corrections, the complete hydrolysis must be regarded as a pair of consecutive bimolecular reactions, but calculating on this basis it was found that effects of an arbitrary variation of one of the determined coefficients could often be largely counterbalanced by adjusting the other. Finally an approximate numerical comparison of the different cases was obtained by calculating the initial velocities from a series of curves representing identical conditions of temperature and initial concentration.

These initial velocities,  $\dot{x}_0$ , which were calculated from the following equations,

$$\dot{x} = K(a - x)(b - x); K_0 = \lim_{x \rightarrow 0} K; \text{ and } \dot{x}_0 = K_0 ab,$$

are exhibited for the disubstituted malonic esters (cyclic and open-chain) in the following table, the last column of which displays the angle between the valencies carrying the carboxyl groups calculated according to the principles advanced by Beesley, Ingold, and Thorpe (*loc. cit.*).

TABLE I.

	$\dot{x}_0 \times 10^4$ .	$\log_{10} \dot{x}_0$ .	$\theta$ .
<i>cyclo</i> Propane-1 : 1-dicarboxylic ester .....	4.95	4.69	116.9°
<i>cyclo</i> Butane-1 : 1-dicarboxylic ester .....	2.3 (5)	4.37	113.0
<i>gem</i> -Dimethylmalonic ester .....	0.45	5.65	109.5
<i>cyclo</i> Hexane-1 : 1-dicarboxylic ester .....	0.10	5.00	107.2
<i>gem</i> -Diethylmalonic ester .....	0.02 (5)	6.40	(105.3)

Reference to Fig. 3 shows that the points connecting the logarithms of the initial velocities and the calculated angles lie on a smooth curve both for the cyclic esters and the *gem*-dimethyl ester. There is no means at present of calculating the angle appropriate to the *gem*-diethyl ester, but the curve indicates a value of 105.3°, which is lower than might be expected from previous investigations with glutaric acids.

It was not found possible to deduce initial velocities in the cases of the tautomeric malonic esters represented in Fig. 1, as the reactions of these substances (excepting *isopropylmalonic ester*) were too rapid at their commencement for accurate measurement. The curves show, however, that the various alkyl groups exert an influence appropriate to their relative size, although it is difficult to express this effect quantitatively.

The fact that the reactions of this group proceed with much greater rapidity than the steric theory would indicate seems to show the operation of an additional mechanism when tautomeric hydrogen is present. Such a supposition would be consistent with that

discussed in the case of amide formation, with racemisation by alkalis of compounds containing potentially mobile hydrogen attached to asymmetric carbon, with the interconversion of sugars by alkalis, and numerous other well-known phenomena.

Fig. 3.

## EXPERIMENTAL.

*Preparation of Material.*—(1) *Ethyl malonate*. A sample of Boots's pure ethyl malonate was carefully fractionated, head and tail fractions being rejected, and the main portion, which boiled well within  $1^\circ$ , being used.

(2) *Ethyl methylmalonate*. To avoid possible contamination of the monomethylation product of ethyl malonate with traces of the latter and of ethyl dimethylmalonate, the crude ester was hydrolysed and the acid crystallised several times from ether and water, and, after washing with hot chloroform, from ethyl acetate. The fully purified acid (m. p.  $130^\circ$ ; recorded m. p.  $129^\circ$ ) was then re-esterified by Fischer and Speier's method. The ester had b. p.  $196\text{--}197^\circ/754$  mm.

(3) *Ethyl dimethylmalonate*. The crude dimethylation product of malonic ester was distilled (b. p.  $193\text{--}195^\circ$ ) and, in view of possible contamination with incompletely methylated products, digested with an equal weight of ammonia ( $d$  0.880), which rapidly converts the latter into amides. The pure dimethyl ester had b. p.  $194\text{--}194.3^\circ/751$  mm. and b. p.  $196\text{--}197^\circ/765$  mm.

- (4) *Ethyl ethylmalonate*. Like (2).
- (5) *Ethyl diethylmalonate*. Boots's sample of this ester was shaken with cold 30% sodium hydroxide sufficiently to hydrolyse any ethyl monoethylmalonate, recovered, and distilled (Michael, *J. pr. Chem.*, 1905, 72, 537).
- (6) *Ethyl n-propylmalonate*. The ester prepared as described by Conrad (*Annalen*, 1880, 204, 124) was purified by distillation until it boiled within 1°.
- (7) *Ethyl isopropylmalonate*. Like (6) (compare Preiswerck, *Helv. Chim. Acta*, 1923, 6, 192).
- (8) *Ethyl cyclopropane-1 : 1-dicarboxylate* (XI) was prepared and purified as described by Perkin (*J.*, 1885, 47, 810). B. p. 210—211°/718·5 mm.
- (9) *Ethyl cyclobutane-1 : 1-dicarboxylate* (XII), prepared as described by Perkin (*J.*, 1887, 51, 2) and purified by repeated fractional distillations, had b. p. 224·5—225·5°/757·7 mm.
- (10) *Ethyl cyclohexane-1 : 1-dicarboxylate* (XIII). The specimen used was kindly given by Mr. W. A. Wightman. It had been subjected to partial hydrolysis, which would have removed any monosubstituted malonic ester if present [see (5)].

*Method of Experiment.*—The hydrolyses were carried out by means of carbonate-free aqueous-alcoholic sodium hydroxide contained in strong bottles, into which thin glass tubes containing the weighed ester (usually 0·005 g.-mol.) were dropped to start the reaction, the alkali having previously attained the thermostat temperature. The portions withdrawn for analysis were run as rapidly as possible into an excess of hydrochloric acid to terminate the reaction and titrated with *N*/50—*N*/60-barium hydroxide. Various temperatures and concentrations of alkali were employed, but in the experiments selected for this record the temperature was uniformly 27·0°, whilst the alkali consisted of 0·8380 g. of sodium hydroxide, 23·26 g. of water and 75·90 g. of alcohol in each case.

*Results.*—The general method of calculating the limiting velocities has been described above, and an instance may here be given of its application. In the following table, the figures of the first row are read from the slope of the smoothed  $x-t$  curve, and those in the bottom row show the asymptotic approach of  $k$  to the value  $k_0 = 0·0000090$ ; whence  $\dot{x}_0 = 0·00049$  can be calculated.

TABLE II.

(Ethyl cyclopropane-1 : 1-dicarboxylate.)

$\dot{x} \times 10^4 \dots$	4·45	3·55	2·95	2·40	1·70	1·30	0·78
$x \times 10^4 \dots$	2·25	6·20	9·50	1·21	1·62	1·92	2·24
$k \times 10^4 \dots$	9·2	9·1	9·5	9·6	10·4	12·4	17·4 (rapidly increasing)

#### IV.—Tesla-luminescence Spectra. Part VI. Some Amino-derivatives.

By WILLIAM HAMILTON McVICKER, JOSEPH KENNETH MARSH,  
and ALFRED WALTER STEWART.

IN previous papers (J., 1923, 123, 642, 817, 2147; 1924, 125, 1743; 1925, 127, 999) accounts were given of the Tesla-luminescence spectra of various benzene derivatives. The present communication contains a description of the emission spectra of some aromatic amino-derivatives. The apparatus used is the same as before, the pressures were 1—2 mm., and the exposure was in each case 15 minutes.

*Aniline*, b. p. 182.9°/748 mm. A strong continuous spectrum, 2880—4000 Å.U., fading off gradually at both ends, with a number of well-defined narrow bands at 2895, 2915, 2927, 2938, 2960, 2976, 2985, 2999, 3010, 3022, 3031, 3050, 3070, 3098, 3122, 3145, 3171, 3199, 3224.

The spectra of the next seven substances faded gradually at both ends, but more so at the end of greater wave-length.

*Monomethylaniline*, b. p. 196.4—196.9°/770 mm. A strong continuous spectrum at approximately 2965—4250 Å.U. The centre of maximum intensity is about 3300 Å.U.

*Monoethylaniline*, b. p. 205.6—206.2°/770 mm. A strong continuous spectrum at approximately 2695—4250 Å.U. The centre of maximum intensity is about 3340 Å.U.

*Dimethylaniline*, b. p. 194.2—194.3°/766 mm. A strong continuous spectrum at approximately 3025—4300 Å.U. Centre of maximum intensity at approximately 3420 Å.U.

*Diethylaniline*, b. p. 213.2—214°/738 mm. Medium continuous spectrum at approximately 3010—4225 Å.U. Centre of maximum intensity at approximately 3375 Å.U.

*isoAmylaniline*, b. p. 253.6—255.6°/766 mm.† Strong continuous spectrum at approximately 2995—4300 Å.U. Centre of maximum intensity at about 3340 Å.U.

*Benzylamine*, b. p. 184.6—185.2°/771 mm. Weak continuous spectrum at approximately 2671—3390 Å.U. Diffuse heads of bands at 2671, 2714, 2800.

*Benzylaniline*, b. p. 320.8—321.0°/775 mm. Strong continuous spectrum at approximately 2980—4225 Å.U. Centre of maximum intensity at approximately 3345 Å.U.

*Diphenylamine*, b. p. 302.6—302.8°/750 mm. Weak continuous spectrum at approximately 3070—3875 Å.U., fading off gradually at both ends.

*Triphenylamine*. Nine times recrystallised from alcohol and boiled once with animal charcoal. M. p. 126.4°. Moderate continuous spectrum at approximately 3260—4220 Å.U., fading off gradually at both ends.

*Benzidine*, m. p. 125—127°. Strong continuous spectrum at about 3200—4600 Å.U., fading off gradually at both ends but more so at the end of shorter wave-length. Centre of maximum emission at approximately 3830 Å.U.

*Hydrazobenzene*, m. p. 126—127°. Very faint, continuous spectrum at approximately 3050—4125 Å.U., fading off gradually at both ends, but more so at end of greater wave-length. Centre of maximum intensity at approximately 3340 Å.U.

*Phenylhydrazine*, b. p. 241.0—241.5°/763 mm. Weak continuous spectrum at approximately 2980—3640 Å.U., fading off gradually at both ends. Possibly there are faint narrow bands at 3024 and 3052 Å.U.

*α-Methylphenylhydrazine*, b. p. 101—103°/28—29 mm. Strong continuous spectrum at approximately 2940—4225 Å.U., fading off gradually at both ends, but more so at the end of greater wave-length. Centre of maximum intensity at approximately 3345 Å.U.

*α-Naphthylamine*, b. p. 299.4—299.7°/774 mm. Intense continuous spectrum at approximately 3320—4700 Å.U., fading off gradually at both ends with a diffuse head at about 3780 Å.U.

Signs of very indistinct bands were observed at approximately 3340, 3399, 3443, and 3506 Å.U., but the phenomena are doubtful.

*β-Naphthylamine*, m. p. 110°. Intense continuous spectrum at approximately 3280—4700 Å.U., fading off gradually at both ends. Centre of maximum intensity at approximately 3800 Å.U.

*Ammonia*. The ammonia spectrum contains two maxima at 3360 and 3371 Å.U. and a band system extending from these in both directions to 3286 and 3450, respectively. Possibly there may be two bands in the visible region at 5690 and 6600 Å.U. These bands are very indefinite. The spectrum in general is that of ammonia in a vacuum tube excited by an ordinary induction coil discharge.

On collating the foregoing data, some points of interest are found. The attachment of the amino-group directly to the benzene ring has the effect of shifting the region of emission towards the red end. Replacement of the hydrogen atoms of the amino-group by alkyl radicals has no profound influence on the spectral character of the emission. When phenyl groups are introduced into the amino-radical, the first phenyl group weakens the intensity of the spectrum as a whole, whilst a second phenyl radical increases the intensity slightly, though not enough to bring it back to the intensity of aniline.

The replacement of one hydrogen atom of the amino-group by the group  $-\text{NH}_2$  so as to form phenylhydrazine, has a marked influence on the spectrum. Aniline has a strong emission with a length of 1120 units; the emission of phenylhydrazine is weak and extends over only 660 units. If the imino-group of phenylhydrazine carries a methyl group,  $\text{NMePh}\cdot\text{NH}_2$ , both the intensity and the extent of the emission are increased. On the other hand, the introduction of a phenyl group, forming  $\text{NHPh}\cdot\text{NHPh}$ , weakens the intensity of the spectrum but increases the extent of the emission.

The influence of constitution upon the spectra is seen by comparing the following data :

		Intensity.	Emission region.
Diphenylmethane	$\text{CH}_2\text{Ph}_2$	Medium	2673—3900
Diphenylamine	$\text{NHPh}_2$	Weak	3070—3875
Dibenzyl	$\text{CH}_2\text{Ph}\cdot\text{CH}_2\text{Ph}$	Faint	2700—4300
Hydrazobenzene	$\text{NHPh}\cdot\text{NHPh}$	Very faint	3050—4125
Benzidine	$\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2$	Strong	3200—4600
Diphenyl	$\text{C}_6\text{H}_5\cdot\text{C}_6\text{H}_5$	Faint	2890—3900

Obviously when imino-groups are substituted for methylene groups the intensity is weakened and the spectrum is truncated at the violet end. Hydrazobenzene has a very faint spectrum, whereas the spectrum of benzidine is strong. The intensity of the benzidine spectrum is not due to the close proximity of the two

phenyl nuclei, since the parent substance, diphenyl, has only a faint spectrum. The difference in the spectra of the two isomeric compounds must therefore be sought in difference between the group  $-\text{NH}-\text{NH}-$  on the one hand and the two primary amino-groups on the other.

The introduction of an amino-group into naphthalene has the effect of shortening the original spectrum at both ends while making it more intense in the region in which it still persists.

We desire to express our indebtedness to the Research Fund Committee of the Society; and also to the Eastman Kodak Company, who supplied us with specially pure specimens of some of our materials.

### V.—*The Solubility of Sodium Iodide in Ethyl Alcohol.*

By FREDERICK ERNEST KING and JAMES RIDDICK PARTINGTON.

THE solubilities of the iodides of the alkali metals in alcohol require reinvestigation on account of the probable presence of moisture in the materials previously employed.

*Preparation of the Materials.*—*Ethyl alcohol.* Two litres of 96% alcohol were poured on to freshly burnt quicklime, refluxed for 6 hours, distilled, and refluxed over a further quantity of lime. The alcohol was distilled on to 5 g. of powdered silver nitrate previously dried at  $110^{\circ}$ , refluxed, and distilled. The distillate was refluxed with about 20 g. of fresh calcium turnings and distilled through a tall column, the first and last fractions of 100 c.c. being rejected. The alcohol was stored in a vessel with a siphon attachment and a guard tube of phosphorus pentoxide. The alcohol was free from aldehyde, ketone, ethyl nitrite, and ammonia. The density ( $D_{20}^{20}$ ) was 0.7851.

*Sodium iodide.* The iodide was prepared by decomposing pure sodium carbonate with hydriodic acid of constant b. p. ( $126^{\circ}$ ), prepared by the action of hydrogen sulphide on iodine in the presence of water. The solution of sodium iodide, slightly coloured with iodine from the decomposition of a little of the acid by the air, was evaporated to dryness and the solid recrystallised three times from water. The crystals of  $\text{NaI} \cdot 2\text{H}_2\text{O}$  were heated in a large porcelain boat in a sloping glass tube through which a slow current of pure dry hydrogen was passing. The electrolytic hydrogen used in these

experiments was contained in a cylinder and was freed from oxygen by passing over heated platinised asbestos. As the water was driven off from the iodide the temperature was increased to  $120^{\circ}$ . The white solid was cooled in dry hydrogen, removed quickly, and ground up in a mortar contained in a desiccator over phosphorus pentoxide (Parker, J., 1914, 105, 1504). Spectrum analysis failed to reveal the presence of other metals and the iodine content was shown to be 84.64% by precipitation as silver iodide (Theory, 84.66%).

FIG. 1.

*Experimental.*—On account of the hygroscopic nature of the solution the apparatus shown in Fig. 1 was devised. The apparatus was carefully dried and an excess of sodium iodide, together with the alcohol, placed in the tube A. The tube was closed with a good cork, which had been dried by heating in a wax-bath at  $120^{\circ}$ , and fitted with a glass stirrer. The air in the tube was displaced by dry hydrogen through the tap,  $T_1$ , and the vessel was then closed by pouring mercury into the seal surrounding the stirrer. Tube B was closed with a rubber bung, through which passed a filter tube packed with dry cotton wool, reaching to the bottom of B, with the top ground to take the end of a standard pipette. The capacity of A was approximately 80 c.c. and that of B 30 c.c. Tube B was filled with dry hydrogen and closed at the top of the filter tube with pressure tubing and a clip. Connexion between A and B could be made through the enclosed tap, T.

The apparatus was placed in a thermostat maintained at  $25.0^{\circ}$ , and the alcohol and iodide were stirred over-night. The stirring was then discontinued, and a sample of the saturated solution of iodide transferred to B through T by suction through  $T_2$ , dry hydrogen being admitted through  $T_1$  to take the place of the solution removed. Quantities of approximately 10 c.c. of the solution were removed in standard pipettes and rapidly transferred to weighed evaporating flasks fitted with ground glass stoppers having two tubes sealed into them, the outer ends being provided with ground glass caps. The weights of the solutions were found, the solutions evaporated to dryness, the residues heated to  $120^{\circ}$  in a stream of dry hydrogen, and weighed. The solubility of sodium iodide in alcohol at  $25^{\circ}$  was found and an approximate value for the density of the solution as compared with water as a standard was calculated.

*Results.*—The figures under  $S^{25}$  represent the solubilities of sodium iodide in ethyl alcohol at  $25^{\circ}$  in g. per 100 g. of alcohol.

Expt. ...	1	2	3	4	5	6	7	8	9	10
$S^{25}$ .....	42.82	42.39	42.20	42.13	42.89	42.83	42.84	42.24	42.50	42.89

Density ( $D^{25}$ ) = 1.037. Mean value of  $S^{25}$  = 42.57.

Pure dry lithium iodide has been prepared by heating the monohydrate in a current of dry nitrogen free from oxygen, and investigations on the influence of the solubility of lithium iodide on the solubility of sodium iodide in alcohol are in progress.

EAST LONDON COLLEGE,  
UNIVERSITY OF LONDON.

## VI.—The Structure of the Normal Monosaccharides. Part III. Rhamnose.

BY EDMUND LANGLEY HIRST and ALEXANDER KILLEN MACBETH.

As earlier work led to the conclusion that normal derivatives of the pentose sugars xylose and arabinose have the amylene-oxidic structure (Hirst and Purves, J., 1923, **123**, 1352; Hirst and Robertson, J., 1925, **127**, 358), it was obviously of interest to determine the structure of normal derivatives of a typical methyl pentose. Evidence is now submitted showing that *l*-rhamnose and its stable derivatives also are amylene-oxidic. This view conflicts with the suggestion of Pringsheim ("Zuckerchemie," 1925, p. 102) that a butylene-oxidic structure for rhamnose follows from the apparently definite furoidal structure of rhamnal (Bergmann and Schotte, *Ber.*, 1921, **54**, 404). Fischer, Bergmann, and Rabe (*Ber.*, 1920, **53**, 2362) found, however, that during the conversion of aceto-

bromorhamnose into triacetyl methylrhamnoside a mixture of isomeric substances is formed by the wandering of acetyl groups accompanied by corresponding changes in the nature of the oxidic linkings. We are therefore of the opinion that it would be unsafe to base the structure of rhamnose derivatives on that of rhamnal, and, when considered in the light of the work now described, the presence of a  $\gamma$ -oxidic linking in triacetyl rhamnal is to be taken rather as evidence of the occurrence of an isomeric change during the reduction of acetobromorhamnose than as proof of the constitution of rhamnose itself.

The observations of Fischer, Bergmann, and Rabe led us to consider with special care the stability of the methoxyl groups in methylated rhamnose, for any wandering of the methyl groups would complicate very seriously the oxidation method we proposed to use in determining the structure of the compound. A wandering of a methyl group from position 6 to position 3 in the glucose molecule has been suggested (Ohle, *Ber.*, 1924, 57, 403) to explain certain discordant observations in the chemistry of the acetone derivatives of the sugars, but, so far as we are aware, no case of such a transformation has been encountered during the oxidation of a methylated carbohydrate. Both  $\gamma$ - and normal derivatives oxidise to stable methoxy-acids without wandering of the methyl groups (compare, *e.g.*, Irvine, Fyfe, and Hogg, *J.*, 1915, 107, 539; Irvine and Oldham, *J.*, 1921, 119, 1744; Pryde, *J.*, 1923, 123, 1808; Levene, *J. Biol. Chem.*, 1924, 60, 167; Haworth and Baker, *J.*, 1925, 127, 365; etc.). A study of methylated rhamnose and its oxidation has convinced us that the course of oxidation is normal in this case also, and that in consequence the structure of methylated rhamnose may be deduced when the nature of the oxidation products is known.

Rhamnose indeed, when methylated under various conditions, has shown a rather unusual capacity for yielding methyl derivatives of one structural form only. On methylation, either by preliminary formation of the crude mixture of  $\alpha$ - and  $\beta$ -methylrhamnosides with acid methyl alcohol followed by use of the Purdie reagents, or by direct treatment with methyl sulphate, only the normal trimethyl rhamnose (Purdie and Young, *J.*, 1906, 89, 1194) was obtained, whereas in many cases mixtures containing both the amylen- and the butylene-oxide form of the methylated sugar are produced (Pryde, Hirst, and Humphreys, *J.*, 1925, 127, 348).

Oxidation of this trimethyl rhamnose by nitric acid not only showed that the compound was free from admixture with isomeric forms of different oxidic linking, but also gave a direct proof of its constitution. The oxidation product under the special conditions

adopted was *l*-arabotrimethoxyglutaric acid, which may also be obtained by oxidising trimethyl arabinose or by methylating *l*-trihydroxyglutaric acid. No methoxy-group was lost during the reaction, but the terminal methyl group was removed. These observations can be interpreted (assuming the stability of the methoxy-groups) only on the basis of an amylenic-oxidic structure for normal trimethyl rhamnose, and from arguments which have been detailed previously this leads to the assigning of the amylenic-oxidic formula to  $\alpha$ - and  $\beta$ -methylrhamnosides and in all probability to rhamnose itself. A summary of the reactions involved is given in the accompanying scheme.

The mechanism of the oxidation is in itself interesting. After the production of the intermediate trimethylrhammonic acid, the action of nitric acid on the terminal  $-\text{CH}(\text{OH})\cdot\text{CH}_3$  group involves a quantitative transformation to  $-\text{CO}\cdot\text{OH}$  and  $\text{CO}_2$ . This must proceed *via* the ketone  $-\text{CO}\cdot\text{CH}_3$ , and the present reaction (although not in accord with the usual behaviour of methyl ketones) is thus brought into line with certain other instances. For example, lævulic acid yields succinic acid on treatment with nitric acid (Tollens, *Annalen*, 1881, 206, 257) and rhamnose itself gives *l*-trihydroxyglutaric acid (Will and Peters, *Ber.*, 1889, 22, 1697). The simple nature of the change is here emphasised because of its contrast with the more complicated course of oxidation undergone by the allied group  $-\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OMe}$ .

A study of the latter question has been completed by one of us in connexion with work on glucose, and details of this will be given in a future communication.

## EXPERIMENTAL.

*Methylation of Rhamnose.*—A mixture of  $\alpha$ - and  $\beta$ -methylrhamnosides (Fischer, *Ber.*, 1895, 28, 1158) was methylated in the manner described by Purdie and Young (*loc. cit.*). The trimethyl  $\alpha$ -methylrhamnoside so prepared showed the properties and physical constants given by these authors (b. p.  $101^{\circ}/9$  mm.;  $[\alpha]_D - 15^{\circ}$  in water;  $[\alpha]_D - 54^{\circ}$  for  $c = 2.15$  in alcohol. The refractive index, hitherto unrecorded, was  $n_D^{15} = 1.4415$ ).

In a second series of experiments rhamnose was treated in the usual way with methyl sulphate and caustic soda. Two such treatments followed by one with silver oxide and methyl iodide gave in good yield the fully methylated sugar as a colourless, uncrystallisable syrup, b. p.  $100-101^{\circ}/9$  mm.,  $n_D^{15} 1.4415$  (Found: C, 54.5; H, 9.2; OMe, 55.2. Calc., C, 54.5; H, 9.1; OMe, 56.3%). It was stable to alkaline potassium permanganate solution and showed  $[\alpha]_D - 11.3^{\circ}$  in alcohol ( $c = 1.77$ ) and  $+ 11.5^{\circ}$  in water ( $c = 2.002$ ). It was therefore a mixture of the  $\alpha$ - and  $\beta$ -forms of trimethyl methylrhamnoside. On hydrolysis with 8% aqueous hydrochloric acid at  $90^{\circ}$ , the specific rotation decreased regularly from the initial value of  $+ 15.5^{\circ}$  ( $c = 1.159$ ) to zero after 40 minutes and then rose gradually to a constant value,  $+ 21.2^{\circ}$  ( $c = 1.085$  as trimethyl rhamnose), after 200 minutes. On plotting the values against time, a curve is obtained which is characteristic of the hydrolysis of a mixture of the  $\alpha$ - and  $\beta$ -forms of a methyl aldside. Experiments on a larger scale gave a final value of  $+ 19.5^{\circ}$  ( $c = 6.4$ ) (compare Purdie and Young, *loc. cit.*). An improved method was employed to isolate the trimethyl rhamnose. After neutralisation of the acid with barium carbonate the hydrolysis product was extracted with chloroform and purified by distillation (yield 75%), being thus obtained as a colourless, viscous syrup, b. p.  $141^{\circ}/19$  mm. (bath at  $153^{\circ}$ ),  $n_D^{15} 1.4565$  (Found: C, 52.3; H, 8.7; OMe, 44.7. Calc., C, 52.4; H, 8.7; OMe, 45.1%).  $[\alpha]_D + 24.9^{\circ}$  (in water,  $c = 2.53$ ),  $- 9^{\circ}$  (in alcohol,  $c = 1.36$ ). It was obviously identical with the trimethyl rhamnose prepared by Purdie and Young.

*Oxidation of Trimethyl Rhamnose.*—A solution of 3.0 g. of trimethyl  $\alpha$ -methylrhamnoside (prepared from  $\alpha$ -methylrhamnoside; or trimethyl rhamnose may be used) in 70 c.c. of nitric acid ( $d 1.2$ ) was heated slowly until oxidation commenced, at  $85^{\circ}$ . The reaction proceeded vigorously and was apparently complete after 4 hours. Heating was then renewed, and continued for a further  $2\frac{1}{2}$  hours. The oxidation product was freed from nitric acid, dried, and esterified with acid methyl alcohol by the method described in previous papers of this series. The ester (2.61 g. or 77% of the

theoretical yield) was purified by distillation and thus obtained as a colourless, uncrystallisable syrup [2.41 g.; b. p.  $135^{\circ}/9$  mm. (bath at  $150^{\circ}$ );  $n_D^{20}$  1.4350;  $[\alpha]_D + 47.6^{\circ}$  (in methyl alcohol,  $c = 1.706$ )]. It behaved as an ester on titration, and analysis and a comparison of its physical constants with those of an authentic sample prepared from arabinose showed it to be dimethyl *l*-arabotrimethoxyglutarate ( $n_D^{21}$  1.4355; b. p.  $143^{\circ}/18$  mm.;  $[\alpha]_D + 47.3^{\circ}$  for  $c = 1.842$  in methyl alcohol) [Found: C, 47.8; H, 7.25; OMe, 60.2; CO<sub>2</sub>Me (by hydrolysis), 46.3. Calc., C, 48.0; H, 7.2; OMe, 62.0; CO<sub>2</sub>Me, 47.2%]. In view of the large difference in rotatory power between the acid and its fully methylated dimethyl ester (Hirst and Robertson, *loc. cit.*), it was of interest to examine the rotation of the sodium salt. A weighed quantity of the ester was hydrolysed with just more than the calculated quantity of caustic soda, and the solution was exactly neutralised with hydrochloric acid;  $[\alpha]_D + 25^{\circ}$  was thus found for the sodium salt (compare Purdie and Irvine, J., 1901, 79, 962, for the rotations of dimethyl *d*-dimethoxysuccinate and the corresponding sodium salt).

When the ester was treated with methyl alcohol saturated with dry ammonia (0.36 g. in 3.6 c.c.), crystals of the diamide separated after 15 hours, and after 3 days 0.20 g. was collected (63% yield). The crystals were washed with cold methyl alcohol and ether and recrystallised once from methyl alcohol; they then had m. p.  $230^{\circ}$ , alone or mixed with an authentic specimen of *l*-arabotrimethoxyglutardiamide. The solubilities, the crystalline form, the behaviour on heating, and the specific rotation of this substance were in exact agreement with those previously recorded.  $[\alpha]_D + 50.4^{\circ}$  ( $c = 0.6942$  in water) (Found: OMe, 41.6. Calc., OMe, 42.3%).

## VII.—*The Specific Heats of Hydrocyanic Acid.* *A Reply.*

By EDITH HILDA INGOLD.

EARLY this year, a paper by Partington and Carroll appeared (*Phil. Mag.*, 1925, 49, 665) dealing with the ratio of the specific heats of hydrocyanic acid. The author's previous measurements of this constant (J., 1922, 121, 1604) were discussed at some length and criticised on two distinct grounds.

The first of these criticisms is summed up in the remark that "the results obtained by Usherwood, although interesting and useful, are approximate only." \* Since results of moderate precision were all that the author attempted to obtain, no exception could be taken to this statement were it not made in association with comments relating to the author's experimental procedure which are without foundation in fact, and are apparently intended to suggest a want of care. Thus, Partington and Carroll state: "The gas used, obtained by the action of dilute sulphuric acid on potassium cyanide,† scarcely fulfils the purity requirements required for the determination of physical constants." It was, however, made clear in the original experimental description (*loc. cit.*, p. 1609), and may again be emphasised, that the "gas used" was not, as this sentence implies, taken *straight from the generating apparatus into the sound-tube*, but was *first liquefied*, dried, fractionated until its boiling point was constant, and frozen, before use. A specimen of hydrocyanic acid, prepared by this method, has recently been sent for the determination of physical constants to another worker, who reports that he has found it satisfactory. Another similar criticism is that the author made no mention of "precautions taken to prevent contamination of the vapour by air, due to leakage into the apparatus." It is true that since the elementary precaution of ensuring that an apparatus is gas-tight is not peculiar to the experiments described, it was omitted from the experimental description. It may now be stated, however, (a) that the apparatus *was* tested for leakage before and after every experiment, (b) that (excepting in preliminary experiments which were not published) no leakage was found, (c) that the arrangement was such that if there had been a leak hydrocyanic acid would have passed into the air, not *vice versa*.

The second main criticism offered by Partington and Carroll is that the results obtained by the author are due not, as was suggested, to the thermal effect accompanying isomeric change, but to the thermal effect accompanying polymerisation, the occurrence of which, in the vapour of hydrocyanic acid, is, according to Partington and Carroll, indicated by the author's measurements of its density.

\* This conclusion is not, as might perhaps be thought, based on any obvious disagreement between the author's results and those of Partington and Carroll; nor do these authors claim that their measurements are of superior precision, although they may well be, having evidently been conducted with great care and attention to detail. They were carried out at the ordinary temperature and under reduced pressures, whereas the author's observations were made at elevated temperatures.

† It was actually pure sodium cyanide, as appears from the description given (*loc. cit.*, p. 1609).

These measurements showed that, although above about  $170^{\circ}$ , the density is normal (ideal) to within the limits of experimental error (estimated as 0.2%), on approaching the point of liquefaction substantially higher densities obtain, the value at the lowest temperature investigated being nearly 4% above the theoretical. This type of behaviour is, of course, well known. Vapour densities about 3—6% higher than the theoretical were observed by S. Young (*Proc. Roy. Soc. Dublin*, 1910, **12**, 374) for a great variety of substances, including many, such as fluorobenzene, benzene, hexane, pentane, etc., which could not be suspected of any noteworthy tendency to polymerise. The inert gases exhibit the same characteristic. Partington and Carroll, however, regard such density values as indicating in the case of hydrocyanic acid, not deviations from the gas laws, that is, deviations due to molecular attraction and molecular size (the  $a$  and  $b$  of van der Waals), but polymerisation. Thus the observed 4% excess over the theoretical density is interpreted as indicating that approximately 8% of the molecules have combined to form  $(\text{HCN})_2$ . This view of vapour density results appears to the author entirely contrary to accepted principles. If it were valid, the continuity of state would demand that compressed gases and even ordinary liquids (the densities of which at *N.T.P.* may be thousands of times their ideal vapour densities) must consist principally of enormously polymerised molecules; indeed there would be no such thing as a non-associated liquid. In contradistinction to this view, the author wishes to maintain that, since hydrocyanic acid behaves, in regard to vapour density, similarly to numerous other substances, including inert gases and paraffin hydrocarbons, which are non-associated *even in the liquid state*, and can therefore safely be assumed to be non-associated as vapour, the densities observed in the case of hydrocyanic acid vapour near the point of liquefaction are to be interpreted, not as proving association, but as effects due to departure from the condition (point-molecules without attraction) imagined in an ideal gas. Partington and Carroll refer to the "association" of water vapour as an established fact, and certainly, since liquid water is markedly associated, its vapour would be expected to afford a particularly favourable case for the detection of association in the gaseous state. Yet Kendall (*J. Amer. Chem. Soc.*, 1920, **42**, 2477; compare Menzies, *ibid.*, 1921, **43**, 851) has proved conclusively that, despite its enhanced density, the degree of association of water vapour, if not zero, is at any rate so small that the most accurate available measurements fail to show it. Numerous other cases in which density results had previously been interpreted as indicating association in the vapour have been shown by Kendall and Menzies

to be completely accounted for by deviations from the gas laws.\*

### VIII.—Resolution of *dl*-Dicentrine.

By ROBERT DOWNS HAWORTH, WILLIAM HENRY PERKIN, jun.,  
and JOHN RANKIN.

IN a previous communication (J., 1925, 127, 2018), the synthesis of a *dl*-base,  $C_{20}H_{21}O_4N$ , having the constitution

suggested by Gadamer (*Arch. Pharm.*, 1911, 249, 701) for dicentrine is described and it was pointed out that the synthetical base exhibits a series of colour reactions identical with those described by Asahina (*Arch. Pharm.*, 1909, 247, 206) as characteristic of naturally occurring *d*-dicentrine. It has now been found that the *dl*-base may be readily resolved into its *d*- and *l*-modifications by means of tartaric acid under conditions similar to those employed by Gadamer (*loc. cit.*, p. 688) for the resolution of *dl*-glaucine. The *d*- and *l*-modifications crystallise well from ether, melt at 169°, and have  $[\alpha]_D + 64.1^\circ$  and  $- 63.5^\circ$ , respectively.

\* Partington and Carroll calculate that at the critical point hydrocyanic acid must "consist almost entirely of double molecules." On similar principles, argon at the critical point should mainly consist of  $A_3$ . On the other hand, the possibility of association near the critical point (*i.e.*, under high pressure) must be admitted in the case of substances which are associated as liquids, and hence critical data must be used with caution in such cases.

Partington and Carroll's remaining criticisms relate principally to the author's method of calculating the results. For instance, they propose correcting for the variation with temperature of the specific heats of air; a correction which was omitted, since it makes a difference of only about 3 units in the fourth significant figure. They also suggest an alternative method (based on "calculated" critical data) for correcting for deviations from the gas laws, but later in their paper declare it to be unjustified for the reason given above. Bredig and Teichmann (*Z. Elektrochem.*, 1925, 31, 449) observed critical data in fairly good agreement with those used by Partington and Carroll, but near the critical point a curved "rectilinear diameter" was obtained, which may indicate appreciable association under these conditions (Guye, *Arch. Sci. phys. nat.*, 1894, 31, 38).

These constants agree closely with those assigned to dicentrine by Asahina (*loc. cit.*; m. p. 168—169°;  $[\alpha]_D + 62.7^\circ$ ) and a direct comparison of the *d*-base with a specimen of *d*-dicentrine which Professor Gadamer kindly sent us definitely established identity.

#### EXPERIMENTAL.

*dl*-Dicentrine was prepared in the way described in our earlier communication (*loc. cit.*). Commencing with 30 g. of homoveratrylhomopiperonylamine, 7.5 g. of the dihydrochloride of 6'-aminoveratrylhydrohydrastinine were obtained and this yielded 1.3 g. of pure *dl*-dicentrine, m. p. 181° (corr.).

In an attempt to devise an alternative method for the preparation of 6'-nitroveratrylhydrohydrastinine, 6'-nitroveratrylnorhydrohydrastinine (1.5 g.), water (7 c.c.), 40% formalin (0.5 c.c.), and anhydrous formic acid (0.8 c.c.) were heated for 6 hours at 160—170° in a sealed tube. The contents of the tube were diluted with water, and the pale yellow needles collected and recrystallised from alcohol (m. p. 119°) and identified as 6-nitrohomoveratrole. The acid solution was made alkaline with sodium hydroxide, allowed to remain for 24 hours, the precipitate collected, washed with water and crystallised from petroleum (b. p. 40—60°), separating in colourless plates, m. p. 56—58° (Found: C, 68.9; H, 6.7. Calc. for  $C_{11}H_{13}O_2N$ , C, 69.1; H, 6.8%). The identity of this substance with hydrohydrastinine was confirmed by the preparation of the methiodide, which crystallised from methyl alcohol in colourless, rhombic prisms, m. p. 229°, and by the fact that on oxidation with iodine a solution was obtained which exhibited the characteristic hydrastinine fluorescence. The formation of 6-nitrohomoveratrole and hydrohydrastinine under the influence of formaldehyde and formic acid involves a reduction, a methylation, and a scission of the molecule of a kind similar to that observed by Hope and Robinson (J., 1911, 99, 2114) when they obtained 2·6-dinitrotoluene and cotarnine by heating anhydrocotarnine-2:6-dinitrotoluene with glacial acetic acid.

*Resolution of dl-Dicentrine.*—A 2*N*-absolute alcoholic solution of *d*-tartaric acid (0.6 c.c.) was added slowly to a solution of *dl*-dicentrine (0.5 g.) in absolute alcohol (25 c.c.) until a faint acid reaction was observed towards litmus. The clear tartrate solution was converted into the hydrogen tartrate by the gradual addition of a further quantity of *d*-tartaric acid (0.6 c.c.); an amorphous precipitate then separated which redissolved on gently warming. On vigorously scratching, *l*-dicentrine hydrogen *d*-tartrate (0.2 g.) separated from the warm solution in small crystals which, after cooling, were collected and washed with alcohol.

The filtrate and washings were evaporated to dryness, the gummy residue dissolved in water, the bases liberated by the addition of sodium hydroxide, extracted with ether, the extract dried, and the ether removed. The residue (0.37 g.) was dissolved in absolute alcohol (20 c.c.) and titrated with a 2*N*-absolute alcoholic solution of *l*-tartaric acid (0.45 c.c.) \* until a faint acid reaction was obtained. The clear solution was then treated with a further quantity of *l*-tartaric acid (0.45 c.c.); an amorphous precipitate then separated which redissolved on gently warming. *d*-Dicentrine hydrogen *l*-tartrate (0.2 g.) separated, on scratching, as a crystalline powder, which was collected and washed with alcohol.

The salts in the filtrate and washings were reconverted into base and the treatment with *d*- and *l*-tartaric acid was repeated under the same conditions, when further quantities of *l*-dicentrine hydrogen *d*-tartrate (0.1 g.) and *d*-dicentrine hydrogen *l*-tartrate (0.1 g.) were obtained.

Both *l*-dicentrine hydrogen *d*-tartrate and *d*-dicentrine hydrogen *l*-tartrate are soluble in water but almost insoluble in alcohol, and both crystallise from alcohol containing a little water in colourless, nodular masses.

*d*-Dicentrine was obtained by dissolving the recrystallised *d*-dicentrine hydrogen *l*-tartrate in water, making slightly alkaline with sodium hydroxide, extracting with ether, drying over anhydrous sodium sulphate, and concentrating the filtered ethereal solution, when *d*-dicentrine separated in long, colourless prisms, m. p. 169° (corr.). When mixed with a specimen of the *d*-dicentrine obtained from Professor Gadamer, no alteration in m. p. was observed. In chloroform solution:  $l = 1$ ,  $c = 1.433$ ;  $\alpha_D^{25} = 0.92^\circ$ , whence  $[\alpha]_D^{25} = +64.1^\circ$ . *d*-Dicentrine is readily soluble in alcohol, ethyl acetate, and benzene, almost insoluble in petroleum, and is more soluble in ether than *dl*-dicentrine. It is readily soluble in chloroform, the solution gradually becoming yellow (compare Asahina, *loc. cit.*). The recovery of the base from the chloroform solutions used for optical measurements is a wasteful process, because when the solutions are concentrated a double compound insoluble in ether separates. This can be decomposed by the addition of a little methyl-alcoholic potassium hydroxide and the *d*-dicentrine crystallised from ether, when it is recovered as prisms (m. p. 169°), which, however, are always yellow.

*l*-Dicentrine was obtained from recrystallised *l*-dicentrine hydrogen *d*-tartrate exactly as described in the case of the *d*-base. It crystallises from ether in long, colourless prisms, m. p. 169°

\* Our thanks are due to Sir W. J. Pope for the *l*-tartaric acid used in these experiments.

(corr.). When mixed in about equal proportions with a specimen of *d*-dicentrine, the mixture softens at  $168^{\circ}$ , but does not melt completely until about  $178^{\circ}$ . In chloroform:  $l = 1$ ,  $c = 1.700$ ,  $\alpha_D^{25} = -1.08^{\circ}$ , whence  $[\alpha]_D^{25} = -63.5^{\circ}$ . *l*-Dicentrine resembles the *d*-base in its behaviour towards solvents and is recovered as yellow prisms, m. p.  $169^{\circ}$ , from a chloroform solution.

One of us (R. D. H.) is indebted to the Commissioners of the 1851 Exhibition for a studentship which has enabled him to take part in this research, and to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of the investigation

### IX.—*Synthetical Experiments in the isoQuinoline Group. Part VI. A Synthesis of Derivatives of Paraberine.\**

By RAY CAMPBELL, ROBERT DOWNS HAWORTH, and WILLIAM HENRY PERKIN, jun.

THE careful investigation of the alkaloids of the palmatine, berberine, corydaline type has not only demonstrated their *isoquinoline* structure, but has also shown that they are all built up on the same curious "angular" skeleton (I), a point which is made clear when the formula of berberine or, still better, of tetrahydroberberine (II) is written alongside.

Furthermore, the alkaloids cryptopine, protopine, and  $\beta$ -homochelidonine, although containing a ten-membered ring, are readily

\* The Editor suggests that the substance

should be named "*paraberine*."

converted into quaternary salts, such as *isocryptopine* chloride, which again are derived from the skeleton (I). It is not clear why this particular angular structure should be selected as the basis of so many of the naturally occurring alkaloids, unless indeed it be that substances of this type are particularly amenable to synthesis. In order to obtain evidence on this point, it appeared to us that it would be of interest to synthesise an alkaloid of the paraberine type containing in the place of (I) the "linear" skeleton (III) and to compare the ease of formation and general properties of such a substance with those of the alkaloids met with in nature.

It will be seen from the experimental section of this communication that, although we were ultimately successful in constructing an alkaloid (IV) derived from the skeleton (III), the smallness of the yields at several stages made the completion of the synthesis a particularly difficult one. It is quite clear to us that substances of the angular type (I) are much more readily synthesised, under the conditions we have employed in this series of researches, than those of the linear type (III), and this fact may have some bearing on the occurrence of the angular type in nature. In attempting to synthesise (IV), the most obvious starting point was 6 : 7-dimethoxy-

4-dihydroisoquinolone,  $C_6H_2(OMe)_2$   $\begin{matrix} \text{CO}-CH_2 \\ \text{CH}_2-NH \end{matrix}$ , but we were unable to obtain this substance either from  $\omega$ -aminoacetoveratrone,  $(MeO)_2C_6H_3-CO-CH_2-NH_2$ , by the action of formalin or from the *N*-formyl derivative of the base by treatment with phosphorus oxychloride. Moreover, *N*-phenacetyl- $\omega$ -aminoacetoveratrone (Robinson, J., 1909, 95, 2167), on treatment with phosphorus oxychloride, yielded not the *isoquinoline* derivative but 5-veratryl-2-benzylloxazole (m. p.  $86^\circ$ ), which Robinson had obtained from the phenacetyl derivative by the action of sulphuric acid. This failure to close the *isoquinoline* ring seems to indicate that it is the carbonyl group in  $\omega$ -aminoacetoveratrone which inhibits ring formation, because when this group is replaced by  $>CH_2$  or  $>CH-OH$  *isoquinoline* derivatives may be readily obtained (Pictet and Gams, *Ber.*, 1909, 42, 2943; Decker, *Annalen*, 1913, 395, 299). After many other unsuccessful attempts, we ultimately succeeded, with the aid of the following scheme, in synthesising 2 : 3-methylenedioxy-11 : 12-dimethoxy-6 : 15 : 16 : 17-tetrahydroparaberine (IV).

3 : 4-Dimethoxyphenyl 3 : 4-methylenedioxyethyl ketone (V),

prepared from acetoveratrone and piperonal by Bargellini and Monti's method (*Gazzetta*, 1914, 44, ii, 25), was reduced by hydrogen in the presence of colloidal palladium to 3:4-dimethoxyphenyl 3:4-methylenedioxy- $\beta$ -phenylethyl ketone, which, on treatment with methyl nitrite and sodium ethoxide, yielded the isonitroso-derivative (VI).

The reduction of this isonitroso-derivative to 3:4-dimethoxyphenyl 3:4-methylenedioxy- $\beta$ -phenyl- $\alpha$ -aminoethyl ketone (VII) proved to be a troublesome operation. When alkaline reducing agents were employed, the pyrazine derivative (VIII) was produced as the result of condensation between two molecules of the base (VII) followed by spontaneous oxidation. Eventually the amine (VII) was obtained by reducing the isonitroso-derivative (VI) with stannous chloride, but in order to obtain even approximately good yields the conditions described on p. 38 must be exactly followed.

The amine (VII) condenses readily with formalin and hydrochloric acid to give 6:7-methylenedioxy-3-(3':4'-dimethoxybenzoyl)-1:2:3:4-tetrahydroisoquinoline (IX), the hydrochloride, oxime, picrate, and benzoyl derivative of which have been prepared. When the base (IX) is oxidised with iodine, it is converted into 6:7-methylenedioxy-3-(3':4'-dimethoxybenzoyl)isoquinoline (X), which is closely related to papaveraldine in structure and properties. It is a weak tertiary base yielding pale yellow salts which are slowly dissociated by water. On fusion with potassium hydroxide, it is decomposed and veratric acid has been isolated from the product, but the basic residue could not be identified, as it was no doubt destroyed during the fusion owing to disruption of the methylenedioxy-group. The formation of veratric acid is, however, welcome confirmation of the validity of the structures (IX) and (X) and it is evident that when the amine (VII) is condensed with formalin it

is again the  $>\text{CO}$  group which inhibits ring closure with the veratryl nucleus.

The base (X), on reduction with zinc dust and acetic acid, yields 6 : 7-methylenedioxy-3-( $\alpha$ -hydroxy-3' : 4'-dimethoxybenzyl)isoquinoline (XI), a secondary alcohol which shows reactions similar to those of papaverinol. When treated with hydrobromic acid and zinc dust (compare Buck, Perkin, and Stevens, J., 1925, 127, 1471), it yielded an oily base the crystalline picrate of which gave analytical figures agreeing with those required for the picrate of 6 : 7-methylenedioxy-3-(3' : 4'-dimethoxybenzyl)isoquinoline (XII), but owing to the small amount of material at our disposal we were unable to isolate the base in a pure state.

The reduction of the substances (IX), (X), and (XI) to 6 : 7-methylenedioxy-3-(3' : 4'-dimethoxybenzyl)-1 : 2 : 3 : 4-tetrahydroisoquinoline (XIII) proved to be a very difficult operation. Reducing agents such as sodium amalgam, zinc and sulphuric acid, as well as electrolytic reduction in the cold, led to the formation of amorphous bases. Since an exactly similar series of substances was obtained from papaveraldine and papaverinol under the same conditions, we are of the opinion that these amorphous bases are of the type (XIV).

Freund and Beck (*Ber.*, 1904, 37, 3321) obtained an amorphous base, which they named "isotetrahydropapaverine," by the electrolytic reduction of papaveraldine in hot dilute sulphuric acid,

but Pyman (J., 1909, 95, 1610) showed that their base is identical with tetrahydropapaverine prepared by reducing papaverine with tin and hydrochloric acid. We have confirmed the identity of the two preparations by a careful comparison of the hydrochlorides, hydriodides, and nitrosoamines. When we applied the conditions employed by Freund and Beck to the electrolysis of the substance (X), we obtained the base (XIII) corresponding with tetrahydropapaverine. It is remarkable that this also is amorphous, but it yields a well-crystallised *hydrochloride*, *hydriodide*, and *nitrosoamine*.

The base (XIII) is converted into 2:3-methylenedioxy-11:12-dimethoxy-6:15:16:17-tetrahydroparaberine (IV) by the action of formalin and hydrochloric acid, but the yield is extremely small and modifications of the process did not lead to any improvement. This experience appears to indicate that the system of rings (III) is produced only with difficulty and when compared with the ease of formation of substances of the tetrahydroberberine type under the same conditions clearly emphasises the greater tendency towards angular ring formation (I) (compare Lellmann and Schmidt, *Ber.*, 1887, 20, 3154; von Braun, *ibid.*, 1922, 55, 1710; Mayer and Schnecko, *ibid.*, 1923, 56, 1408).

In spite of the poor yield we have been able to examine the properties of the base (IV) in some important directions. It was to be expected that, owing to analogy in constitution, the base (IV) would exhibit properties closely allied to those of tetrahydroberberine and still more to those of tetrahydro- $\psi$ -berberine (Haworth, Perkin, and Rankin, J., 1924, 125, 1696). The latter two are characterised by the facility with which they crystallise as well as by the sparing solubility of their salts. But the most striking characteristic is their behaviour on oxidation with iodine, when they yield quaternary salts such as berberinium iodide or  $\psi$ -berberinium iodide (*loc. cit.*, p. 1698) which are not decomposed by alkali with separation of a base.

2:3-Methylenedioxy-11:12-dimethoxy-6:15:16:17-tetrahydroparaberine (IV; m. p. 222°) resembles tetrahydroberberine (m. p. 168°) and tetrahydro- $\psi$ -berberine (m. p. 177°) in being rather sparingly soluble and yielding sparingly soluble, beautifully crystalline salts. The *methiodide* (m. p. 268°), like tetrahydroberberine

methiodide (m. p.  $251^{\circ}$ ) and tetrahydro- $\psi$ -berberine methiodide (m. p.  $260^{\circ}$ ), exhibits remarkable stability to boiling alcoholic potassium hydroxide. On the other hand, when it is treated with iodine, base (IV) does not undergo a change corresponding with the conversion of tetrahydro-berberine or - $\psi$ -berberine into the quaternary berberinium salts. The product consists mainly of a bright yellow, crystalline *hydriodide*,  $C_{20}H_{19}O_4N.HI$ , from which the corresponding *hydrochloride* is obtained by the action of silver chloride, and the latter, in contact with ammonia, is immediately decomposed with separation of an amorphous base,  $C_{20}H_{19}O_4N$ , which is clearly a 2:3-methylenedioxy-11:12-dimethoxydihydroparaberine (6:17 or 6:15) having one or other of the constitutional formulæ (XV and XVI).

The reason for this difference in behaviour is difficult to understand, since the formula of base (IV) contains the grouping which is responsible for the formation of berberinium salts in the berberine series.

#### EXPERIMENTAL.

3:4-Dimethoxyphenyl 3:4-Methylenedioxy- $\beta$ -phenylethyl Ketone.—3:4-Dimethoxyphenyl 3:4-methylenedioxy-styryl ketone (V) was obtained in quantitative yield from piperonal and acetoveratrone under the conditions described by Bargellini and Monti (*loc. cit.*), but in reducing large quantities of this substance the following method is more suitable than that of the above-mentioned investigators. The styryl ketone (50 g.), glacial acetic acid (500 c.c.), 3% palladium chloride (15 c.c.), and gum arabic (0.5 g. in a little water) were introduced into a flask, connected to the hydrogen supply and immersed in a water-bath at  $50-60^{\circ}$ . The flask was fitted with a vigorously acting air-tight mechanical stirrer, the air displaced, and the mixture stirred, when a rapid absorption of hydrogen took place for 2 hours. The hot, colourless solution was filtered, most of the solvent removed, with the aid of a column, under diminished pressure, and methyl alcohol added, when the residue set to a mass of white crystals (41 g.); these crystallised from methyl alcohol in white, woolly needles, m. p.  $102-103^{\circ}$  (B. and M., *loc. cit.*, give  $98-100^{\circ}$ ). The *oxime*, prepared by boiling the phenylethyl ketone with potassium acetate and hydroxylamine hydrochloride in alcoholic solution, crystallised from aqueous alcohol in slender needles, m. p.

119—121°. The *isonitroso*-derivative (VI) was obtained by adding the phenylethyl ketone (10 g.) to boiling alcohol (200 c.c.) in which sodium (2.5 g.) had been dissolved. The hot solution was treated with a stream of dry methyl nitrite (Slater, J., 1920, **117**, 587), cooled, completely saturated with methyl nitrite, and kept in a stoppered flask for 12 hours at the room temperature, when a small amount of solid separated. Most of the alcohol was removed under diminished pressure, the residue diluted with water, and impurities extracted with benzene. Air was drawn through the aqueous layer, which was then rendered slightly acid with acetic acid, the precipitate collected,\* dried (8 g.), and crystallised from aqueous acetic acid, separating in colourless needles, m. p. 137° (Found: C, 62.9; H, 5.1; N, 4.3.  $C_{18}H_{17}O_6N$  requires C, 62.9; H, 5.0; N, 4.1%). This *isonitroso*-derivative is soluble in alcohol, chloroform, or ethyl acetate, slightly soluble in ether, and sparingly soluble in water or petroleum. An attempt to reduce it with zinc dust and acetic acid at 60° led to the regeneration of the phenylethyl ketone (m. p. 102—103°).

*3:4-Dimethoxyphenyl 3:4-Methylenedioxy-β-phenyl-α-aminoethyl Ketone* (VII).—Anhydrous stannous chloride (56 g.) dissolved in absolute alcohol (300 c.c.) was saturated with dry hydrogen chloride at -10°, the finely powdered *isonitroso*-derivative (40 g.) added, and the solution again saturated with hydrogen chloride at -10°. After remaining over-night, the crystalline *stannichloride* of the base (VII) which had separated was collected, dissolved in water, decomposed with hydrogen sulphide, filtered, and the filtrate concentrated until the hydrochloride separated as an oil which rapidly hardened. This (40 g.) was crystallised from a mixture of alcohol and ether, separating in slender, colourless needles, m. p. 218—219° (decomp.) (Found: C, 59.5; H, 5.5.  $C_{18}H_{18}O_5N \cdot HCl$  requires C, 59.9; H, 5.5%). This *hydrochloride* is sparingly soluble in cold alcohol, but dissolves readily in water or warm alcohol. The *picrate* was prepared in alcoholic solution and crystallised from alcohol in yellow needles, m. p. 213° (Found: C, 51.7; H, 4.1.  $C_{24}H_{22}O_{12}N_4$  requires C, 51.6; H, 3.9%). When sodium hydroxide is added to the aqueous solution of the hydrochloride, a turbid solution is first produced and after some time a brown, sticky solid separates which is evidently produced by the base undergoing condensation and oxidation to the pyrazine (VIII).

The *pyrazine* (VIII) is best prepared by stirring a solution of the *isonitroso*-derivative (VI) in sodium hydroxide with zinc dust

\* The mother-liquors contain a little *isonitroso*-compound together with some veratric acid, evidently produced by the hydrolysis of some of the *isonitroso*-derivative.

for 3 hours at the room temperature. The sticky solid which separates is extracted with chloroform, dried, the solvent removed, and the syrup crystallised from a mixture of alcohol and chloroform, when pale yellow needles, m. p.  $205^{\circ}$ , are obtained (Found : C, 69.0; H, 5.2.  $C_{36}H_{32}O_8N_2$  requires C, 69.6; H, 5.2%). This pyrazine is insoluble in alkali and is a weak base dissolving in concentrated hydrochloric acid, from which it is precipitated by dilution with water.

6 : 7-Methylenedioxy-3-(3' : 4'-dimethoxybenzoyl)-1 : 2 : 3 : 4-tetrahydroisoquinoline (IX).—A solution of the hydrochloride of the amine (VII) (2 g.) in methyl alcohol (25 c.c.) and 40% formalin (5 c.c.) was decomposed with sodium bicarbonate, boiled for 20 minutes, diluted with water, and the reddish-brown condensation product collected, washed free from formalin, and digested on the steam-bath with 20% hydrochloric acid. The mass dissolved and in a few minutes the hydrochloride of the base (IX) began to separate, the quantity increasing during 20 minutes. The mixture was cooled, the hydrochloride collected, washed with water, and re-crystallised from very dilute hydrochloric acid. It was then dissolved in water and the base liberated by the addition of ammonia, collected, and crystallised from ethyl alcohol, from which it separates in rosettes of almost colourless needles, m. p.  $137^{\circ}$  (Found : C, 67.2; H, 5.7.  $C_{19}H_{19}O_5N$  requires C, 66.9; H, 5.5%). The base (IX) is readily soluble in chloroform, acetone, hot alcohol, or hot benzene, and sparingly soluble in ether, petroleum, cold alcohol, or cold benzene. It dissolves in concentrated sulphuric acid to a pale yellow solution, which becomes blood-red on the addition of a crystal of potassium nitrate. The hydrochloride crystallises from very dilute hydrochloric acid in slender needles containing water of crystallisation, which is lost at  $115$ – $120^{\circ}$ . The hydrated salt is very soluble in alcohol and the addition of ether to an alcoholic solution precipitates the anhydrous hydrochloride in fine needles, m. p.  $232$ – $234^{\circ}$  (decomp.), which are now insoluble in alcohol. The hydrated salt dried at  $120^{\circ}$  lost 9.7%  $H_2O$ ;  $C_{19}H_{20}O_5NCl \cdot 2H_2O$  requires  $H_2O$ , 8.7% (Found : C, 60.0; H, 5.5.  $C_{19}H_{20}O_5NCl$  requires C, 60.4; H, 5.3%). The benzoyl derivative, obtained by the action of benzoyl chloride and sodium hydroxide on a solution of the hydrochloride, crystallises from alcohol in long, slender needles, m. p.  $187$ – $188^{\circ}$  (Found : C, 69.7; H, 5.2.  $C_{26}H_{23}O_6N$  requires C, 70.1; H, 5.2%). The picrate, prepared from an alcoholic solution of the hydrochloride, crystallises from alcohol in yellow needles containing solvent of crystallisation, m. p.  $157$ – $158^{\circ}$  (decomp.) (Found : C, 50.9; H, 4.5.  $C_{25}H_{22}O_{12}N_4 \cdot H_2O$  requires C, 50.9; H, 4.1%). The oxime was obtained by heating the hydro-

chloride with hydroxylamine hydrochloride for 1 hour in pyridine solution. The mixture was diluted with water and saturated with carbon dioxide; the oxime then slowly separated in needles, m. p. 205—209° (decomp.).

6 : 7-Methylenedioxy-3-(3' : 4'-dimethoxybenzoyl)isoquinoline (X).—The base (IX) (2 g.) was dissolved in ethyl alcohol (50 c.c.) containing potassium acetate (2 g.) and the solution boiled for  $\frac{1}{2}$  hour during the gradual addition of a 2% alcoholic solution of iodine (200 c.c.). On cooling, a mass of crystals separated which were collected, washed with sulphurous acid, water, and alcohol and crystallised from 50% alcoholic glacial acetic acid, separating in colourless needles, m. p. 222° (Found : C, 67.1; H, 4.5.  $C_{19}H_{15}O_5N$  requires C, 67.6; H, 4.4%). This substance (X) is sparingly soluble in alcohol, but readily soluble in glacial acetic acid or chloroform. It is insoluble in water, but dissolves in warm dilute hydrochloric acid to a yellow solution, from which the free base separates on cooling. The *sulphate* crystallises from 20% sulphuric acid in pale yellow plates which slowly dissociate on washing with water. The *oxime* was obtained by boiling an alcoholic solution of the base (X) with hydroxylamine hydrochloride and potassium acetate for 8 hours. The solid was collected and washed with water, when the oxime remained as slender, colourless needles, m. p. 234—236° (decomp.). The base (X) (1 g.) was fused at 180° with potassium hydroxide (10 g.) and a little water. After 5 minutes the brown mass was dissolved in water, the black solution saturated with carbon dioxide, and the brown, amorphous precipitate collected. The filtrate was acidified, extracted with chloroform, the extract dried, and the solvent removed, when a brown solid remained. This was warmed with sodium bicarbonate solution, filtered, the filtrate acidified, the solid collected and crystallised from hot water containing animal charcoal, when needles, m. p. 178°, were obtained which were identified as veratric acid.

6 : 7-Methylenedioxy-3-( $\alpha$ -hydroxy-3' : 4'-dimethoxybenzyl)isoquinoline (XI).—The substance (X) (2 g.) dissolved in glacial acetic acid (20 c.c.) was heated on a water-bath during the gradual addition of zinc dust (0.4 g.). After 4 hours, the solution was filtered, the filtrate diluted with water, allowed to remain for some time, and the small precipitate of unchanged (X) removed. The filtrate was saturated with hydrogen sulphide, the zinc sulphide removed, the filtrate concentrated and made alkaline with concentrated ammonia, when a sticky solid separated which gradually hardened. This was collected, and crystallised from alcohol in colourless needles, m. p. 153° (Found : C, 67.4; H, 5.1.  $C_{19}H_{17}O_5N$  requires C, 67.3; H, 5.0%). This base (XI) is insoluble in water, sparingly soluble

in cold alcohol, but readily soluble in hot alcohol, acetone, or chloroform. It dissolves in concentrated sulphuric acid to a magenta-coloured solution, which becomes deep green on the addition of a crystal of potassium nitrate. The *picrate* separated as an oil which rapidly hardened when an alcoholic solution of the base (XI) was treated with picric acid. It crystallises from much alcohol in yellow needles which darken at  $183^{\circ}$  and melt at  $195^{\circ}$  (decomp.) (Found: C, 53.1; H, 3.7.  $C_{25}H_{20}O_{12}N_4$  requires C, 52.8; H, 3.5%).

6 : 7-Methylenedioxy-3-(3' : 4'-dimethoxybenzyl)isoquinoline (XII).—The base (XI) (0.5 g.) was allowed to remain for 12 hours in glacial acetic acid (5 c.c.) saturated with hydrogen bromide. The solution was then heated to  $30^{\circ}$ , stirred, and excess of zinc dust added slowly during 3 hours. After filtration, the solution was diluted with water (50 c.c.), made alkaline with ammonia, extracted with chloroform, the extract dried and concentrated, when a thick syrup was obtained which did not crystallise. The *picrate* was prepared in alcoholic solution and crystallised from much alcohol in yellow needles, m. p.  $206-207^{\circ}$  (Found: C, 53.9; H, 3.7.  $C_{25}H_{20}O_{11}N_4$  requires C, 54.3; H, 3.6%). All attempts to decompose the *picrate* by digesting with ammonia or sodium hydroxide were unsuccessful.

6 : 7-Methylenedioxy-3-(3' : 4'-dimethoxybenzyl)-1 : 2 : 3 : 4-tetrahydroisoquinoline (XIII).—The substance (X) (4 g.) was suspended in 10% sulphuric acid (200 c.c.) and placed in an enamelled metal can, which constituted the cathode compartment of an electrolytic cell. The solution was heated to  $90-95^{\circ}$  and subjected to a current of 10 amperes, when the suspended sulphate gradually dissolved to a yellow solution which became colourless after 2 hours. The hot solution was filtered, made alkaline with strong ammonia, and extracted with chloroform; a red syrup remained on removing the solvent. This was extracted with boiling dilute hydrochloric acid, the solution filtered, and the filtrate treated with solid potassium iodide, when a sticky *hydriodide* separated which gradually hardened on cooling. This separated from alcohol, in which it was sparingly soluble, in small crystals, m. p.  $226^{\circ}$  (decomp.) (Found: C, 50.2; H, 5.0.  $C_{19}H_{21}O_4N_4HI$  requires C, 50.1; H, 4.8%). The *hydrochloride*, obtained by digesting an aqueous solution of the *hydriodide* with silver chloride, crystallised from alcohol in small needles, m. p.  $220-222^{\circ}$  (decomp.). The *nitrosoamine* separated, on the addition of sodium nitrite to a solution of the *hydrochloride*, as an oil which hardened, and crystallised from alcohol in short needles, m. p.  $128^{\circ}$  (Found: C, 63.8; H, 5.7.  $C_{19}H_{20}O_5N_2$  requires C, 64.0; H, 5.6%).

2 : 3-Methylenedioxy-11 : 12-dimethoxy-6 : 15 : 16 : 17-tetrahydro-*paraberine* (IV).—The *hydriodide* of the base (XIII) (2 g.), dissolved

in methyl alcohol (10 c.c.), was decomposed with sodium bicarbonate and boiled for a few minutes with 40% formalin solution (10 c.c.). The mixture was cooled, diluted with water, sodium chloride added, and the solution decanted from the semi-solid mass which had separated. The latter was well washed with water, digested with concentrated hydrochloric acid (10 c.c.) on the steam-bath for a few minutes, diluted with water, and made alkaline with ammonia; an oil then separated which rapidly hardened. This was collected, triturated with methyl alcohol (15 c.c.), and the insoluble, colourless base (IV) (0.3 g.) collected and crystallised from benzene, from which it separated in small, colourless prisms, m. p. 221—222° (Found: C, 70.8; H, 6.4.  $C_{20}H_{21}O_4N$  requires C, 70.8; H, 6.2%). The base (IV) is insoluble in water, sparingly soluble in ether, petroleum, or cold alcohol, moderately easily soluble in warm alcohol or benzene, and readily soluble in chloroform. The *hydrochloride* crystallises from water, in which it is fairly soluble, in small, colourless needles, m. p. 236—238°. The *picrate*, prepared in alcoholic solution, crystallises from alcohol in yellow nodules, m. p. 199—201° (decomp.) (Found: C, 54.5; H, 4.3.  $C_{26}H_{24}O_{11}N_4$  requires C, 54.9; H, 4.2%). The *methiodide* was prepared by boiling a benzene solution of the base (IV) with an excess of methyl iodide for 1 hour, the solvent removed, and the residue crystallised from methyl alcohol, separating in large prisms, m. p. 268° (Found: C, 52.2; H, 5.2.  $C_{21}H_{24}O_4NI$  requires C, 52.4; H, 5.0%). This methiodide was boiled with a large excess of 25% methyl-alcoholic potassium hydroxide for 6 hours, but, on cooling, crystals of the unchanged methiodide separated and no other substance could be isolated from the product. The methiodide was digested for 3 hours with an aqueous suspension of silver chloride and filtered, when the *methochloride* separated as a gelatinous precipitate, m. p. 260° (decomp.), from the filtrate. The methochloride was recovered after boiling for 6 hours with 25% methyl-alcoholic potassium hydroxide.

2 : 3-Methylenedioxy-11 : 12-dimethoxy-6 : 17 or -6 : 15-dihydro-*paraberine* (XV or XVI).—The base (IV) (1 g.), dissolved in alcohol (20 c.c.) containing potassium acetate (1 g.), was treated with a 1% alcoholic solution of iodine (200 c.c.). After boiling for  $\frac{1}{2}$  hour, the mixture was cooled, and the crystalline periodide was collected and converted, by the action of sulphurous acid, into the bright yellow hydriodide; this was collected, boiled with water and the solution filtered hot. The residue consisted of a high-melting, orange-coloured hydriodide, the yield of which was too small to allow of detailed investigation. A small quantity, however, was converted into the hydrochloride by means of silver chloride, and this

gave an immediate precipitate with ammonia, showing that it was not a quaternary salt. The filtrate, on cooling, deposited pale yellow needles, m. p. 225—226° (Found: C, 51.5; H, 4.4.  $C_{20}H_{19}O_4N$ , HI requires C, 51.6; H, 4.3%). This *hydriodide* is sparingly soluble in cold water or cold alcohol, but moderately soluble in the warm solvents. The *hydrochloride* was obtained by digesting an aqueous solution of the hydriodide with silver chloride and separated from a little water in bright yellow needles which melted at 120° with loss of water of crystallisation. On drying at 120°, it lost 11.5%  $H_2O$  (Found: C, 63.3; H, 5.5.  $C_{20}H_{19}O_4N \cdot HCl \cdot \frac{1}{2}H_2O$  requires C, 62.9; H, 5.5%). The *base* (XV or XVI) was obtained as a pale yellow, amorphous, gelatinous precipitate by the addition of ammonia to an aqueous solution of the hydrochloride, and was collected and dried. It was soluble in the usual organic solvents with the exception of petroleum, but it could not be obtained in the crystalline state. The addition of petroleum (b. p. 40—60°) to the dry ethereal solution precipitated the base as a pale yellow, amorphous powder melting indefinitely between 180° and 190° (Found: C, 70.9; H, 5.7.  $C_{20}H_{19}O_4N$  requires C, 71.2; H, 5.6%).

One of us (R. C.) is indebted to the Trustees of the Earl Grey Memorial Fellowship of Armstrong College, Newcastle-on-Tyne, for a fellowship, and another (R. D. H.) to the Commissioners of the 1851 Exhibition for a studentship. Our thanks are also due to the Research Fund Committee of the Chemical Society and to the Government Grant Committee of the Royal Society for grants which have defrayed some of the expense of this investigation.

## X.—Keto-enol Isomerism of Ethylenebisacetylacetone.

By GILBERT T. MORGAN and CYRIL JAMES ALLAN TAYLOR.

IN their reactions with inorganic reagents acetylacetone and its homologues exhibit the behaviour of three dynamic isomerides: (1) a diketonie form manifested in condensation with tellurium tetrachloride, (2) a *trans*-monoenolic form with selenium tetrachloride, and (3) a *cis*-monoenolic modification with copper acetate, ferric chloride and other metallic salts (Morgan and Drew, J., 1924, 125, 1044).

Ordinary acetylacetone consists principally of enolic forms and in 1921 K. Meyer and Hopff, by distilling the diketone under reduced pressure in silica vessels, succeeded in separating the

enolic and keto-forms, which, however, reverted rapidly to the equilibrium mixture (*Ber.*, 1921, 54, 579).

With certain derivatives of acetylacetone the individual modifications are more stable. Thus Knoevenagel (*Ber.*, 1903, 36, 2150) indicated two isomeric forms of methylenebisacetylacetone, one a solid and the other an oil, both of which developed deep violet colorations with ferric chloride. He regarded the oil as the dienolised form, since with ammonia it yielded diacetyldihydrolutidine, whereas the solid, which gave no dihydropyridine derivative with ammonia, he regarded as the mono-enolised compound.

Schiff claimed to have isolated no fewer than six isomeric varieties of benzylidenebisacetylacetone, namely, a keto-form, two mono-enols (*cis* and *trans*) and three dienols (*dicis*, *ditrans* and *cis-trans*). He did not, however, characterise these various modifications (*Annalen*, 1899, 309, 206).

In the present communication, ethylenebisacetylacetone, prepared by the condensation of sodium acetylacetone and ethylene dibromide, is shown to exist in at least three isomeric forms, which have been identified definitely as a keto-form (I), a mono-enolic modification (II), and a dienolic variety (III).

1. keto-*Ethylenebisacetylacetone* (I) is a mobile, colourless liquid of high boiling point; its alcoholic solution only slowly develops a violet colour with ferric chloride.

2. mono-enol-*Ethylenebisacetylacetone* (II) is obtained in prismatic crystals, m. p. 99°; its alcoholic solution develops instantaneously a deep violet coloration with ferric chloride.

3. dienol-*Ethylenebisacetylacetone* (III) separates in cubical crystals, m. p. 140–143°, and reacts immediately with ferric chloride. This form is, however, less stable in air than the preceding varieties and the melting point of the crystals soon falls to about 100–110°.

The foregoing isomerides were characterised by an application of Meyer's method for estimating the percentage of enolic modification in a tautomeric substance such as acetylacetone (*Annalen*, 1911, 380, 212; 1913, 398, 49; *Ber.*, 1911, 44, 2718; 1912, 45, 2843), which depends on the rapid addition of bromine to the enolic modification, but not to the ketonic form. When treated with excess of hydroxylamine, keto-ethylenebisacetylacetone and enol-

ethylenebisacetylacetone both yield stereoisomeric tetraoximes. In the latter oximation, it is evident that hydroxylamine causes the enolic modification to revert to the ketonic isomeride.

## EXPERIMENTAL.

*Interaction of Sodium Acetylacetone and Ethylene Dibromide.*—Sodium acetylacetone (210 g.) was mixed with excess of ethylene dibromide (600 g.) and refluxed at 160° for 12 hours; the mixture was then allowed to cool and the deposit of sodium bromide washed with ether. The weight of bromide corresponded nearly quantitatively with the amount of sodium originally in the sodium acetylacetone.

The brown ethereal filtrates were distilled, ether and ethylene dibromide being collected up to 135° and acetylacetone from 135° to 145°; the residue was transferred to a Claisen flask and distilled under reduced pressure (3—5 mm.), and the following fractions were collected: (1) b. p. 60—80°—contained the remainder of the ethylene dibromide and acetylacetone; (2) b. p. 80—100°—25 g. of a slightly yellow liquid boiling under ordinary pressure at about 200°. Its alcoholic solution gave no immediate coloration with ferric chloride, but a violet coloration slowly developed; it did not give a copper salt with ammoniacal copper acetate; (3) b. p. 120—130°—8.5 g. of a yellow oil; its alcoholic solution gave an immediate violet colour with ferric chloride and a small precipitate of copper salt with ammoniacal cupric acetate; (4) b. p. 170—200°—19 g. of a brown, viscid oil which gave an instantaneous ferric coloration and a copious precipitate with ammoniacal cupric acetate.

I. *keto-Ethylenebisacetylacetone* (I).—The principal product of the reaction, represented by the second fraction (b. p. 80—100°), was redistilled under reduced pressure, when about 80% distilled between 83° and 85°/4 mm. The resultant liquid was slightly yellow, readily miscible with water, alcohol, benzene, ether, or chloroform, but not with light petroleum; it dissolved in dilute sodium hydroxide to a yellow solution. A sodium salt was formed by adding metallic sodium to the liquid dissolved in ether.

After several distillations under reduced pressure, *keto-ethylenebisacetylacetone* boiled at 97—99°/20 mm. (Found: C, 63.3, 63.9; H, 7.9, 7.9.  $C_{12}H_{18}O_4$  requires C, 63.7; H, 8.0%).

II. *Dehydration Product of Ethylenebisacetylacetone.*—The third fraction (b. p. 120—130°) did not solidify on keeping in the ice chest and was therefore dissolved in alcohol and treated with an excess of ammoniacal cupric acetate, when on dilution with water a small amount of copper salt was precipitated, but the major part of the substance evidently remained dissolved in the aqueous-

alcoholic filtrate. By diluting further with water and extracting several times with ether, a light brown oil was obtained, which soon crystallised. After repeated crystallisation from alcohol, the substance separated in colourless, hexagonal plates or laminae, but only a very small amount was isolated. Its alcoholic solution did not respond to ferric chloride (Found: C, 72.2, 72.4; H, 8.2, 7.3.  $C_{24}H_{30}O_5$  requires C, 72.4; H, 7.5%, thus corresponding with a possible dehydration product of ethylenebisacetylacetone:  $2C_{12}H_{18}O_4 - 3H_2O = C_{24}H_{30}O_5$ ) (Knoevenagel, *loc. cit.*).

III. enol-Ethylenebisacetylacetone (II).—The fourth fraction (b. p. 170—200°) was cooled in ice, when crystallisation set in. The first deposit consisted of a mass of needles which, after washing with a little ether, were colourless and melted at 134°. Recrystallisation from alcohol or benzene gave a product with indefinite melting point, liquefaction commencing at about 100°, but not being complete until 130°. Its alcoholic solution gave an intense violet colour with ferric chloride and a copper derivative with ammoniacal cupric acetate.

When left in the ice chest for several days, the mother-liquors deposited prismatic crystals; these, when washed free from oil with the aid of ether, melted at 98—99°. Recrystallisation from benzene gave a mass of glistening, white needles, m. p. 99—100°; recrystallisation from alcohol also gave very fine needles melting at 99°. A mixture of the original crystals with those obtained after recrystallisation from alcohol and from benzene also melted at 98°, which indicated a definite substance and not a mixture (Found: C, 63.6, 63.7; H, 8.0, 8.2.  $C_{12}H_{18}O_4$  requires C, 63.7; H, 8.0%).

This monoenol-ethylenebisacetylacetone (p. 44) when dissolved in alcohol gave an instantaneous deep violet coloration with ferric chloride and a precipitate of a copper salt with ammoniacal cupric acetate. After keeping for some months, its melting point became 146—152°.

IV. dienol-Ethylenebisacetylacetone (III).—The mother-liquors from the crystals of the monoenol showed no further signs of crystallisation and were converted into the copper derivative by treating an alcoholic solution with excess of ammoniacal cupric acetate. After drying, the mass was extracted with benzene; a faintly yellow solution was obtained which on evaporation of the solvent left a few drops of a brown oil, whilst the copper salt remained as an insoluble greenish-grey powder. It had no definite melting point, but decomposed above 250°, and was quite insoluble in all organic solvents. It contained 18% of copper.  $C_{24}H_{34}O_8Cu$  requires Cu, 12.3 and  $C_{12}H_{16}O_4Cu$  requires Cu, 22.1%.

The copper salt was decomposed with sulphuric acid in the presence of ether; a white precipitate was formed and was filtered off, whilst the ethereal layer was allowed to evaporate. The insoluble product with indefinite melting point of 100—107° was subsequently shown to be a mixture of mono- and di-enolic forms. The product separating from the ethereal layer formed colourless, cubic crystals which after washing with ether melted more definitely at 140—143° and consisted chiefly of dienol-*ethylenebisacetylacetone* (Found: C, 63.6; H, 7.9.  $C_{12}H_{18}O_4$  requires C, 63.7; H, 8.0%).

When kept for some time, the melting point of the dienol became indefinite; melting commenced at 100°, but was not complete until about 140°. This change in fusibility probably indicated a partial transformation into a mixture of the mono- and di-enolic forms.

V. *Comparative Study of the Behaviour of the Three Isomerides towards Bromine*.—A known weight of the isomeride under investigation, dissolved in sufficient alcohol to give an approximately *M*/20-solution, was treated with *N*/10-bromine (alcoholic) in the cold until the yellow colour persisted; an alcoholic solution of  $\beta$ -naphthol was then quickly added to absorb the excess of bromine. Potassium iodide was added and the solution gently warmed; iodine was liberated and titrated by means of *N*/10-thiosulphate without the use of an indicator, 1 g.-mol. of iodine being equivalent to one double bond, that is, to one hydroxyl group.

(a) *The liquid keto-ethylenebisacetylacetone*: 1 g.-mol. liberates  $0.033 \times 127$  g. of iodine, corresponding with the presence of about 0.8% of the enolic form.

(b) *enol-Ethylenebisacetylacetone*, m. p. 98—99°: 1 g.-mol. liberates  $2 \times 127$  g. of iodine, corresponding with the pure mono-enolic form of ethylenebisacetylacetone.

(c) *dienol-Ethylenebisacetylacetone*, m. p. 140—143°: 1 g.-mol. liberates  $2.5 \times 127$  g. of iodine; this indicates the presence of about 1.25 hydroxyl groups per g.-mol. or a mixture of 25% of the dienolic with 75% of the mono-enolic form of ethylenebisacetylacetone.

From these results, we conclude that in the case of the liquid and the solid, m. p. 98°, we are dealing with the comparatively stable ketonic and mono-enolic forms of ethylenebisacetylacetone, respectively. The other product, m. p. 140—143°, may be an equilibrium mixture; or more probably it represents in the solid state the true dienolic form, which in alcoholic solution becomes transformed into an equilibrium mixture.

*Comparative Study of the Ketonic and Monoenolic Forms of Ethylenebisacetylacetone*.—*Stereoisomeric tetraoximes*. The liquid *keto*-ethylenebisacetylacetone and the solid enol modification were each heated on the water-bath for 2 hours in dilute alcohol with

excess of hydroxylamine hydrochloride (6—8 mols.) and sodium acetate. On the mixture being poured into water, the  $\alpha$ -tetraoxime from the keto-form remained in solution, and was extracted with ether. It separated from the concentrated ethereal extract in colourless crystals, m. p.  $165^{\circ}$  (Found: N, 19.15.  $C_{12}H_{22}O_4N_4$  requires N, 19.6%).

The  $\beta$ -tetraoxime from the enol form separated as a white solid crystallisable from hot water in minute, colourless needles decomposing at  $220$ — $222^{\circ}$  (Found: N, 19.7%).

*Tellurium Tetrachloride and keto-Ethylenebisacetylacetone.*—The liquid keto-form (9 g. = 2 mols.) and 5.4 g. (1 mol.) of tellurium tetrachloride were refluxed in chloroform solution. The mixture immediately blackened, but little or no hydrogen chloride was evolved until after  $\frac{1}{2}$  hour; the gas was then freely evolved during 3 hours. The filtrate from tellurium (0.4 g.) was concentrated in a vacuum desiccator. A black tar remained; no crystallisation took place even after one month or on treatment with various solvents. On extraction with *n*-hexane, the tar remained undissolved, but after evaporation of the hydrocarbon crystalline laminae were left. By pressing these on a porous plate, white crystals were obtained, which were purified by crystallisation from hexane. Hexagonal prisms resulted, m. p.  $79^{\circ}$ , yield 1 g. The product was readily soluble in alcohol and the solution gave an immediate intense purple colour with ferric chloride; it also yielded a copper salt. Qualitative tests showed the absence of tellurium, but chlorine was present and could be detached by boiling with aqueous potash (Found: C, 52.0, 51.6; H, 7.0, 6.9.  $C_7H_{11}O_2Cl$  requires C, 51.7; H, 6.8%). This analysis corresponds with a removal of one acetylacetone residue and the formation of  $\beta$ -chloroethylacetylacetone,  $CH_2Cl \cdot CH_2 \cdot CH(CO \cdot CH_3)_2$ .

*Transformations of enol-Ethylenebisacetylacetone into its Isomerides.*—*Ketonisation.* The mono-enol formed stable, prismatic crystals, m. p.  $99^{\circ}$ . It was slightly soluble in water and the solution reacted faintly acid to litmus. It readily dissolved in dilute caustic soda to a yellow solution of the sodium salt; no precipitate was produced when this solution was acidified with sulphuric acid in the cold, and extraction with ether yielded an oil which failed to colour ferric chloride and was probably the ketonic form.

*Dienolisation.* The copper salt, prepared from the mono-enolic form by treating a solution in alcohol with excess of ammoniacal cupric acetate, dried to an amorphous, greenish-grey powder quite insoluble in all organic solvents, thus differing from the usual co-ordinated copper derivatives obtained from the  $\beta$ -diketones. It contained 19.3% of copper; the amount calculated for the copper

derivative of the monoenol is 12.3, and for that of the dienol 22.1%. When decomposed in the usual manner with sulphuric acid in the presence of ether, an amorphous, white solid is precipitated which is only sparingly soluble in ether; after washing with ether and drying, this melts at 98° and is the monoenolic form, but the substance which crystallises from the ethereal solution has an indefinite melting point; it softens and loses its crystalline form at 110°, but does not run down the tube to a clear liquid until 130—134°, behaving as a mixture of the di- and mono-enolic forms; Meyer's test indicates the presence of about 20% of the dienolic form with 80% of the monoenolic. It is evident that under the influence of ammoniacal cupric acetate the monoenol changes partly to the dienol.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research and to the Government Grant Committee of the Royal Society for grants which have helped to defray the expense of this investigation.

## XI.—*The Solubilities of Sodium, Potassium, and Calcium Ferrocyanides. Part I.*

By MONICA FARROW.

THIS investigation was undertaken on account of the uncertainty of the solubility data for the ferrocyanides of sodium and potassium, and the lack of data for the calcium salt. Early workers, e.g., Michel and Kraft (*Ann. Chim. Phys.*, 1854, **41**, 482), Étard (*ibid.*, 1894, **2**, 546), and Schiff (*Annalen*, 1860, **113**, 350), obtained values varying from 25 to 40 g. of potassium ferrocyanide in 100 g. of water at 20°. Determinations for the potassium and sodium salts were made at a few temperatures by Conroy (*J. Soc. Chem. Ind.*, 1898, **17**, 104), by Harkins and Pearce (*J. Amer. Chem. Soc.*, 1916, **38**, 2716) at 25° only, by Fabria (*Gazzetta*, 1921, **51**, ii, 374) over the whole range from the cryohydric point to 100°, and by Vallance (*Chem. News*, 1922, **125**, 7) for the potassium salt only, at low temperatures.

*Purification of the Salts.*—The purest sodium and potassium ferrocyanides obtainable were further purified by rapid crystallisation from hot water. By simple qualitative tests the absence of the most likely impurities, calcium and ammonium, was proved.

The purest calcium salt obtainable, for which we are indebted

to Mr. W. G. Adam of the Gas Light & Coke Co., was slightly tinged with blue. It was purified by precipitation with absolute alcohol in the cold (to avoid oxidation) from an air-free saturated solution. The pure lemon-yellow, finely crystalline product was centrifuged, dried in vacuum desiccators, first over charcoal for 24 hours, then over the partly dehydrated salt, and stored in the dark in dark glass-stoppered bottles. No discoloration appeared after 18 months. No trace of sodium, potassium, or ammonium could be detected in the residue left after decomposition of the salt with concentrated sulphuric acid. Determinations of calcium as oxalate in the original and the purified salt proved that no measurable change of composition had resulted from the purification process :

Orig. salt : 16.2, 16.2, 16.2, 16.3, 16.25, 16.1, 16.2, 16.2.  
Mean, 16.2% Ca.

Recryst. salt : 16.2, 16.25, 16.2, 16.2, 16.2, 16.2, 16.2, 16.3.  
Mean, 16.2% Ca.

There has been some doubt about the precise number of molecules of water in the calcium salt. The above determinations, which lie much nearer to the theoretical value for a hydration of  $11\text{H}_2\text{O}$  (16.3% Ca) than to that for  $12\text{H}_2\text{O}$  (15.8% Ca), support the conclusion of Berkeley, Hartley, and Burton (*Phil. Trans.*, 1908, 209A, 177) that the lower figure is correct. The lower figure is also in accordance with the recent careful determinations of Cumming (J., 1924, 125, 240).

*Method of Determining Solubility.*—A solution was heated in contact with excess of the solute to the required temperature and after the attainment of equilibrium a definite volume was withdrawn in a weight pipette to be weighed and analysed, and the density calculated.

The ferrocyanide in all three salts was estimated volumetrically with permanganate by the simple method of de Haen (Treadwell, "Quantitative Analysis," p. 632). This method after practice gave concordant results; it is essential to standardise the solution used against standard potassium ferrocyanide and not against the customary oxalic acid. The calcium ferrocyanide was also determined independently as oxalate.

Cumming's method of estimating ferrocyanides with benzidine hydrochloride (J., 1924, 125, 240) was tried, but it did not appear so suitable for these metallic ferrocyanides as the simple permanganate method and was therefore not employed.

Pure dilute boiling sodium oxalate solution was used in the determination of the calcium salt as oxalate, because ammonium oxalate and oxalic acid as precipitants produced insoluble double calcium

ammonium ferrocyanide and insoluble hydroferrocyanic acid, respectively. In the first experiments, in which an alundum cone was used as a filter, no sharp end-point could be obtained on the addition of permanganate, owing to slow diffusion of oxalate from the inner pores of the cone. Gooch crucibles were substituted for the cones, but even then the permanganate readings were not concordant. The asbestos used had no reducing action on permanganate, and experiment also showed that no measurable occlusion occurred at the dilutions used. The cause of the error was traced to the appreciable solubility of calcium oxalate in water. The washing was therefore limited to three fillings of the Gooch, and this procedure was kept constant throughout the experiments.

*Apparatus.*—The solubility vessel consisted of a wide tube of about 200 c.c. capacity, fitted with a rubber bung and stirrer. In order to hold the pipette in place in the solubility vessel the bung carried a short glass tube which was closed when not in use. The temperature of the thermostat was constant to within  $0.2^{\circ}$ .

The weight pipette, which had a volume of about 4.5 c.c. (Fig. 1), was of a design which has been used for several investigations in this laboratory, but has not previously been described. It is warmed to the temperature of experiment and introduced into the solution with its shorter arm fitted with a glass-wool filter adapted to the ground end. The solution can then be admitted by opening the ground-in plug, A; when it has reached the required level, which can be accurately read by means of the graduations, the plug is replaced. The pipette is then removed, the filter immediately replaced by a ground-on cap, and the whole cleaned and weighed after attaining room temperature. The pipette was repeatedly calibrated with pure mercury to give accurate volume readings for the density determinations.

FIG. 1.

Owing to the high solubilities of the calcium salt, these solutions were very viscous and consequently difficult to introduce into the pipette. To hasten the filling, slight pressure was applied to the solution in the solubility vessel. The determinations of solubility and density were in almost every case repeated at least once, and, as the data of the table show, the individual solubility experiments very seldom differed from the mean by more than 0.1 unit, or the densities by more than 0.002, except at the highest temperatures,

when the experimental difficulties already mentioned make the determinations somewhat less concordant.

*Solubilities and Densities.*

\* As oxalate, the rest as ferrocyanide.

*Results of Experiments.*—The values obtained for the solubilities of calcium and potassium ferrocyanide lie on two smooth curves (Fig. 2). The values obtained by Vallance and by Fabria (*loc. cit.*) for the potassium salt, which are plotted on our curve for purposes of comparison, are in good agreement with our measurements except at temperatures above 84°, where Fabria's values are considerably higher. To what extent the divergence is due to his having kept his solutions at these high temperatures for as long as 3 hours we are unable to say, but we have repeatedly noticed that solutions of the calcium salt show green coloration on

cooling, owing presumably to incipient decomposition. The experimental difficulties with the calcium salt solutions at high temperatures were considerable. The solutions had both high viscosity and high density; the former made the rate of flow into the pipette very slow, and also prevented the very small particles of solid salt from settling rapidly. It was almost impossible to prevent the capillary entrance to the pipette from being blocked, and although five determinations were made for the solubility at

FIG. 2.

79.6° these are not given, as they show almost the same value as that obtained at 65°.

As may be seen from the graph, the solubility curve of sodium ferrocyanide shows a sharp break at 81.7°. This transition temperature does not appear to have been observed before, though it is apparently responsible for the reported transition in the curve for the potassium salt of Étard (*loc. cit.*). Work is in progress on the three-component system calcium ferrocyanide-sodium ferrocyanide-water, and the identity of the lower hydrate of the sodium

salt will be investigated. The four points given by Conroy (*loc. cit.*) for the solubility of the sodium salt lie almost exactly on our curve, though, as the number of his determinations was small, the transition point evidently escaped his observation. The density results (Fig. 2) require little comment. No other work appears to have been done on this property of the saturated solutions. The three curves are of the same general form as the corresponding solubility ones. In the case of the sodium salt, the points evidently lie on two curves and are consistent with the transition at  $81.7^{\circ}$  as given by the solubility curve.

*Verification of the Transition Temperature of Sodium Ferrocyanide.*

—The transition point was verified by the two following methods :  
1. *The cooling curve.* On allowing the salt to cool from about  $90^{\circ}$  to  $75^{\circ}$  in a jacketed test-tube carrying a copper stirrer and a sensitive thermometer, arrests were observed, in three experiments, at  $81.0^{\circ}$ ,  $81.2^{\circ}$ ,  $81.3^{\circ}$ , giving a mean value of  $81.2^{\circ}$ .

2. *Dilatometer.* The dilatometer used was of the ordinary form and had a graduated capillary neck about a foot long. The bulb contained the hydrate ( $10\text{H}_2\text{O}$ ) and sufficient paraffin to rise to a convenient level in the capillary when the temperature was in the region of  $81^{\circ}$ . Before the dilatometer was introduced into the thermostat it was heated above  $81^{\circ}$  so as always to have some of the higher-temperature hydrate present to facilitate the change. In all, six experiments were carried out at temperatures ranging from  $80.6^{\circ}$  to  $82.6^{\circ}$ .

At the highest temperature,  $82.6^{\circ}$ , there was a rapid rise of 1 inch in nearly 3 minutes, and at  $81.9^{\circ}$  the level of the oil still rose, although at the rate of only  $\frac{1}{2}$  inch in  $\frac{1}{2}$  hour. In the next three determinations at  $81.2^{\circ}$ ,  $81.3^{\circ}$ , and  $81.3^{\circ}$ , respectively, no change in the oil level could be observed. Finally, at  $80.6^{\circ}$ , there was a fall in the level of  $\frac{1}{2}$  inch in  $\frac{1}{4}$  hour. These experiments show that the change from the higher-temperature hydrate to the  $10\text{H}_2\text{O}$ -hydrate occurs with a volume decrease and vice versa, and that the most probable value of the transition temperature is  $81.5^{\circ}$ . The values obtained by the less accurate methods, namely,  $81.7^{\circ}$  by the solubility, and  $81.2^{\circ}$  by cooling curves, give as a mean value one very close to the most trustworthy value of  $81.5^{\circ}$ .

*Summary.*

1. The solubility of sodium, potassium, and calcium ferrocyanide in water has been determined, together with the density of the saturated solutions.
2. Sodium ferrocyanide has a transition point at  $81.5^{\circ}$ . Neither the potassium nor the calcium salt shows any transition over the

range investigated, the transition point of the potassium salt recorded by Étard being probably due to contamination with sodium ferrocyanide.

OXFORD.

[Received, October 12th, 1925.]

## XII.—*Studies of Valency. Part VII. Surface Polarity and the Reaction of Ethylene and Chlorine—The Effect of the Adsorbed Water Layer.*

By RONALD GEORGE WREYFORD NORRISH and GRIFFITH  
GLYN JONES.

THE reaction between ethylene and bromine which occurs only at the surface of the reaction vessel (Stewart and Edlund, *J. Amer. Chem. Soc.*, 1923, 45, 1014) has been shown by one of us to depend greatly on the nature of the surface (Norrish, *J.*, 1923, 123, 3006). The following figures represent the mean bimolecular velocity coefficients found for the surfaces specified in vessels of uniform dimensions: Glass, 0.0506; stearic acid, 0.0864; cetyl alcohol, 0.0266; paraffin wax, 0.0030. The low value for paraffin wax suggested that these figures might be taken as a measure of the polarity of the surfaces and that with an improvement in technique the method might be used as a general measure of surface polarity.

The present research has been undertaken to investigate the effect of moisture on the reactivity of glass and paraffin surfaces and to test a suggestion put forward in the previous paper on ethylene and bromine (*loc. cit.*), that the absolute reactivity of a paraffin surface is vanishingly small.

In these experiments we have substituted chlorine for bromine since it is more easily manipulated than the latter and admits of the pressures of the reactants being increased tenfold. Furthermore, an easier means of experimentation, which gives accurate and reproducible results, has been devised. As was expected, in view of the previous results, the reaction between ethylene and chlorine (in the absence of light) has been found to occur entirely at the surface, and to depend on the nature of the surface in the same way as the reaction of ethylene and bromine already studied. It has further been shown that whilst the rate of reaction at a paraffin wax surface is independent of the presence of water vapour, this is not so for a glass surface, the gases, in the presence of water vapour at 6 mm. pressure, uniting 1.3 times as fast as when they were dried

by phosphoric acid. Further, by taking special precautions to prevent accidental exposure of the glass, it was found possible practically to suspend the reaction in a paraffin vessel, less than 0.1 of the total reactants combining in the course of 12 hours, whilst, in the case of a glass vessel of the same dimensions, the reaction was practically complete in 30–40 minutes. This indicates a reactivity for a paraffin surface some 1200 times smaller than for a glass surface of the same dimensions, whereas the earlier ethylene-bromine experiments indicated a reactivity for paraffin wax only 18 times smaller than that for glass.

FIG. 1.

FIG. 2.

### EXPERIMENTAL.

The reaction vessel (Fig. 1, A) consisted of a glass tube 35 cm. long and either 1.3 or 2.7 cm. in diameter. The tube was water-jacketed by an outer metal vessel, B, which served to screen it from light and was kept at constant temperature by a current of water circulated by a pump from a thermostat regulated to  $0.1^\circ$ , the temperature being indicated by a thermometer T. One end of the reaction vessel was connected *via* tap 1 and a long capillary tube to a vertical mercury manometer M; the other end was connected *via* tap 2 to the gas supply and water-pump. As it was necessary frequently to remove the reaction vessel, its connexion with taps 1 and 2 was made at first by paraffined rubber pressure tubing and

later by ground glass joints. The apparatus could be evacuated *via* taps 2, 4, 9, 11, by way of the drying tubes, J, containing phosphoric oxide, and the expansion chamber, D, containing calcium chloride. Dry air could be admitted *via* the drying tubes, G, containing calcium chloride and phosphoric oxide, by way of taps 10, 5, 4, 2. Air saturated with water vapour could be admitted by way of the saturators L and K and taps 10, 8, 7, 4, 2. The saturators were so arranged that the air bubbled through the liquid in L and passed over the surface of the liquid in K. Ethylene was stored in the aspirator, C, and could be expanded into the reaction vessel by way of the calcium chloride-phosphoric oxide drying system, and taps 3 and 2. Dry chlorine was obtained *via* taps 6 and 2 from the chlorine chamber, E, which was kept continually filled by the passage of chlorine from a cylinder, through the phosphoric oxide drying system, F. The technique of the chlorine manipulation was similar to that already described by Norrish and Rideal (J., 1925, 127, 787).

An experimental run was carried out as follows. The vessel A was evacuated as far as possible by the water-pump, and washed out with dry air and re-evacuated several times. Finally air, either dry or moist as required, was admitted to a pressure of about 300 mm. The connecting tubes were evacuated and washed out two or three times with ethylene, and then dry ethylene was admitted to the reaction vessel to a partial pressure of 200 mm. Finally, after the connecting tubes had been washed out as before, dry chlorine was admitted to a partial pressure of 200 mm. Stop-cocks 1 and 2 were kept closed throughout the reaction and readings of the pressure were made at intervals by momentarily putting the mercury manometer into communication with A by opening tap 1; when these precautions were taken, the mercury of the manometer was not affected by the chlorine if this gas was the last to be admitted to the system.

The bimolecular reaction coefficient used as a measure of the reactivity of a given surface was calculated by the formula

$$k = x/a(a - x)t,$$

where  $a$  is the initial pressure of ethylene or chlorine, and  $x$  the fall in pressure of either gas at time  $t$ . The value of  $a$  was fixed at 200 mm., and the value of  $x$  calculated from the fall of pressure in the reaction chamber, account being taken of the fact that the ethylene dichloride is initially formed as a gas and finally separates as a liquid when its saturation vapour pressure is reached. This vapour pressure is 55 mm. at 18°, and 60 mm. at 20° (Rex, *Z. physikal. Chem.*, 1906, 35, 358); hence if  $dp$  represents the pressure fall at time  $t$  at 20°, then, when  $dp < 60$  mm.,  $x = dp$ , and when

$dp > 60$  mm.,  $x = (dp + 60)/2$ . There was, in general, no noticeable change in the value of  $k$  at the moment when liquid ethylene dichloride separated, a fact which proves that the liquid exerts no appreciable catalytic activity in the reaction.

For a reaction which occurs solely at the surface, as in the present case, it may be shown that the reaction coefficient, calculated as above in terms of pressure changes, must be multiplied by the factor  $v/s$ , representing the ratio of volume to surface of the reaction vessel, in order to obtain comparable figures for different-sized vessels. In the present experiments, cylindrical tubes of uniform length were used as the reaction vessels, for which  $v/s \propto d$ , where  $d$  is the diameter of the tube. Thus, by taking the product  $kd$  we obtain comparable figures for surface reactivity. In Tables I and IV examples are given in full of various experiments. The further account of this work will be limited to giving figures for surface reactivity, in Tables II and III, calculated as described above from the mean reaction velocity coefficients.

water vapour in the gas phase increases the reactivity of a glass surface by about 30%.

It will be seen from the data for a given tube that the presence of water vapour has no measurable effect upon the reactivity of a paraffin wax surface. Further, the velocity coefficient does not vary in inverse ratio to the diameter of the tube as it would if the reactivities of the paraffin surfaces were uniform, and it was therefore thought that the measured reactivity was to be ascribed in part at least to the presence of the rubber connexions. In order to measure the absolute reactivity of a paraffin wax surface, the rubber connexions were replaced by ground glass joints, which together with the stop-cocks were lubricated with a grease made by melting together "nujol" and paraffin wax. The tube was constructed as shown in Fig. 2; the gases being introduced through the end A, and the end B being attached to the manometer. The paraffin

wax was introduced molten into the tube, and allowed to cool with constant agitation under a vacuum, the process usually having to be repeated several times before a uniform coat was obtained. The tube fitting the ground glass joint, and communicating with the manometer, was paraffined carefully on both sides of the tap C. Great difficulty was experienced in preparing satisfactory tubes; in most cases there was some small surface of glass incompletely protected which enabled a slow reaction to proceed. After many trials, however, two cases of very low reactivity were obtained. In the better of the two, with both reactants at *ca.* 200 mm. pressure, less than 0.1 of the total reaction had occurred after 12 hours. The experimental figures are in Table IV.

TABLE IV.

525	52.0	3.7	1182	42.0	0.95

To ascertain that the gases remained unreacted in the tube, in experiment ii, they were slowly withdrawn, after 20 hours, through potassium iodide solution. The quantity of unreacted chlorine (estimated by the amount of iodine set free, equiv. to 7.20 c.c. of 0.1*N*- $Na_2S_2O_3$ ) was in satisfactory agreement (5%) with that (7.56 c.c.) calculated from the known volume of the tube (48 c.c.) and the observed pressure changes.

The reactivity of the tube in experiment ii was much lower than that in experiment i, a fact which suggests that this residual activity was entirely due to the accidental exposure of glass surface.

*Reactivity of a Stearic Acid Surface.*—As data for comparison with the experimental results of the ethylene-bromine reaction (*loc. cit.*), figures were obtained for the reactivity of a stearic acid surface, a tube of 2.7 cm. diameter being used. The tube was coated with stearic acid under the conditions described above for paraffin wax and the initial pressure of each reactant was fixed at 200 mm. The

constancy of the velocity coefficients was good, there being no variation from the mean values greater than 5%. In two experiments the mean values were  $4.52 \times 10^{-4}$  and  $4.20 \times 10^{-4}$ .

In Table V is a comparison of the relative surface reactivities measured by the ethylene-chlorine and by the ethylene-bromine reactions. These are referred to the reactivity of glass, taken as unity, by computing the ratios of the reactivities of the given surfaces to that of glass, the reactivity being measured, in the way described above, as the product of the bimolecular reaction coefficient and the diameter of the tube.

TABLE V.

Comparative surface reactivities by two methods.

Surface	Glass; gas dry.	Glass; gas wet.	Stearic acid; gas dry.	Paraffin wax with rubber.	Paraffin wax, optimum.
$C_2H_4-Br_2$	1.0	—	1.7	0.06	—
$C_2H_4-Cl_2$	1.0	1.3	1.06	0.076	0.0008

It will be seen that the results of the earlier work have been confirmed, while the prediction that the non-polar surface of paraffin wax is entirely unreactive has been practically demonstrated.

The results described above, when considered with reference to the adsorbed water layer which is known to exist at the surface of glass, would seem to have an important bearing on any explanation of the suspension of reactions by extreme drying. The adsorbed water layer, under "dry" conditions, is probably but one molecule thick, but tends to pile up as the vapour pressure is increased towards saturation point (McHaffie and Lenher, J., 1925, 127, 1559). Hence, if we assume that the water layer is the polar catalyst in the case of the glass surfaces, we can explain the increased reactivity of moist gases as due to the more complete saturation of the surface water film. When the surface is covered with paraffin wax, it seems reasonable to assume that the water layer cannot form, in agreement with the fact that water shows no tendency to wet paraffin wax. There is thus no reaction, either with dry or with wet gases, a fact which shows also that no volume reaction sets in, in the presence of water vapour. It seems highly probable that we are here imitating the effects of Baker: by the extreme drying of his systems we may suppose that he was removing the water from the walls, while by using walls composed of a substance in which water cannot condense we achieve the same result, even in the presence of moist gases. Finally, if a polar group such as carboxyl or hydroxyl be introduced into the paraffin molecule, we can imitate the effect of the water layer on glass; thus with walls composed of stearic acid, or cetyl alcohol, the surface becomes once more reactive.

If we inquire further as to the mechanism of the present reaction, there is little evidence to guide us. It seems probable, however, that the presence of water on the surface might cause a greater modification of the dielectric constant in the immediate vicinity of the surface than can be brought about by a single molecule in the ternary complex  $[A \cdot H_2O \cdot B]$ , so that the whole reaction takes place through the medium of the adsorption layer, even in the presence of water vapour. It seems significant also that all the polar catalysts so far obtained contain oxygen, and we might regard their function as the formation of a complex with the chlorine molecule, through the medium of quadrivalent oxygen (e.g.,  $\begin{array}{c} H \\ | \\ H > O < \begin{array}{c} Cl \\ | \end{array} \end{array}$ ) which, under the influence of the surface forces, is more dissociable than the chlorine molecule itself.

#### *Summary.*

A study has been made of the reaction between ethylene and chlorine, each at an initial partial pressure of 200 mm., at the surface of glass, paraffin wax, and stearic acid. By taking special precautions, a paraffin wax-surface was prepared showing a reactivity some 1200 times smaller than that of glass and about 70 times less than that previously found for a paraffin wax surface in the experiments on the union of ethylene and bromine. It has been shown that water vapour present at a partial pressure of 6 mm. increases the reactivity of the glass surface by 30%, whilst it has no effect on the paraffin wax surface. These results are discussed from the point of view of surface polarity and in the light of our knowledge of the adsorbed water film existing at the surface of many solid substances.

### XIII.—*The Chemistry of the Caryophyllene Series.* *Part I.*

By GEORGE GERALD HENDERSON, JOHN MONTEATH ROBERTSON,  
and (in part) CARL ALOYSIUS KERR.

$\beta$ -CARYOPHYLLENE belongs to the dicyclic series of sesquiterpenes, but as no naphthalene or benzenoid derivative can be obtained from it by the sulphur method (Ruzicka and Stoll, *Helv. Chim. Acta*, 1923, 6, 854), it cannot be assigned to either of the known cadinene or eudesmol types. Its structure is therefore largely a matter of conjecture, although Semmler and Mayer (*Ber.*, 1911, 44, 3657) consider that it consists of a mixture of two forms, for which, from

a study of the ozonide products, they have advanced formulæ I and II. The existence of the bridge ring system is, however, based upon the supposed identity of caryophyllenic acid with *cis*-2 : 2 : 3-trimethylcyclobutane-1 : 3-dicarboxylic acid, and until this is definitely established these formulæ must be regarded as tentative.

Wallach and Walker (*Annalen*, 1892, **271**, 285) showed that caryophyllene forms a crystalline hydrate known as caryophyllene alcohol,  $C_{15}H_{25}\cdot OH$ , upon hydration with a mixture of sulphuric and acetic acids. The properties of this alcohol and in particular its relation to the hydrocarbon have not previously been fully examined. As there is some evidence that certain of its derivatives possess a different molecular configuration from that assigned to  $\beta$ -caryophyllene, experiments were carried out with a view to obtain more information in this connexion.

The alcohol prepared by the hydration method was found to be remarkably stable in certain respects. Thus, after heating with hydrogen peroxide for 52 hours, practically the whole of the alcohol was recovered unchanged. On treatment with permanganate the alcohol was again recovered unchanged. Towards bromine in chloroform solution it behaved as a fully saturated substance.

All dicyclic sesquiterpene alcohols of the formula  $C_{15}H_{25}\cdot OH$  are unsaturated, uniting additively with bromine and being readily oxidised. It is evident that caryophyllene alcohol does not belong to this class, and therefore cannot be regarded as a direct hydrate of the hydrocarbon, as previously supposed. Apparently the hydrating agents have induced ring closure with the formation of a new tricyclic structure. Confirmation of this view is found in the fact that the alcohol can be formed through the agency of formic acid, which is a well-known means of effecting ring closure in the sesquiterpenes (Robertson, Kerr, and Henderson, J., 1925, **127**, 1944). Moreover, it has long been known that caryophyllene alcohol upon dehydration yields a hydrocarbon, clovene, which is not identical with caryophyllene, but which appears to be tricyclic from its physical properties (Wallach and Walker, *loc. cit.*).

Although it is not feasible to determine the molecular refractivity of caryophyllene alcohol directly owing to its high melting point. (compare Semmler, *Ber.*, 1903, **36**, 1037), it appeared probable that the necessary information might be obtained from the physical

properties of certain of its esters, which were prepared in the course of this work. The following figures were therefore determined for the formate and the acetate, and they clearly indicate the tricyclic nature of the caryophyllene radical.

Ester.	<i>t.</i>	$d_4^{20}$	$n_D^{20}$	Found.	[ $R_L$ ] <sub>D</sub> .		
					Calc. for C <sub>15</sub> H <sub>25</sub> -R. Tricyclic.	Typical * C <sub>15</sub> H <sub>25</sub> -R. Dicyclic.	Calc. for C <sub>15</sub> H <sub>25</sub> -R. Dicyclic.

Acetate, C <sub>17</sub> H <sub>23</sub> O <sub>2</sub> †	17°	1.003	1.4919	76.37	75.64	78.13	77.37

\* Semmler and Jonas, *Ber.*, 1914, 47, 2068, 2072.

† We wish to take this opportunity of correcting the density for the formate previously given (J., 1925, 127, 1945), where  $d_4^{20}$  1.22 should be  $d_4^{20}$  1.024.

‡ Determined on the super-cooled liquid.

It will be observed that the exaltation found in the case of the caryophyllene derivatives is not greater than the corresponding divergence for a typical dicyclic member.

It is noteworthy that the limonene form (II) of active caryophyllene could readily adapt itself to such ring formation as is indicated by the above results. The course of the reaction and the dehydration of the alcohol to clovene may therefore be represented by the following scheme :

In addition to caryophyllene alcohol, Wallach's hydration method gives rise to a liquid product. We find this substance to consist of an unsaturated hydrocarbon, C<sub>15</sub>H<sub>24</sub>, b. p. 110–114°/9 mm.,  $d_4^{20}$  0.9263,  $n_D^{20}$  1.5010,  $[\alpha]_D^{25}$  –19.56°, which evidently differs from  $\beta$ -caryophyllene and is perhaps identical with the tricyclic caryophyllene obtained from the dihydrochloride by the quinoline method (Semmler and Mayer, *Ber.*, 1910, 43, 3451) which had b. p. 122–123°/13 mm.,  $d_4^{20}$  0.927,  $n_D^{20}$  1.50246,  $[\alpha]_D^{25}$  –57°. Clovene, also regarded as tricyclic, has closely similar properties. The possible identity of these three substances is under examination.

Our experiments were next directed towards the synthesis of hydroxyl derivatives from caryophyllene corresponding to the dicyclic structure of the hydrocarbon, since it has been shown that Wallach and Walker's hydration method leads to ring closure. From caryophyllene dihydrochloride by the action of silver acetate in glacial acetic acid solution we obtained products which upon hydrolysis yielded an unsaturated alcohol, C<sub>15</sub>H<sub>25</sub>·OH, a saturated glycol, C<sub>15</sub>H<sub>26</sub>(OH)<sub>2</sub>, and some regenerated hydrocarbon. The

alcohol,  $C_{15}H_{25}\cdot OH$ , which may be termed *caryophyllol*, has properties corresponding closely to those of a dicyclic sesquiterpene alcohol. Although it reacts with sodium, no ester has yet been obtained by any of the usual methods, which indicates that the alcohol is tertiary. By the action of a chloroform solution of bromine in the cold it is converted into a rather unstable *dibromide*,  $C_{15}H_{26}OBr_2$ .

The compound  $C_{15}H_{26}(OH)_2$  is quite a stable substance, and is probably a glycol with both hydroxyl groups attached to tertiary carbon atoms. It possesses properties closely similar to those of cadinene glycol (Henderson and Robertson, J., 1924, 125, 1992). The fact that the hydrocarbon product of the reaction gives a good yield of caryophyllene dihydrochloride on treatment with hydrogen chloride indicates that these hydroxyl derivatives also retain the dicyclic caryophyllene structure.

Wallach and Walker (*loc. cit.*) found that caryophyllene alcohol gives a series of halogen derivatives, of which the chloride,  $C_{15}H_{25}Cl$ , can be readily obtained. We have found that this compound also, as was to be expected from the above results, behaves as a fully saturated substance like the alcohol, and therefore must also be regarded as being tricyclic. It thus becomes of interest to enquire whether hydrogen chloride can be eliminated from this compound by any of the usual methods, because if this proved to be the case, a new type of tricyclic sesquiterpene would be expected, of which the above-mentioned compound would be the hydrochloride.

We have found that this chloride is much more stable than the known hydrochlorides of the sesquiterpene series. Even after prolonged heating in a concentrated alcoholic solution of sodium ethoxide, or with quinoline, practically all the compound was recovered unchanged. On treatment with sodium acetate in glacial acetic acid solution, however, chlorine was removed from the molecule, but the product of the reaction in this case proved to be the *acetate* of caryophyllene alcohol,  $C_{15}H_{25}\cdot OAc$ . Wallach and Tuttle (*Annalen*, 1894, 279, 393) mention a caryophyllene acetate, but as no melting point or other data are given, it is impossible to state whether the compound we have obtained is similar to theirs.

Since hypochlorous acid has proved of service in investigating the simpler terpenes (compare Slawinski, *Ber.*, 1899, 32, 2064; Henderson and Marsh, J., 1921, 119, 1492; Henderson and Kerr, J., 1924, 125, 102), we examined the action of this reagent on  $\beta$ -caryophyllene. In this case, however, instead of using a dilute aqueous solution of the acid we adopted Detoeuf's method of preparing chlorohydrins (*Bull. Soc. chim.*, 1922, 31, 102, 169, 176)

through the agency of chlorocarbamide, which in acid solution undergoes hydrolysis with formation of carbamide and hypochlorous acid. In order to regulate the reaction and to diminish the rate of hydrolysis of the chlorocarbamide, the caryophyllene was dissolved in 4—5 times its bulk of acetone. The first product of the reaction was not obtained in a pure state, but appeared to be a *dichlorohydrin* of caryophyllene,  $C_{15}H_{24}Cl_2(OH)_2$ . On treatment with acetic anhydride it yielded a small quantity of a *monoacetate*, but also in an impure state. When distilled at 1 mm. pressure, it was converted into a *saturated compound* of the formula  $C_{15}H_{24}OCl_2$ . This substance, a colourless liquid, appears to be the anhydride of the dichlorohydrin. The chlorine in this compound is not easily replaced, and oxidation with hydrogen peroxide yielded no definite product except some succinic acid.

If  $\beta$ -caryophyllene has the constitution (II) given above, the constitution of the dichlorohydrin may be represented by the formula (III) and that of the anhydride by (IV).

It is true that the supposed anhydride does not undergo hydration to the corresponding glycol on treatment with dilute sulphuric acid, but Franke and Lieben (*Monatsh.*, 1914, **35**, 431) have shown that the anhydrides of 1:4- and 1:5-glycols are quite stable in this respect.

#### EXPERIMENTAL.

*Preparation and Properties of Caryophyllene Alcohol.*—The  $\beta$ -caryophyllene used in the following experiments was purified by fractional distillation (compare Robertson, Kerr, and Henderson, *loc. cit.*). To 1 litre of acetic acid containing 12 c.c. of sulphuric acid and 40 c.c. of water, 150 g. of caryophyllene were added and the whole was maintained at 80—100° for 30 hours. The product was steam distilled. At first acetic acid and an oil passed over, then the solid alcohol slowly distilled. After crystallisation from light petroleum at a low temperature it melted at 94—96° (yield, about 30%).

The liquid product of the hydration was collected by means of light petroleum and dried. On removing the solvent and allowing the product to remain 24 hours at 0°, a further quantity of the alcohol separated and was removed. The resulting oil was distilled under diminished pressure and the main fraction was finally redis-

tilled over sodium in a vacuum. The product consisted of a colourless oil with a pleasant odour which had b. p. 110—114°/9 mm.,  $n_D^{20}$  1.5010,  $d_4^{20}$  0.9263,  $[\alpha]_D^{25}$  -19.56°.  $[R_L]_D$  found, 64.8; calc. for a tricyclic sesquiterpene, 64.4 (Found: C, 87.7; H, 11.7.  $C_{15}H_{24}$  requires C, 88.2; H, 11.8%). This substance was unsaturated towards bromine.

Caryophyllene alcohol (50 g.) in glacial acetic acid (200 c.c.) and 30% hydrogen peroxide (55 c.c.) were heated together at 50—55° for 52 hours. The solution was then neutralised, when practically the whole of the caryophyllene alcohol was recovered unchanged. M. p. 94°. On standing in the cold with 1% permanganate the latter was not decolorised, and the alcohol was recovered unchanged. When the alcohol was gradually treated with bromine, both in chloroform solution at room temperature, no absorption or substitution could be detected.

*Preparation and Properties of Other Hydroxyl Derivatives of Caryophyllene.*—The dihydrochloride of caryophyllene was prepared by gradually treating caryophyllene (100 g.) in anhydrous ether (100 c.c.) with dry hydrogen chloride, the temperature of the reaction being kept at 0°. After remaining a further 24 hours at 0°, the ether was removed by passing a current of dry air over the surface of the liquid. On reducing the temperature to -20°, practically the whole of the liquid crystallised. Recrystallised from ethyl acetate, caryophyllene dihydrochloride had m. p. 69°,  $[\alpha]_D^{25}$  +67° in 2.5% ethyl-alcoholic solution. Failure to observe the conditions stated, in particular with regard to temperature, results in a greatly diminished yield of the dihydrochloride.

A solution of caryophyllene dihydrochloride (50 g.) in glacial acetic acid (250 g.) was gradually treated with silver acetate (70 g.). The mixture was shaken for 2 to 3 hours at room temperature, and the reaction completed by gently warming on the water-bath. On cooling, the silver chloride was filtered off, and the acetic acid neutralised with sodium carbonate. The resulting product, consisting principally of acetates, was collected by means of ether and hydrolysed by warming with dilute methyl-alcoholic potash for  $\frac{1}{2}$  hour. After the alcohol had been distilled off, the product was rendered neutral with carbon dioxide and steam distilled. The portion volatile in steam was collected with ether, dried over anhydrous sodium sulphate, and distilled under reduced pressure. After several distillations, three principal fractions were obtained: (a) b. p. 122—130°/10 mm., (b) b. p. 130—140°/10 mm., and (c) b. p. 140—150°/10 mm. The fraction (a) consisted of regenerated caryophyllene. When treated with hydrogen chloride in the manner described above, an almost theoretical yield of the dihydrochloride,

m. p. 69°, was obtained. The fraction (c), which represented about 20% of the product, on further purification had b. p. 142–150°/10 mm.,  $d_4^{20}$  0.9632,  $n_D^{20}$  1.5015;  $[R_L]_D$  found, 68.03; calc. for a dicyclic sesquiterpene alcohol, 68.12 (Found: C, 80.6; H, 11.2.  $C_{15}H_{26}O$  requires C, 81.1; H, 11.7%). This substance gave no solid derivative when treated in the usual manner with phthalic anhydride, or with phenylcarbimide, and therefore appears to be a tertiary alcohol. On boiling with acetic anhydride, dehydration occurred yielding a hydrocarbon. The alcohol is unsaturated towards bromine and alkaline permanganate. When slowly treated with bromine at 0°, both in chloroform solution, absorption occurred but no substitution was detected. The chloroform was removed under reduced pressure, leaving a colourless, oily dibromide (Found: Br, 40.1.  $C_{15}H_{26}OBr_2$  requires Br, 41.8%) which slowly decomposed on exposure to light. The fraction (b) consisted of a mixture of the above alcohol and the hydrocarbon. A small higher-boiling fraction was also obtained, containing a higher percentage of oxygen, which probably consists of a mixture of the above alcohol with a small amount of the glycol referred to below.

The residue from the steam distillation contained a thick brown oil, which was repeatedly extracted with ether and dried. On removing the ether, most of this substance crystallised and by the addition of a small amount of light petroleum the remainder was deposited in minute, white needles. The substance was recrystallised from ether as a flocculent mass of minute needles, m. p. 173° (yield 3%). The composition corresponds with that of caryophyllene glycol,  $C_{15}H_{26}(OH)_2$  (Found: C, 74.5; H, 11.7.  $C_{15}H_{28}O_2$  requires C, 75.0; H, 11.7%). The substance is very soluble in alcohol, slightly soluble in ether, and almost insoluble in light petroleum. It does not decolorise bromine or alkaline permanganate solution.

*Reactions of Chlorodihydrocaryophyllene.*—The chloro-compound,  $C_{15}H_{25}Cl$ , was prepared by the action of phosphorus pentachloride on the alcohol (Wallach and Walker, *loc. cit.*) and purified by crystallisation from light petroleum. M. p. 63° (Found: Cl, 14.9. Calc., Cl, 14.8%). The yield was almost theoretical.

A portion was refluxed at 100° with a concentrated solution of sodium ethoxide for 12 hours. No action took place and the chloride was recovered unchanged. Another portion was heated at 210° in quinoline solution for 3 hours, but again the compound was recovered unchanged. A third portion (20 g.) was dissolved in glacial acetic acid (150 c.c.), and anhydrous sodium acetate (19 g.) gradually added. The solution was boiled for 3 hours. After 1 hour, sodium chloride began to be deposited. On cooling, the product was diluted with water and extracted with light

petroleum. After removing the solvent from the dried extracts, the product was distilled under reduced pressure, when a colourless oil was obtained, b. p. 149—152°/10 mm., which was saturated towards bromine. When mixed with light petroleum and cooled to -20°, a solid mass of small, white crystals separated, which on purification melted at 40°. The yield was nearly theoretical. This substance is fairly soluble in alcohol and in petroleum. Acid ethyl-alcoholic hydrolysis yielded ethyl acetate, and by hydrolysis with methyl-alcoholic potash a theoretical yield of caryophyllene alcohol, m. p. and mixed m. p. 95°, was obtained. The substance is therefore caryophyllene acetate,  $C_{15}H_{25}O \cdot CO \cdot CH_3$  (Found: C, 76.8; H, 10.6.  $C_{17}H_{28}O_2$  requires C, 77.2; H, 10.6%).

*The Action of Hypochlorous Acid on  $\beta$ -Caryophyllene.*—A solution of 108 g. of chlorocarbamide (2 mols.) in 300 c.c. of water was added slowly to a cooled solution of 120 c.c. of  $\beta$ -caryophyllene (1 mol.) and 10 c.c. of acetic acid in about 500 c.c. of acetone, and the mixture shaken for several hours until all the hypochlorous acid had disappeared. The acetone was then distilled off, the residual liquid extracted with ether, and the extract dried and distilled. The product, which presumably was the dichlorohydrin of  $\beta$ -caryophyllene,  $C_{15}H_{24}(OH)_2Cl_2$ , was a yellow, oily liquid, which could not be obtained in crystalline form, was not volatile in a current of steam, and could not be distilled without partial decomposition. The compound did not give a semicarbazone nor a nitrobenzoate, but when a portion was warmed with acetic anhydride (2 mols.) after addition of a drop of sulphuric acid reaction took place quickly. The product was extracted and after repeated distillation under diminished pressure yielded a colourless liquid, b. p. 190—200° of which the composition approximated to that of a monoacetate of the dichlorohydrin (Found: C, 57.1; H, 6.9; Cl, 19.9.  $C_{17}H_{28}O_3Cl_2$  requires C, 58.1; H, 7.1; Cl, 20.2%). The supposed dichlorohydrin distilled at 1 mm. with little decomposition. Repeated fractionation finally yielded a colourless liquid, b. p. 125—140°/1 mm., which was essentially the anhydride of the dichlorohydrin (Found: C, 62.3; H, 7.9; Cl, 23.4.  $C_{15}H_{24}OCl_2$  requires C, 61.8; H, 8.3; Cl, 24.3%).

This compound is saturated towards both bromine and potassium permanganate. It does not react with *p*-nitrobenzoyl chloride, with semicarbazide acetate, or with ammoniacal silver nitrate. It is not attacked by boiling aqueous 2% sulphuric acid or by dilute aqueous potassium hydroxide, but when heated with an aqueous alcoholic solution of the last reagent yielded an oily liquid which contained only a trace of chlorine, was unsaturated, and did not give the reactions of an alcohol.

Attempts to replace the chlorine in this compound by hydrogen were not successful. Addition of successive quantities of sodium amalgam to an alcoholic solution containing a trace of water resulted in the production of a yellow, oily liquid, which distilled for the greater part at  $120\text{--}130^\circ/1\text{ mm.}$ , and still contained 14.20% of chlorine. Thus by this treatment approximately one atom of Cl was replaced ( $\text{C}_{15}\text{H}_{25}\text{OCl}$  requires Cl, 13.8%). Prolonged heating of the compound with zinc dust and alcohol failed to yield a substance free from chlorine.

On oxidation with 30% hydrogen peroxide in glacial acetic acid solution the chloroanhydride yielded a small quantity of a viscous neutral product, some succinic acid, and another acid, in the form of a brown oily liquid, which has not been identified.

We are grateful to the Carnegie Trust for the award of grants which assisted us to prosecute this work.

#### XIV.—*The Density of Boric Oxide Glass and the Suspected Variation in the Atomic Weight of Boron.*

By HENRY VINCENT AIRD BRISCOE, PERCY LUCOCK ROBINSON,  
and GEORGE EDWARD STEPHENSON.

THROUGH the courtesy of Messrs. Borax Consolidated, Ltd., the authors, in 1922, were in possession of several parcels of boron minerals obtained from various parts of the world and containing a high percentage of boron. At that time an attempt was made to compare the atomic weights of the several specimens of boron contained in these minerals by preparing from each a specimen of boric acid, purifying these specimens by rigorous fractional crystallisation, and determining the density at  $25.00^\circ \pm 0.02^\circ$  of their aqueous solutions saturated at that temperature. The accuracy of the results as measured by their reproducibility fell short, however, of that necessary to give trustworthy evidence of any difference in atomic weight and this method of attack was abandoned.

Thereafter three of the samples of boron were used for determinations of the atomic weight by measurement of the ratio  $\text{BCl}_3 : 3\text{Ag}$  which have already been reported (J., 1925, 127, 700). These determinations gave evidence of an appreciable variation in atomic weight among the three samples. Therefore, as sufficient of all the original mineral samples was still available, a fresh attempt was made to obtain a comparative estimate of the atomic weights by deter-

mining the densities of samples of a solid boron compound prepared from the several sources. Of the available compounds, boric oxide glass appeared to be the most suitable; boric acid is easily prepared from the minerals, its low solubility in cold water renders its recrystallisation an excellent method of purification and it readily dehydrates to yield boric oxide glass, which, because of its chemical stability and transparent glassy character, seemed to be especially well suited to precise density determinations.

Although much attention has been given to the improvement of the specific gravity bottle (see, *e.g.*, Berkeley, J., 1907, 90, 56; Baxter, J. *Amer. Chem. Soc.*, 1908, 30, 46; Johnson and Adams, *ibid.*, 1912, 34, 563), it is difficult to attain high accuracy in the determination of the density of solids by displacement methods. Moreover, as boric oxide is extremely hygroscopic, being in fact coated with an opalescent film of hydrated oxide in less than one minute when exposed to air of ordinary humidity, it is clear that the use of any form of specific gravity bottle for the determination of its density is attended by very serious difficulty. Therefore it was decided to use a modification of the flotation method suggested by Andreae (*Z. physikal. Chem.*, 1911, 76, 491). Beads of pure boric oxide glass prepared from each of six sources, with all precautions to exclude traces of moisture, were sealed up in tubes containing the same mixture of dry, inert organic liquids of suitable density; then careful observations were made of the *temperature* of flotation of the beads of each sample. Separate determinations of the density and thermal expansion of the liquid mixture enabled the actual densities of the boric oxide samples to be calculated. Thence, using the ascertained atomic weight of the boron in one sample as a standard, it was possible, assuming identity of atomic volume for all specimens of boron, to calculate the atomic weights of the specimens of boron in the remaining samples.

#### EXPERIMENTAL.

*Preparation of Beads of Pure Anhydrous Boric Oxide.*—The sources of the various samples were:

- No. 1. Calcined borate of lime; Ascotan, Chile.
- No. 2. Calcined colemanite; Death Valley, California, U.S.A.
- No. 3. Borate of lime; the Argentine.
- No. 4. Borate of lime; Peru.
- No. 5. Boracite; Sultan Tchair, Asia Minor.
- No. 6. Crude boric acid; Volterra, Italy.

Samples 1 to 5 were separately treated as follows: 200 g. of mineral were dissolved as far as possible in hot 10% hydrochloric

acid, the solution was filtered hot, cooled quickly, and the precipitated boric acid was removed by filtration. The acid was twice recrystallised from pure water, the product was fused in platinum and then dissolved in pure hot water and allowed to crystallise. From this stage all the samples of boric acid, including No. 6, were twice recrystallised from pure water and each batch of crystals was tested for purity.

Owing, presumably, to the insolubility of calcium borate and the comparative insensitivity of available tests for calcium, no trace of that metal could be detected in the boric acid even at an early stage of the purification, but sulphate and chloride were then present in detectable amounts. Therefore the progress of purification in the later crystallisations was followed by tests for sulphate and chloride, and the apparent absence of these radicals in the final main crops of boric acid and in the mother-liquors whence these had come was taken as an indication of high general purity. The purified boric acid was stored in clean stoppered bottles, capped to exclude dust.

In the preparation of beads 10 g. of each sample were fused for 4—5 hours in a *suitable* covered platinum crucible heated at about 900° in an electric muffle furnace. The term *suitable* is stressed because it was only after several trials that a platinum crucible was found from which iron was not leached by the melt. Even after this drastic treatment, boric oxide still contains water, presumably because the high viscosity of the melt hinders its escape, and in order to dehydrate the material completely and prepare suitable individual samples for flotation, the crucible was again heated over a Méker burner and a quantity of the fused oxide was collected on a platinum wire. This was heated in a hot bunsen flame for 1 minute and if it then showed no sign of bubbles—a clear indication of the complete absence of water—it was allowed to drop from the wire directly into a clean cold platinum basin, which had been previously heated to redness and then rested in a desiccator over phosphoric oxide, the lid of the desiccator being raised for the minimum time. When bubbles appeared in a bead, the material was rejected, as it was found that such beads could be almost completely volatilised before losing their vesicular structure. The beads were about 3 mm. in diameter and from 30—35 were prepared from each sample. A number of test beads examined under the microscope were isotropic, contained no visible bubbles and, between crossed Nicols, appeared free from strain.

*Preparation of the Flotation Liquid.*—No single liquid of suitable chemical nature having the required density could be found, so a **binary mixture** was used. It appeared that the constituents of this mixture should be chemically stable and non-reactive, should be

capable of being thoroughly dried by means of phosphoric oxide, should have densities slightly below and above 1.8, should have closely similar and preferably rather high boiling points and fairly low viscosities. The requirements of the case were met by a mixture of pentachloroethane (b. p.  $161.7^{\circ}$ ,  $D$  1.693) and trimethylene dibromide (b. p.  $165.0^{\circ}$ ,  $D$  1.987) containing 61.07% by volume of the former liquid. Both liquids were obtained from Messrs. British Drug Houses, Ltd.; and were further purified by fractional distillation, about 20% being rejected as head and tail fractions. The main fraction of pentachloroethane was collected between  $160^{\circ}$  and  $162.5^{\circ}$  at 762.6 mm. and that of trimethylene dibromide between  $164.0^{\circ}$  and  $167.0^{\circ}$  at 762.6 mm.

About 120 c.c. of the mixture were left in contact with phosphoric oxide for 24 hours. Slight decomposition and darkening occurred, probably owing to slight conversion of trimethylene dibromide into propylene dibromide (b. p.  $141.7^{\circ}$ ,  $D$  1.9), but the method of experiment ensured that any change in the density or volatility of the mixture thus produced would have no effect on the density found for boric oxide.

The apparatus used for the final purification and preservation of the flotation mixture is shown in Fig. 1. Both it and the other apparatus to be described later were constructed throughout of "Durosil" glass and before use were soaked in a solution of chromic acid in strong nitric acid, washed very thoroughly with pure water, dried in an air-oven at  $150^{\circ}$ , and finally swept out for some time

with a slow stream of air which had been cleaned by bubbling through concentrated aqueous potash and dried by passage over solid caustic potash and phosphoric oxide. The tubes at H and I being temporarily sealed by fusion, a stream of dry air was passed in at C and out through a phosphoric oxide guard-tube on D, and the liquid mixture was introduced through E into the vessel A: tubes E and C were then sealed. A was cooled with ice and the apparatus was evacuated by a Gaede pump through D, which was finally sealed off at the constriction F. At this stage the liquid was almost completely distilled from A to B. Then both A and B were cooled with ice, dry air was slowly admitted at C, and the vessel B was sealed off from A at G. The reason for thus admitting air was to displace the vapour of the organic liquids from the connecting tube before sealing off: in this way perfectly clean seals were obtained, whereas the vapour, if present, carbonises when heated to redness. The vessel B was stored in a dark place until required.

*Filling of the Flotation Tubes.*—These tubes, of the form shown in Fig 2, were constructed of very thin-walled Durosil tubing of about 8 mm. bore, had a fine bent capillary at J, and were slightly constricted at L and K. The length of the tube between K and J was about 30 cm. Each tube bore an etched number corresponding with the sample of boric oxide it was to contain, and was charged with beads as follows: While dry air was passed through J up the perfectly clean and dry tube, beads, from 30—35 in number, of one sample of boric oxide were quickly removed from the phosphoric oxide desiccator and poured into this tube: the tube was then immediately sealed off first at L and then at J.

The procedure for filling the tubes with liquid was necessarily elaborate, but worked without a hitch in practice. A large aspirator bottle, containing a quantity of loose phosphoric oxide and air under slight pressure, was connected to the sealed tip of F (previously scratched with a file) by pressure tubing, through a train consisting of a tap, a phosphoric oxide guard-tube and a T-piece opening to the atmosphere by means of a tap and phosphoric oxide guard-tube on the side limb. The apparatus having been very thoroughly dried, pressure was raised in the aspirator and the whole was allowed to stand for over an hour to ensure adequate drying of the additional air. Thereafter the tip F was broken inside the rubber tube and the fine delivery tube I was also opened near the tip and at once inserted in a guard-tube carrying a current of dry air. Then each flotation tube in turn was cracked just below L by means of a sharp file and a hot rod, the top was lifted off, a fine bent tube delivering a current of dry air was passed down below the constriction K, and then the flotation tube was slipped quickly over

the jet I of the reservoir B, from which the guard-tube had been that instant removed. By admitting air from the aspirator, liquid was forced over from B until the flotation tube was filled to a depth of about 20 cm. The flow of liquid was stopped by shutting off B from the aspirator and releasing the pressure in B by opening to the air the guarded tap in the connecting train. Then the flotation tube was withdrawn from I (and replaced immediately by the guard-tube), the fine tube delivering air was lifted just above the constriction K, and the flotation tube was sealed with the blow-pipe at that point.

After the drill had been mastered by practice runs on blank apparatus, this procedure occupied much less time than it takes to describe. In the final experiments, the time required to fill a tube averaged four minutes, and no one tube was open for more than  $4\frac{1}{2}$  minutes.

*Determination of the Density and Thermal Expansion of the Liquid.*—For this purpose a special pycnometer of the form shown at M (Fig. 3) and holding about 10 c.c. was used. It had at N a taper ground carefully to fit both the cap, O, and the bent extension tube, P, and at R a fine engraved reference mark. Both tubes of the pycnometer were of very fine bore. It was weighed against a precisely similar pycnometer as tare, on a balance having a sensitivity of 20 scale divisions per mg., by means of a set of weights carefully calibrated in air for atomic weight work.

Five determinations of the weight of the pycnometer empty, made after various washings, fillings and immersions in the thermostat bath, gave concordant results, and thus afforded evidence that the error of weighing was probably insignificant. The weights of the pycnometer filled with pure water at  $17.00^{\circ}$  and  $19.45^{\circ}$  were determined in triplicate and thus, by means of the known specific volume of water, the absolute volume of the pycnometer at these temperatures was ascertained.

In filling the pycnometer with the flotation liquid the reservoir B (Fig. 3) was opened at Q, the carefully dried extension tube P (closed at the ground end by means of a rubber cap) was slipped in, and an air-tight joint made by sliding the wired-on rubber sleeve over the tube P. The reservoir was opened through a phosphoric oxide guard-tube at H. Both reservoir and pycnometer were then clamped to a retort stand and immersed over the barrels in the water of the thermostat tank maintained at  $17.00^{\circ} \pm 0.02^{\circ}$ . After 20 minutes, the retort stand was lifted from the bath, the pycnometer was connected by the ground joint N to the reservoir and filled with liquid forced over by admitting dry air through H. Then the pycnometer was disconnected and P was closed with its rubber cap.

These operations having been carried out very quickly, the stand and vessels were returned to the thermostat and held at  $17.00^{\circ}$  for a further 30 minutes. Then the liquid level in the pyknometer was adjusted by drawing off the excess with a piece of pure filter-paper, and the pyknometer was stoppered, removed from the bath, dried carefully, and weighed with all due precautions. It was then replaced in the thermostat, maintained at  $19.45^{\circ} \pm 0.02^{\circ}$  for 40 minutes, the liquid level was again adjusted, and the pyknometer was stoppered, dried, and weighed as before.

These determinations gave the data necessary to ascertain with the requisite precision the absolute density of the liquid at two temperatures, comprising between them the range of flotation temperatures. The density at intermediate temperatures was obtained on the assumption, clearly justifiable for so short a temperature range, that the relation of density to temperature is linear, and was read from a large-scale graph.

*Determination of Temperature of Flotation.*—The six flotation tubes, together with an open-scale thermometer graduated in  $0.1^{\circ}$ , were mounted vertically by means of rubber bands on two horizontal rods clamped to a retort stand. The whole apparatus was then immersed in a copper tank, with plate glass sides, containing about 27 litres of water. The tank was fitted with a motor-driven paddle, and at about room temperature this arrangement proved to be sufficiently thermostatic for its purpose. In a preliminary test, the temperature was raised slowly from about  $17^{\circ}$  to about  $19.5^{\circ}$  by the addition of quantities of 100 c.c. of hot water at regular intervals, and the approximate temperatures of flotation of the several samples of beads were observed. The final observations were made in each tube separately, and the temperature at which the beads remained suspended was noted for each sample. In all cases one or two beads—never more—whilst of the same order of density, appeared to be slightly heavier than the rest and sank first. The movement of the next lot in order of density, usually upwards of 6 (which were followed down almost immediately by the main bulk), was therefore observed with the aid of a fixed telescope, and the bath temperature was carefully regulated until they were brought to rest midway in their fall through the liquid. These beads were maintained stationary in suspension for 30 minutes and the temperature was observed every 3 minutes: these temperature readings did not vary over a greater range than  $0.02^{\circ}$  and the mean value was taken as the flotation temperature.

As the beads floated for  $\frac{1}{2}$  hour at a substantially constant temperature, it is evident that they must have been in thermal equilibrium with the liquid. Any small defect in this respect would have

a negligible effect on the results owing to the smallness of the thermal expansion of boric oxide glass. Samsoen (*Compt. rend.*, 1925, **181**, 354) has shown that up to  $240^{\circ}$  this has a value about  $15 \times 10^{-6}$ , whence a change of temperature of  $0.1^{\circ}$  (which is large in relation to the present measurements) changes the density of the glass by about one unit in the eighth decimal place.

Further, the prompt movement of the beads when the slightest perceptible change was made in the bath temperature showed that the flotation liquid within the tubes acquired the temperature of the bath with very little delay, probably within one minute. This is the more probable because other experiments in progress in these laboratories have shown that some 60—100 c.c. of liquid contained in a sealed tube 30 mm. in diameter with walls  $1\frac{1}{2}$  mm. thick, without agitation, requires only some 8—15 minutes to acquire within  $0.01^{\circ}$  the temperature of a water-bath in which it is wholly immersed.

### Results.

The following values for the density of the liquid, relative to water at  $4^{\circ}$ , are each the mean of two concordant determinations:—

Temperature .....	17.00°	19.45°
Volume of pycnometer .....	9.7822 c.c.	9.7825 c.c.
Weight of liquid contained by pycnometer ...	17.5858 g.	17.5471 g.
Density of liquid .....	1.79773	1.79372

The table given below shows for each sample of boric oxide the flotation temperature, the corresponding density, the atomic weight calculated from the density, and, in the case of three samples, the atomic weight derived from determinations of the ratio  $\text{BCl}_3 : 3\text{Ag}$  using boron trichloride prepared from the same original sample. In calculating the atomic weight corresponding to the ascertained density, sample 5, derived from boracite from Sultan Tchair, Asia Minor, was taken as standard, with the atomic weight  $B = 10.818$ . Hence for any other sample, X, the atomic weight is found by:

$$\text{At. wt. of boron in X} = \frac{1}{2} \left( \frac{\text{Density of X} \times \text{Mol. wt. of standard B}_2\text{O}_3 - 48}{\text{Density of standard B}_2\text{O}_3} \right).$$

Sample No.	Place of origin.	Flotation temp.	Density.	Relative atomic weight.	
				Calc. from density.	Determined from ratio $\text{BCl}_3 : 3\text{Ag}$ .
2	California	17.36°	1.79711	10.847	10.841
6	Tuscany	18.15	1.79583	10.823	10.825
5	Asia Minor	18.30	1.79558	10.818 (standard)	10.818
1	Chile	18.30	1.79558	10.818	
3	Argentina	18.65	1.79501	10.806	
4	Peru	19.25	1.79404	10.788*	

\* The beads of this sample showed a considerably greater variation in density among themselves than was observed in the case of the other samples. Hence the authors attach less weight to this figure than to the data for samples 1—5 inclusive.

*Discussion of Results.*

The method of determining densities here described may clearly be made to yield extremely precise results and is applicable to a great variety of solids, provided that a suitable flotation liquid can be obtained. The values recorded show that the mean density of pure fused boric oxide is 1.7952 and that the value 1.88 commonly used is considerably in error.

The estimated maximum error in the determination of the specific gravity of the flotation liquid is  $\pm 0.00008$ : the actual error is probably rather less at temperatures intermediate between 17.00° and 19.45°. Owing to the means adopted to ensure that all the flotation tubes were filled at one time from the same well-mixed bulk of liquid, the *relative* values of the specific gravity deduced from the flotation temperatures are probably uncertain only in so far as those temperatures are uncertain. It is unjustifiable to attempt to report in detail the very numerous and detailed records of the observations of flotation temperatures, but they have been subjected to the most critical examination by the three authors working independently and the utmost difference of opinion thus elicited in their interpretation would not affect by one unit the third decimal of the atomic weight in any case. Hence it seems probable that the relative densities have an error less than 1 part in 10,000 parts, and that the maximum error in the relative values of the atomic weight does not exceed four or five units in the third decimal.

Admitting the view here expressed as to the precision of these results, the observed differences among them require explanation. The authors believe that the samples of boric oxide are very pure and, moreover, that the uniformity so carefully observed in their purification and subsequent treatment should have ensured that any impurity, for example, a possible trace of water, which they may have retained can have had little influence on the *relative* values found for their densities. Hence the observed differences are attributed to a variation in the atomic weight of one of the elements present and as there exists no evidence that such variation is possible in the case of oxygen, it is assumed to occur in the atomic weight of boron. The good agreement in three cases between the relative atomic weights deduced from the density values and found by the determination of the ratio  $\text{BCl}_3 : 3\text{Ag}$  (Briscoe and Robinson, J., 1925, 127, 696) can scarcely be accidental, and the authors believe that the present work confirms the conclusions drawn in the paper cited.

If these atomic weight values are correct, it is remarkable that the atomic weights of boron from the Argentine and Peru are very appreciably lower than any values hitherto recorded.

Evidently a determination of the boron halide : silver ratio for material from these sources would constitute a valuable check on the present results and conclusions, and the authors have considered undertaking this investigation. It appears to them, however, that any further work they might do on the atomic weight of boron can add but little to the value of the evidence they have already advanced, and that they should now leave it to other chemists to confirm or refute the conclusion, drawn from that evidence, that boron, like lead, has an atomic weight varying with its source. It is much to be hoped that this further investigation will be undertaken.

The authors desire to acknowledge a grant from the Department of Scientific and Industrial Research enabling one of them (G.E.S.) to take part in this work.

## XV.—*Butyl Esters of the Simpler Amino-acids.* *Part I.*

By WALTER THOMAS JAMES MORGAN.

HITHERTO, with few exceptions, only the ethyl esters of the amino-acids have been prepared and examined (Curtius, *Ber.*, 1883, 16, 753; 1884, 17, 953; *J. pr. Chem.*, 1888, 37, 150; Fischer, *Ber.*, 1901, 34, 433). Butyl esters have now been prepared. These are more stable than the corresponding ethyl esters—inasmuch as quantities up to 20 g. distil almost completely, whereas ethyl esters distilled under similar conditions invariably leave a brown residue—and are much less volatile in ether vapour under diminished pressure. They should be, therefore, the more suitable form in which the monoamino-acids produced by the hydrolysis of proteins may be estimated. Since the application of this method for the separation of the monoamino-acids of protein is now unavoidably postponed, it seems desirable to publish the work so far completed.

### EXPERIMENTAL.

*n*-Butyl Glycine Hydrochloride.—Glycine (5 g.) suspended in 100 g. of dried and carefully fractionated butyl alcohol was esterified by the method of Curtius (*Ber.*, *loc. cit.*). Several similar preparations of the hydrochloride were made using the dry lead salt of the acid. The finely divided lead chloride that separates has, according to Foreman (*Biochem. J.*, 1919, 13, 378), a favourable catalytic effect

on the rate of esterification. The mixture saturated with hydrogen chloride was heated on a boiling water-bath until the amino-acid dissolved, the excess of butyl alcohol was then distilled under reduced pressure, and the pale yellow syrup of the *ester hydrochloride* crystallised from ethyl acetate. The solid so obtained was quickly ground, kept for 2 days over solid potassium hydroxide, and crystallised from ether-ethyl acetate (1 : 2), separating in flat laminæ, m. p. 69—71°. (All melting-point determinations were carried out in sealed capillary tubes owing to the hygroscopic nature of the ester hydrochloride.) It dissolved readily in water, alcohol, acetone, or ethyl acetate, but was only sparingly soluble in ether or chloroform (Found : N, 8.2; Cl, 21.1.  $C_6H_{14}O_2NCl$  requires N, 8.3; Cl, 21.2%)\*.

*n-Butyl Glycine*,  $NH_2 \cdot CH_2 \cdot CO \cdot O \cdot C_4H_9$ .—To a vigorously shaken suspension of the hydrochloride (21.5 g.) in dry ether (250 c.c.) at 0°, anhydrous baryta was added, in portions of about 1 g., until it was in excess; even so, some hydrochloride remained, but this decomposed on addition of 5 c.c. of 70% potassium hydroxide solution. The whole was immediately shaken and filtered and the residue, consisting of baryta, barium chloride and a little undissolved ester, was shaken with two further quantities of ether. The combined ethereal filtrates were concentrated under reduced pressure to about 40 c.c., the temperature being kept below 30° to prevent volatilisation of the ester with the ether vapour. The ester distilled at 81—81.5°/18 mm. as a colourless oil having the characteristic odour of all amino-acid esters (yield, 14 g. or 83%;  $d_{16}^{20}$  0.9703). The ester is soluble in water, ether, or alcohol (Found : N, 10.6.  $C_6H_{13}O_2N$  requires N, 10.7%).

In a sealed glass tube, the freshly distilled ester (5 g.) changed completely in 24 hours into a white, crystalline solid. This substance gave an intense biuret reaction, charred without melting at 240°, and was insoluble in alcohol, chloroform, glacial acetic acid, or benzene but fairly easily soluble in hot water (Found in material washed free from butyl alcohol : C, 48.6; H, 7.7. Triglycylglycine butyl ester requires C, 47.7; H, 7.3%). A further preparation of this compound is being carried out, when it is hoped to recrystallise the substance and determine its molecular weight.

The *picrate* was prepared by warming together at 60° for  $\frac{1}{2}$  hour an alcoholic solution of the ester (3 g.) and a solution of picric acid (5.2 g.) in 50% alcohol. On cooling, the *picrate* separated in pale yellow laminæ, m. p. 113°, which were very soluble in acetone, somewhat soluble in chloroform or ether, and insoluble in light petroleum or ligroin (Found : N, 15.6.  $C_{12}H_{16}O_9N_4$  requires N, 15.5%).

The *benzoquinone* derivative,  $(C_4H_9 \cdot O \cdot CO \cdot CH_2 \cdot NH)_2C_6H_4O_2$ ,

separated in scarlet needles from the dark red solution produced by the interaction of the ester (3 g.) and benzoquinone (4 g.) in ether at 0°. The crystals were washed with ether and freed from quinol by dissolution in chloroform; the quinone compound, m. p. 179—180°, was precipitated from the solution by light petroleum (Found: N, 7.6.  $C_{18}H_{26}O_6N_2$  requires N, 7.6%).

*n*-Butyl carbamidoacetate,  $H_2N \cdot CO \cdot NH \cdot CH_2 \cdot CO \cdot O \cdot C_4H_9$ , separated in tufts of colourless needles, m. p. 119°, when butyl glycine hydrochloride (2.8 g.), dissolved in a minimum of water, was warmed with a solution of potassium cyanate (1.7 g.) on a water-bath. It was soluble in hot ethyl alcohol, sparingly soluble in cold acetone, and insoluble in light petroleum or ligroin (Found: N, 16.1.  $C_7H_{14}O_3N_2$  requires N, 16.2%).

*iso*Butyl Glycine Hydrochloride.—A suspension of glycine (15 g.) in dry *isobutyl* alcohol (250 c.c.) was saturated with hydrogen chloride, and solution completed by heating on a boiling water-bath for  $\frac{1}{2}$  hour. The subsequent procedure was as described in the case of the *n*-butyl ester hydrochloride. The *hydrochloride*, m. p. 84—88°, is very hygroscopic and quickly liquefies on exposure to air. It is readily soluble in alcohol or ethyl acetate, but only sparingly soluble in ether or chloroform (Found: N, 8.4; Cl, 21.2.  $C_6H_{14}O_2NCl$  requires N, 8.4; Cl, 21.2%).

*iso*Butyl glycine was obtained from its hydrochloride (37 g., recrystallised from ether-ethyl acetate [2:1] and dissolved in 750 c.c. of dry ether) in the same way as the normal ester. The ether was dried over anhydrous potassium sulphate. The pure *ester* is a colourless, oily liquid with a characteristic odour (yield, 73%), b. p. 79.5—80.5°/18 mm.,  $d^{20}_D$  0.9609,  $d^{17}_D$  0.9618. It is readily soluble in water, alcohol, or chloroform (Found: C, 54.9; H, 9.9.  $C_6H_{13}O_2N$  requires C, 55.1; H, 9.9%).

The *picrate* was obtained by warming together an alcoholic solution of the ester (2 g.) and an aqueous-alcoholic solution of picric acid (1 mol.) and pouring the mixture into water. The *picrate* was crystallised from benzene, dried in a vacuum desiccator, and, as the melting point was not sharp, recrystallised from alcohol and was thus obtained in needles, m. p. 82—87°. It was only slightly soluble in ether or light petroleum (b. p. 40—60°) and insoluble in ligroin (Found: N, 15.5.  $C_{12}H_{16}O_9N_4$  requires N, 15.5%).

The *benzoquinone* derivative was prepared and purified as was the preceding isomeride. The scarlet needles obtained, m. p. 171—172°, were insoluble in hot or cold water or ligroin, somewhat soluble in ether, and readily soluble in cold chloroform or 50% aqueous alcohol (Found: C, 59.2; H, 7.3; N, 7.7.  $C_{18}H_{26}O_6N_2$  requires C, 59.0; H, 7.1; N, 7.7%).

Unless stated otherwise, the following substances were prepared in essentially the same ways as the corresponding compounds already described.

*n*-Butyl dl-Alanine Hydrochloride.—Prepared from racemic alanine (15 g.) and recrystallised from ethyl acetate, this compound melted at 58–61° (sealed tube), rapidly deliquesced in moist air, and was only slightly soluble in ligroin or ether but readily soluble in ethyl alcohol, benzene, chloroform, or acetone (Found : N, 7.7; Cl, 19.5.  $C_7H_{16}O_2NCl$  requires N, 7.7; Cl, 19.6%).

*n*-Butyl dl-alanine was obtained as a colourless, oily liquid, b. p. 81.5–82°/16 mm.,  $d^{20}_D$  0.9342 (yield 66%), having the usual characteristic odour. It is soluble in water, ether, alcohol, or chloroform. After being kept in a sealed glass tube for 3 weeks, the ester showed no signs of anhydride formation (Found : N, 9.7.  $C_7H_{15}O_2N$  requires N, 9.6%).

The *picrate*, m. p. 124°, crystallised in needles from 30% and 50% alcohol and in opaque, dendritic crystals from 5% alcohol (Found : N, 14.7.  $C_{13}H_{18}O_9N_4$  requires N, 14.9%).

Several attempts were made to isolate the benzoquinone derivative. A solution of the ester and benzoquinone in dry ether developed a bright scarlet colour, but after cooling for several hours in a freezing mixture nothing separated; on cooling in solid carbon dioxide and ether, crystals of quinol were deposited. Evaporation of the ether solution gave only a red syrup which could not be crystallised. Precipitation with light petroleum gave only a dark red oil. The isolation of this compound is being further studied.

*iso*Butyl dl-Alanine Hydrochloride.—The syrup obtained was very difficult to crystallise even after drying in a vacuum desiccator over phosphoric oxide. Precipitation with ether of a solution of the hydrochloride in ethyl acetate gave a syrupy liquid which crystallised in flat, soft, soapy plates, m. p. 60–63° (sealed tube), which changed into a syrup on being exposed to air for a few minutes (Found : N, 7.6.  $C_7H_{16}O_2NCl$  requires N, 7.7%).

*iso*Butyl dl-alanine, prepared from the ester hydrochloride (31 g.) and distilled at 77–78°/19 mm., was a colourless, oily liquid soluble in water, alcohol, ligroin, or chloroform (yield 95%);  $d^{20}_D$  0.9330 (Found : N, 9.7.  $C_7H_{15}O_2N$  requires N, 9.6%).

As in the case of the *n*-butyl ester, all attempts to isolate the quinone derivative failed.

The *picrate* was obtained quantitatively in small, flat plates, m. p. 132–133°, by warming the ester (2.5 g.) with a solution of picric acid (3.6 g.) in 50 c.c. of 50% alcohol at 70–80° for  $\frac{1}{2}$  hour and cooling over-night. It was soluble in alcohol, ether, or acetone,

sparingly soluble in chloroform, and insoluble in light petroleum or ligroin (Found : N, 15.1.  $C_{13}H_{18}O_9N_4$  requires N, 15.0%).

*n-Butyl dl-Valine Hydrochloride*.—Prepared from *dl*-valine (5 g.) and crystallised from ethyl acetate, the *hydrochloride* was obtained in colourless, deliquescent needles, m.p. 59—60°, which were readily soluble in alcohol or acetone and sparingly soluble in dry ether or light petroleum (Found : N, 6.7.  $C_9H_{20}O_2NCl$  requires N, 6.7%).

*n-Butyl dl-valine* was obtained from the hydrochloride (3.5 g.) in the usual way; the combined ethereal filtrates were dried with anhydrous sodium sulphate and the ether was evaporated below 25°. The *ester*, b. p. 98—98.5°/17 mm.,  $d^{20}_4$  0.9266, was a colourless, syrupy liquid (yield 97.5%) having the usual characteristic odour. It was soluble in water, alcohol, ether, or chloroform (Found : N, 8.3.  $C_9H_{19}O_2N$  requires N, 8.1%).

The *picrate* formed long, yellow needles, m. p. 91—92°, which were soluble in acetone, ether, or chloroform, somewhat soluble in benzene, and insoluble in light petroleum (Found : N, 13.9.  $C_{15}H_{22}O_9N_4$  requires N, 13.9%).

*n-Butyl dl-Leucine Hydrochloride*.—Leucine (6 g.) was esterified in the usual manner. After standing in the ice-chest for 48 hours, the alcoholic solution deposited flat, colourless plates, which were recrystallised from ether and dried in a vacuum desiccator; m. p. 110—111°. The *hydrochloride* was exceedingly hygroscopic, and very soluble in alcohol but only slightly soluble in chloroform or ether. It crystallised from ethyl acetate in stellate clusters of colourless needles (Found : N, 6.4; Cl, 16.0.  $C_{10}H_{22}O_2NCl$  requires N, 6.3; Cl, 15.9%).

*n-Butyl dl-leucine*, prepared from the hydrochloride (4 g.), was a clear, colourless, oily liquid (yield 69%), b. p. 113.5°/18 mm.,  $d^{18.5}_4$  0.8733, which was soluble in water, alcohol, ether, or chloroform (Found : N, 7.4.  $C_{10}H_{21}O_2N$  requires N, 7.5%).

The *picrate* was obtained in yellow needles, m. p. 139°, which were soluble in alcohol, ether, or acetone and insoluble in ligroin or benzene (Found : C, 46.1; H, 13.6.  $C_{16}H_{24}O_9N_4$  requires C, 46.2; H, 5.8; N, 13.5%).

*isoButyl dl-Leucine Hydrochloride*.—This compound was a clear, colourless syrup which slowly crystallised on standing for 2 or 3 days over solid caustic potash in a vacuum desiccator; it was recrystallised from ethyl acetate, washed with ether, and again dried in a vacuum desiccator (yield 81%); m. p. 97—99° (Found : N, 6.3; Cl, 15.7.  $C_{10}H_{22}O_2NCl$  requires N, 6.3; Cl, 15.9%).

*isoButyl dl-leucine*, b. p. 110°/19 mm.,  $d^{18.5}_4$  0.9066, was obtained as a colourless, oily liquid (yield 88%) which was soluble in alcohol,

chloroform, or ether (Found : C, 64.1; H, 11.0; N, 7.4.  $C_{10}H_{21}O_2N$  requires C, 64.2; H, 11.2; N, 7.5%).

The *picrate* crystallised from dilute alcohol in flat plates, m. p. 135—136°, which were soluble in hot water, chloroform, or ethyl alcohol, slightly soluble in cold water or ether, and insoluble in light petroleum (Found : C, 46.0; H, 6.0; N, 13.6.  $C_{16}H_{24}O_9N_4$  requires C, 46.2; H, 5.8; N, 13.5%).

The author wishes to express his gratitude to Dr. G. Dean for his kind interest at all times, and to the Chemical Society for assistance in the purchase of materials.

WEST HAM MUNICIPAL COLLEGE.

## XVI.—*The Nitration of $\beta$ -Naphthoic Acid and Some New Amino- and Nitro-naphthoic Acids.*

By HAROLD AINSWORTH HARRISON and FRANK ALBERT ROYLE.

### *The Nitration of $\beta$ -Naphthoic Acid.*

THE earliest work on the nitration of  $\beta$ -naphthoic acid was carried out by Kuchenmeister (*Ber.*, 1870, **3**, 740), and by Ekstrand (*ibid.*, 1879, **12**, 1393), but yielded little if anything of permanent value. Later, Ekstrand (*J. pr. Chem.*, 1890, **42**, 273), by fractional crystallisation of the mixture of ethyl esters obtained from the crude nitration product, isolated five supposedly distinct compounds. Of these, one (m. p. 111°) gave a free acid, m. p. 295°, which was identical with that previously prepared by Graeff (*Ber.*, 1883, **16**, 2252) from the nitration product of  $\beta$ -naphthonitrile, and was shown to be 8-nitro-2-naphthoic acid. The second ester (m. p. 121°; free acid, m. p. 288°) was that of 5-nitro-2-naphthoic acid. From the small fractions which remained, one ester melting at 75° was isolated (free acid, m. p. about 285°), and two others were described in the following year (*ibid.*, 1891, **43**, 409); of these, one melted at 92° (free acid, m. p. 272° [279°] \*) and the other at

\* This nitro-acid on reduction gave an aminonaphthoic acid, m. p. 211°. Now 5-amino-1-naphthoic acid melts at this temperature, and the 5-nitro-isomeride is to be expected from the nitration of  $\alpha$ -naphthoic acid, if any occurred as impurity in Ekstrand's initial material. Further, 8-nitro-1-naphthoic acid, which would also be formed, cannot be esterified by the method employed (hydrogen chloride in alcoholic solution; compare Ekstrand, *ibid.*, 1888, **38**, 156) and therefore would not appear in the esterified mixture. Finally, the ethyl ester of 5-amino-1-naphthoic acid melts at 92° (compare above). The free nitro-acid, however, melts at 242° (Graeff, *loc. cit.*, p. 2250).

131°. (This last ester charred when warmed with sulphuric acid in the usual way, and the corresponding nitro-acid was not isolated.) No constitutions were assigned by Ekstrand to these isomerides.

Of the seven possible mononitro-derivatives of  $\beta$ -naphthoic acid, Ekstrand had thus claimed to have detected the presence of five. These did not include the 1-nitro-compound, m. p. 239°, which has since been prepared by Mayer and Oppenheimer (*Ber.*, 1918, 51, 1239). The characteristics of this derivative as described by these authors do not coincide with those of any of Ekstrand's supposed nitronaphthoic acids.

Repetition of Ekstrand's experiments, using his second method of nitration (*i.e.*, in absence of any solvent), has shown that approximately equal amounts of 5- and 8-nitro-2-naphthoic acids are formed in at least 95% combined yield. Some low-melting indeterminate fractions of the esters resulting from the use of alcohol or benzene as crystallising medium were all easily resolved by employing ethyl acetate and light petroleum. With regard to Ekstrand's highest-melting ester (m. p. 131°) which charred with sulphuric acid, it is to be noted that the ethyl ester of 7-nitro-2-naphthoic acid (prepared by the present authors at a later stage) melts at 131°, but can be hydrolysed quite easily to give a quantitative yield of the nitro-acid. No trace of this ester was detected in the nitration product.

In addition to the 5- and 8-nitro-isomerides, we have succeeded in establishing the presence of traces of 1-nitro-2-naphthoic acid in the nitration mixture.\* This acid cannot be esterified by the passage of hydrogen chloride into an alcoholic solution, and consequently was easily separated from the reaction material. It was never obtained quite pure, but reduction with ferrous sulphate and ammonia produced an aminonaphthoic acid, m. p. 202–205° (decomp.), the *acetyl* derivative of which crystallised from alcohol in long, gorse-like needles, m. p. 184°. This was identical with an authentic specimen of 1-acetylamino-2-naphthoic acid prepared synthetically (see Friedländer and Littner, *Ber.*, 1915, 48, 330).

During the nitration of  $\beta$ -naphthoic acid, therefore, between 60–80° with excess of nitric acid (*d* 1.42) only 5-nitro-2-naphthoic acid (m. p. 291° instead of 288°) and 8-nitro-2-naphthoic acid

\* Ekstrand (*ibid.*, 1890, 42, 273) digested the mixture of nitro-acids with sodium hydroxide during an attempt to separate them by fractionation of their sodium salts. But Friedländer and Littner (*Ber.*, 1915, 48, 330) have proved that hydrolysis of 1-nitro-2-naphthonitrile by alkaline reagents (even barium hydroxide) causes the replacement of the nitro-group by a hydroxyl group, and this also takes place in the case of the acid. It is therefore probable that Ekstrand had destroyed any 1-nitro-compound present.

(m. p. 295°) are formed in large quantity, together with a trace of 1-nitro-2-naphthoic acid.

*Some New Amino- and Nitro-naphthoic Acids.*

Of the seven theoretically possible amino-derivatives of  $\alpha$ -naphthoic acid, only four (the 2-, 4-, 5-, and 8-amino-1-naphthoic acids) have hitherto been prepared. Even fewer of the nitro- $\alpha$ -naphthoic acids are known, since no compound containing one nitro-group in any of the four  $\beta$ -positions is recorded. Of the substituted derivatives of  $\beta$ -naphthoic acid, only one amino-acid, the 6-derivative, had not been prepared, but there were still four unknown nitro-isomerides, *viz.*, the 3-, 4-, 6- and 7-nitro-2-naphthoic acids.\* As a result of the present work, 6- and 7-amino-1-naphthoic acids, 6-amino-, 6- and 7-nitro-2-naphthoic acids have been obtained for the first time.

The method adopted for the preparation of these aminonaphthoic acids consists in heating the neutral sodium salt of the corresponding hydroxynaphthoic acid † with ammonia and bisulphite under pressure. Möhlau and Kriebel (*Ber.*, 1895, 28, 3096) had already employed strong ammonia (without bisulphite) to convert 3-hydroxy-2-naphthoic acid into the amino-acid. Repetition of their experiment, however, showed no appreciable conversion, either with the 3-isomeride or any other. Neither could the 3-amino-compound be obtained when bisulphite was used, though the conditions were varied over a wide range.  $\beta$ -Naphthylamine was the sole product of reaction, as it was also from the anilide of 3-hydroxy-2-naphthoic acid (naphthol A.S.). Similarly, 1-hydroxy-2-naphthoic acid yielded  $\alpha$ -naphthylamine.

In addition to the new aminonaphthoic acids mentioned, 5- and 8-amino-2-naphthoic acids have also been prepared by the use of the bisulphite modification.

All the amino-2-naphthoic acids thus obtained were converted into nitronaphthoic acids by treatment of the diazotised product with copper powder and excess of sodium nitrite, as described by Veselý and Dvořák (*Bull. Soc. chim.*, 1922, 31, 421; 1923, 33, 319). The 5- and 8-nitro-2-naphthoic acids so prepared were used

\* Mention is made (*A.*, 1923, 124, i, 119) of a nitronaphthoic acid, m. p. 225—227°, obtained by Ruzicka and Stoll (*Helv. Chim. Acta*, 1922, 5, 923) as a by-product in the oxidation of 2-methyl-8-isopropyl-naphthalene with dilute nitric acid, the main product being 2 : 8-naphthalenedicarboxylic acid. The nitronaphthoic acid in question is really a nitro-8-isopropyl-2-naphthoic acid; the abstract is somewhat misleading.

† For the details of preparation of the various hydroxynaphthoic acids see Butler, Royle, and Schedler (*J.*, 1923, 123, 1641, 1649).

to confirm the identity of the nitration products of  $\beta$ -naphthoic acid (see previous section).

#### EXPERIMENTAL.

*Conversion of Hydroxy-acids into Amino-acids.*—The hydroxy-naphthoic acid (15 g.) is dissolved in water with the aid of sodium bicarbonate (6.3 g.); ammonia (100 c.c.,  $d$  0.88) is added, followed by a solution, saturated at 15°, of sulphur dioxide in water (25 c.c.). The whole is diluted with water (110 c.c.), and heated in an autoclave at 200–210° (pressure about 50 atmospheres) for 10 hours. The solution is boiled to drive off most of the ammonia, filtered, and slightly acidified by the gradual addition of acetic acid. Under these conditions 5- and 8-amino-2-naphthoic acids separate in a very satisfactory condition. With 6-amino-2-naphthoic acid (and to a less extent with 6- and 7-amino-1-naphthoic acids) it is advisable to add an excess of warm dilute hydrochloric acid to the acetic acid solution. After extraction with ether to remove impurities, the solution is concentrated and the amino-hydrochloride allowed to crystallise. The free acid is regenerated by dissolving in a small quantity of sodium carbonate solution and carefully neutralising with acetic acid. 7-Amino-2-naphthoic acid is best isolated through its difficultly soluble sodium salt, by the addition of sodium hydroxide to the autoclave liquor after removal of excess of ammonia. The yield in every case is almost theoretical.

The various aminonaphthoic acids differ but slightly from one another as regards their solubilities. They are easily soluble in alcohol or acetic acid, somewhat less easily soluble in ether, acetone or ethyl acetate, and very sparingly soluble in benzene.

*6-Amino-1-naphthoic acid* crystallises from alcohol in light brown aggregates, m. p. 203° (Found: C, 70.4; H, 4.8.  $C_{11}H_9O_2N$  requires C, 70.6; H, 4.8%). The *hydrochloride* crystallises from water in clumps of needles, and the *acetyl* derivative from alcohol in white needles, m. p. 170–172°.

*7-Amino-1-naphthoic acid* crystallises from alcohol in light brown prisms, m. p. 223–224° (Found: C, 70.3; H, 5.0%). The *hydrochloride* separates from water in warty clusters of needles, and the *acetyl* derivative from alcohol in almost white needles, m. p. 229–230°.

*6-Amino-2-naphthoic acid* crystallises from dilute alcohol in very pale yellow needles, m. p. 225° \* (Found: C, 70.8; H, 4.7%).

\* Since this work was completed a compound described as "6-amino-2-naphthoic acid" has been obtained by Dzięwoński, Schoenówna, and Waldmann (*Ber.*, 1925, 58, 1211). These authors give the melting point as 222–223°; but the acetyl derivative, from which the free amino-acid

The *hydrochloride* is not very soluble in cold but rather more soluble in hot water, crystallising in small flakes. The *acetyl* derivative separates from dilute alcohol or from acetone in white needles, m. p. 230—232°.

7-Amino-2-naphthoic acid crystallises from alcohol in pale yellow leaflets, m. p. 245°. Its *acetyl* derivative separates from dilute alcohol in almost white, flat needles, m. p. 200—201° (decomp.).\*

*Types of Fluorescence shown.*

Solvent.	$\alpha$ : 6-.	$\alpha$ : 7-.	$\beta$ : 4-.	$\beta$ : 5-.	$\beta$ : 6-.	$\beta$ : 7-.	$\beta$ : 8-.
Alcohol	Green	Emerald green	Blue	Green	Purple	Sea green	Emerald green
Ether	Light blue	Emerald green	Royal blue (Blue)	Cobalt blue (Green)	Purple	Pale blue	Turquoise blue
Acetic acid	Pale violet	Bluish-green			Cobalt blue	Bluish-purple (Blue)	Leaf green
Benzene	Royal blue	Sky blue	Bluish-purple	Light blue	Violet blue		Greenish-blue
Ethyl acetate	Turquoise blue	Turquoise blue	Blue	Greenish-blue	Reddish-violet	Blue	Bluish-green
Acetone	Greenish-blue	Turquoise blue	Royal blue	Turquoise blue	Reddish-violet	Blue	Bluish-green

A few of these fluorescences require magnesium light or the light from an iron arc to render them visible; such are indicated by brackets. The majority are very marked, even in subdued daylight. The colours given in the table are those induced by arc light; they vary slightly in one or two instances from the fluorescences in daylight.

In addition to the preceding observations on the fluorescent properties of aminonaphthoic acids taken under approximately standard conditions, 1-amino-2-naphthoic acid furnishes an appreciable blue fluorescence in alcohol, ether, or acetic acid, while 3-amino-2-naphthoic acid (according to Möhlau and Kriebel, *loc. cit.*) gives a green fluorescence in alcohol or ether.

It is worthy of note that the aminonaphthoic acids whose configurations correspond to those of possible naphthaquinones produce more intensely fluorescent solutions than those not having a potentially quinonoid structure; e.g.,  $\beta$ : 8- is stronger than  $\beta$ : 5-;  $\beta$ : 6- than  $\beta$ : 7-; and  $\alpha$ : 7- than  $\alpha$ : 6-.

was prepared, melts at 271—272°. It is to be observed that the configuration of this isomeride was only arrived at by a process of exclusion. On the other hand, the constants given do not coincide with those of any other amino-2-naphthoic acid, all of which are now known.

\* It is important to carry out the melting-point determinations of these acetyl derivatives in a standardised manner, in order to ensure concordant results. No method other than the one here described gives a definite fluid melt. The tube is inserted when the temperature of the bath is only about 5° below the expected m. p. of the substance, and the time taken for the necessary rise in temperature must be less than 2 minutes. Incipient softening usually precedes liquefaction, and on increasing the temperature the substance reverts to the solid state, melting a second time, though not sharply, at a somewhat higher temperature. (To suggest that the m. p.—271—272°—recorded in the previous note is really this higher melting point would be somewhat premature, since the range is limited to 1°.)

*Conversion of Amino-acids into Nitro-acids.*—The aminonaphthoic acid (8 g.) is dissolved in warm glacial acetic acid (30 g.), and sulphuric acid (16 g.), diluted with an equal volume of water, added with constant stirring. The sulphate which separates is at once diazotised at 0° with sodium nitrite (3.5 g.) dissolved in water (15 c.c.). The clear diazo-solution is poured in small portions into a solution of sodium nitrite (35 g. in 140 c.c. of water) containing also clean copper bronze (30 g.). The reaction liquor, on standing at room temperature for 4 hours with regular shaking, deposits the whole of the nitronaphthoic acid, which is filtered off and purified by repeated extractions with boiling alcohol (charcoal). The filtered alcoholic solution is concentrated to a small bulk; the addition of water then precipitates the nitronaphthoic acid as a yellow powder. The total yield is about 0.5 g.

6-Nitro-2-naphthoic acid crystallises from alcohol in pale yellow plates, m. p. 310° (Found: C, 60.5; H, 3.4.  $C_{11}H_7O_4N$  requires C, 60.8; H, 3.2%). The ethyl ester, m. p. 177°, crystallises in brownish-yellow, rectangular plates from ethyl acetate, in needles from alcohol. The acid can be recovered from the ester by hydrolysis with strong sulphuric acid on the water-bath for a few hours.

7-Nitro-2-naphthoic acid crystallises from alcohol in yellow needles, m. p. 262° (Found: C, 60.6; H, 3.4%). It is moderately soluble in acetic acid, but dissolves with difficulty in other solvents. The ethyl ester crystallises from alcohol in pale salmon-coloured, silky needles, m. p. 131°. This ester shows no sign of charring when hydrolysed with sulphuric acid in the usual way (compare Ekstrand's ester, m. p. 131°; see p. 85).

One of us (H. A. H.) desires to express his thanks to the Department of Scientific and Industrial Research for a maintenance grant, and to the Research Fund Committee of the Chemical Society for a grant for chemicals. We are also indebted to Professor Lapworth for his interest in the work.

THE UNIVERSITY, MANCHESTER.

## XVII.—A Revision of the Structural Formula of Glucose.

By WILLIAM CHARLTON, WALTER NORMAN HAWORTH, and  
STANLEY PEAT.

THE discovery of the methylglucosides and the interpretation of the phenomena of mutarotation of sugars furnished the strongest reasons for the allocation of an oxide ring structure to the mono-

saccharides, and this formulation has been universally accepted. Tollens first ascribed to glucose a heterocyclic structure, and this conception was adopted by Fischer, who represented the normal methylglucosides by a five-membered or pentaphane ring, constituting the  $\gamma$ -oxide formula, which is the current and generally recognised basis for the formulation of sugars.

The methylglucosides were isolated in  $\alpha$ - and  $\beta$ -stereochemical forms, and it was shown that corresponding to these there existed also  $\alpha$ - and  $\beta$ -modifications of glucose. In 1914, Fischer (*Ber.*, 47, 1980) prepared a new methylglucoside which differed profoundly in stability from the  $\alpha$ - and  $\beta$ -modifications. This he described as " $\gamma$ "-methylglucoside. The nomenclature he adopted seemed unfortunate inasmuch as in this case the Greek letter was not intended to have any stereochemical significance but merely represented a third or novel form. Fischer recognised that the new variety of methylglucoside was a structural isomeride, and thus the term  $\gamma$ -sugar introduced in this connexion had no essential relationship to the  $\gamma$ -lactones. Confusion has naturally arisen from the use of this terminology, and especially so since the term " $\gamma$ -oxide form" was already applied to the normal sugars.

An experimental basis for the definite allocation to glucose of a  $\gamma$ -oxide (butylene oxide) constitution rather than that of any other oxide or heterocyclic structure was definitely lacking. Assuming, however, the spatial distribution of the oxygen valencies to be similar to those of carbon, and applying the considerations arising from the Baeyer strain theory, it was apprehended that a five-membered ring would involve the least strain in the sugar molecule, and this type of ring should, therefore, be capable of easy formation. It is tacitly assumed here that the conditions of strain in such a ring would be analogous to those in *cyclopentane*, where the carbon atoms carry only hydrogen. These conditions seemed to be supported by the facility with which sugars give rise to lactones, and by the properties which the latter display suggesting their resemblance to  $\gamma$ -lactones. Kiliani and Kleemann (*Ber.*, 1884, 17, 1300) attempted to obtain direct proof of the structure of gluconolactone, but it was left to Hudson to furnish, by his brilliant theoretical studies, the most convincing evidence of the  $\gamma$ -lactonic nature of the products of the oxidation of sugars.

In considering twenty-four lactones of the sugar series derived from the corresponding polyhydroxy-monobasic acids, Hudson (*J. Amer. Chem. Soc.*, 1910, 32, 345) found that if it were postulated that ring formation occurred at the  $\gamma$ -carbon atom, a remarkable parallelism was exhibited between the position of the lactone ring

and the sign of the rotation of the lactone, and that there were no cases of disagreement on the basis of this hypothesis. On the other hand, it was demonstrated that if this linking occurred at the  $\alpha$ -,  $\beta$ -, or  $\delta$ -carbon atom, the number of cases of disagreement with this "rule" were found to be 8, 10, and 12, respectively, out of the twenty-four lactones examined. He calculated that, on the theory of probability, the chances are 17 millions to one that the lactone will have the lactonic ring engaging the  $\gamma$ -carbon atom. This conclusion is supported by an abundance of other cases, and in the absence of direct synthetic evidence to the contrary, this view of the constitution of lactones derived from unsubstituted sugars must be adopted.

It has, however, been too readily assumed that an analogy should be drawn between this principle of lactone ring formation and the type of ring structure existing in the parent sugars. In instituting the inquiry of which details are given in this communication, the present authors have attempted to test the validity of the latter assumption.

It was considered that there should be recognisable differences in stability between lactones of the usual  $\gamma$ -type and those having a smaller or larger number of atoms than five constituting the ring, and that these differences would be reflected in a variation both in the rate and in the extent of hydrolysis to the open-chain acid. During the past 4 years the necessary synthetic materials and the data for this comparison have been accumulated, and in recent communications some of these results have been recorded by one of us without reference, however, to their essential bearing on the present problem.

The degree of accuracy attainable by direct titration of aqueous solutions of the lactones was insufficient for the purpose indicated. A more sensitive method of comparison was provided by studying the polarimetric changes accompanying ring scission from lactone to open-chain acid, using either aqueous or alcohol-water solutions.

Polarimetric data furnished by the completely methylated lactones derived from glucose, galactose, mannose, arabinose, and xylose led to a recognition of two types. Those lactones prepared from the normal forms of these sugars, by first methylating the aldoses and then submitting them to oxidation with bromine water, exhibited a rapid diminution or increase in specific rotation when dissolved in water or aqueous alcohol. Conversely, those lactones prepared from the labile or  $\gamma$ -sugars displayed a very slow and much less marked change in specific rotation.

*Observed Changes in the Specific Rotation of the Lactones  
from the following Sugars (aqueous solutions).*

	$\gamma$ -Forms (Time, 20 days).	Normal forms (Time, 24 hrs.).	Nos. of Curves.
Tetramethyl glucose ...	+61.5° $\rightarrow$ 39.6°	+101.1° $\rightarrow$ 25.6°	i and ii
Tetramethyl galactose ...	-27.1° $\rightarrow$ 25.2°	+161.5° $\rightarrow$ 27.2°	iii and iv
Trimethyl arabinose ...	-42.2° $\rightarrow$ 25.1°	+145° $\rightarrow$ 22.4° *	v and vi
Trimethyl xylose .....	+74.1° $\rightarrow$ 61.4°	-3.8° $\rightarrow$ +20.8° (Time, 7 days)	vii and viii
Tetramethyl mannose.	+65.2° $\rightarrow$ 56.3°†	+105° $\rightarrow$ 45.6°	

\* This value was determined by Pryde, Hirst, and Humphreys (*J.*, 1925, 127, 348).

† This figure is explained in the text, since it was obtained by Levene and Meyer from methylated mannonolactone. The time intervals are not recorded.

The curves given in Fig. 1 are those of the lactones related to glucose, galactose, and arabinose. Inspection of these curves suggests that the lactones represented by i, iii, and v are of the same type, and that those shown by ii, iv, and vi belong to a second and distinct type.

This second series illustrates the polarimetric data given by the lactones prepared from the normal forms of tetramethyl glucose, tetramethyl galactose and trimethyl arabinose, which exhibit a marked decline in specific rotation when dissolved in water. The equilibrium between the cyclic compound and open-chain acid is speedily reached and hydrolysis is also more nearly complete as revealed by direct titration at this stage.

On the other hand, the first series (Nos. i, iii, and v) represents lactones prepared from the labile or  $\gamma$ -sugars, and it is seen that the initial rotations are lower and that a much less profound change in the optical values occurs. Moreover, equilibrium between lactone and hydroxy-acid is only attained after several weeks, and at this stage hydrolysis is not nearly so complete as in the case of the former series.

The curves shown in Fig. 2 differ in a similar sense, but not in the same degree; the steeper of the two represents the lactone from normal trimethyl xylose, whilst the remaining curve, which is almost linear, is given by the lactone from trimethyl  $\gamma$ -xylose.

Fortunately, it is possible to correlate these data with constitutional formulæ which have been already determined for several of these sugars and their derived lactones, but for reasons which will be outlined later the constitution of the two glucoses and their gluconolactones had not yet admitted of any proof.

The method which is adopted in this communication shows that the data now recorded render it possible to reach a reasonable

conclusion as to the structure of glucose and its  $\gamma$ -derivatives by observing the analogy which is found to subsist between their lactones and those of the other sugars of known constitution.

Of the four sugars examined (five, including mannose), two have been subjected to close constitutional study by direct methods

FIG. 1.

FIG. 2.

of oxidation. Thus Hirst and Robertson (J., 1925, 127, 358) have demonstrated that the normal form of trimethyl *L*-arabinose must have the constitution (II), since it gives the dibasic acid (IV), namely, arabo-trimethoxyglutaric acid; and, since the properties of the trimethyl arabinose are in every respect similar to those of natural arabinose, the latter is given the constitution (I).

Another form of trimethyl arabinose was prepared by Baker and Haworth (J., 1925, **127**, 365), and this may be described as the " $\gamma$ "-sugar. The formula (V) was allocated to this compound, since it gave rise to the levorotatory lactone (VI) and, on further oxidation, to the dibasic acid (VII) which contained only two methoxyl residues. This latter, on complete methylation, was identical with Hirst and Robertson's acid (IV).

The same constitutional relationships have been established also for normal trimethyl xylose (VIII) (Hirst and Purves, J., 1923, **123**, 1352), which is found to give on oxidation the xylo-trimethoxyglutaric acid, stereoisomeric with the acid of formula (IV); and in a forthcoming paper by Haworth and Westgarth the preparation will be described of trimethyl  $\gamma$ -xylose, to which is allocated the structural formula (IX) analogous to that ascribed above (V) to trimethyl  $\gamma$ -arabinose.

Taking the two examples of the pentoses, xylose and arabinose, it is clear that the normal sugars are amyleno-oxidic in structure, and that the labile or  $\gamma$ -forms are butyleno oxides. The related lactones are therefore  $\delta$ -lactones for the normal sugars and  $\gamma$ -lactones for the labile or  $\gamma$ -sugars.

Coming now to the case of galactose, it must be stated that the evidence as to structure depends here on Hudson's rule. Pryde (J., 1923, **123**, 1808) has shown that normal tetramethyl galactose (XI) changes to tetramethyl- $\delta$ -galactonolactone (XII) on oxidation,

and therefore normal or naturally occurring galactose is given the constitution (X). The corresponding labile or  $\gamma$ -sugar (XIII) was prepared by Haworth, Ruell, and Westgarth (J., 1924, 125, 2468) and this on oxidation gave rise to the  $\gamma$ -lactone (XIV), which is also obtained on passing from ordinary or normal galactose or from galactonic acid (XV) to its lactone. The rotations of the compounds resulting from all these transformations are completely in accord with Hudson's rule, which, it may be emphasised, requires that galactonolactone must be a  $\gamma$ -lactone (see p. 90).

Similarly, mannose has been shown to conform to the above structural scheme. Levene and Meyer (*J. Biol. Chem.*, 1924, 60, 167) found that normal tetramethyl mannose gave a lactone,  $[\alpha]_D + 105^\circ \rightarrow 45.6^\circ$ , whilst methylation of the lactone from mannonic acid led to the isolation of a different and crystalline tetramethyl mannolactone having  $[\alpha]_D + 65.2^\circ \rightarrow 56.3^\circ$ . These optical values will be found to be closely similar to those quoted later for  $\delta$ - and  $\gamma$ -lactones, respectively, but as the authors did not record the intermediate rotation values at short period intervals the curves could not be included in Figs. 1 and 2.

It only remains, therefore, to apply this analogy to the lactone from normal tetramethyl glucose, which is indicated by the remaining curve (ii) in this series. This conforms definitely to the same type as the other three (Nos. iv, vi, and viii), and we therefore regard it as a  $\delta$ -lactone, and the normal tetramethyl glucose is therefore considered to be amylene-oxidic and consequently we assign to it the structural formula (XVII), whence glucose has the formula (XVI).

The other curves in Figs. 1 and 2, Nos. i, iii, v, and vii, clearly belong to a different category from those already discussed. All these represent the lactones prepared from the methylated " $\gamma$ "-sugars. We have demonstrated that, since three of the four substances are  $\gamma$ -lactones, the sugars from which they are prepared are butylene-oxidic in structure, and by analogy the curve No. i is considered to be that of tetramethyl  $\gamma$ -gluconolactone, whence it follows that tetramethyl  $\gamma$ -glucose should be given the constitution (XVIII).

A second line of argument as to the constitution of glucose is provided by evidence drawn from the study of 2:3:6-trimethyl glucose. This sugar has been repeatedly examined and the relative positions of its three methyl groups are definitely determined (Denham and Woodhouse, J., 1914, 105, 2361; Haworth and Leitch, J., 1918, 113, 191; Haworth and Hirst, J., 1921, 119, 193; Irvine and Hirst, J., 1922, 121, 1213). We are concerned only with the ring structure of this compound, which, if the argument already presented in this paper be accepted, should now be revised from that indicated by formula (XIX) to the new formula (XX).

Now it is known (Haworth and Hirst, *loc. cit.*) that the sugar is converted on further methylation into normal tetramethyl glucose and earlier in this paper the structural formula (XVII) has been ascribed to the latter on the ground that the derived lactone is a  $\delta$ -lactone (XXII).

Inspection of the two alternative formulæ (XIX and XX) sug-

gests, however, a possible application of this sugar as a means of testing the validity of this reasoning and of the conclusions already drawn. Thus this sugar on oxidation to the monobasic acid offers a choice of two free hydroxyl positions for the attachment of the lactone ring, namely, those on carbon atoms (4) and (5) (formula XXI), and this applies no matter which of the two sugar formulæ is the correct one.

Adopting Hudson's rule, this choice must be restricted to that of the  $\gamma$ -lactone (XXI). If now this trimethyl  $\gamma$ -gluconolactone should, on complete methylation, be shown to be identical with that tetramethyl gluconolactone derived from normal tetramethyl glucose, then the latter sugar (and therefore glucose also) would be butylene-oxidic in structure and the formula hitherto generally accepted for glucose would continue to hold.

In the actual event this was found not to be the case; it was observed that 2:3:6-trimethyl glucose gave a gluconolactone (XXI) which on methylation was identical with the tetramethyl  $\gamma$ -gluconolactone derived from the labile or  $\gamma$ -form of tetramethyl glucose (XVIII), and therefore the constitutional formula for the latter is substantiated, and fresh support is provided for the argument outlined in the former part of this communication.

Moreover, the crystalline phenylhydrazides of the tetramethyl gluconolactones from the three sources were prepared and analysed, and the following are the data for the melting points:

*Phenylhydrazides of tetramethyl gluconolactones.*

	M. p.	Mixed m. p. with (c).
(a) From normal tetramethyl glucose .....	109—112°	102—118°
(b) From tetramethyl $\gamma$ -glucose .....	131—134	130—133
(c) From 2:3:6-trimethyl glucose .....	130—133	

Thus we again reach the conclusion that ordinary glucose should be given the formula (XVI). This assumes that ordinary free glucose is identical in structure with normal tetramethyl glucose, but this is shown to be the case because  $\alpha$ - and  $\beta$ -methylglucosides give crystalline tetramethyl glucose on methylation followed by hydrolysis, as do those natural di-, tri-, and poly-saccharides which contain the glucose residue, and moreover, E. F. Armstrong has shown that  $\alpha$ - and  $\beta$ -glucose are stereochemically parallel to  $\alpha$ - and  $\beta$ -methylglucosides.

All the commonly occurring aldoses are therefore shown to exist normally as amylene- or 1:5-oxide forms, or, reverting to the older nomenclature which we prefer, they may now be described as  $\delta$ -oxides. So far this has been shown to apply to glucose,

galactose, mannose, arabinose, and xylose. By a curious coincidence the so-called " $\gamma$ "-sugars of the aldose type, which have now been shown to give rise to  $\gamma$ -lactones, may be more accurately described as  $\gamma$ -oxides, since they exist as butylene- or 1 : 4-oxide forms.

There remain to be mentioned the ketoses, and the constitutional study here has been confined to fructose, which occurs naturally as a  $\gamma$ -form in sucrose, raffinose, and inulin. The results of oxidation experiments conducted on tetramethyl  $\gamma$ -fructose derived from sucrose indicate that, in this sugar, an amylen- or  $\delta$ -oxide ring is present (Haworth and Linnell, Haworth and Mitchell, J., 1923, 123, 294, 301). On the other hand, Irvine and Patterson (J., 1922, 121, 2696) have examined the constitution of the normal form of tetramethyl fructose, which is crystalline, and which has not yet been isolated from a naturally occurring carbohydrate. This sugar they found to have the structure of a butylene- or  $\gamma$ -oxide. Thus, in the series of the ketoses, the position as compared with the aldoses would seem to be reversed, in that the labile sugar is the  $\delta$ -oxide form, and the normal sugar the  $\gamma$ -oxide. It would therefore appear that, in nature, both aldoses and ketoses occur as amylen- or  $\delta$ -oxides, a result which is in keeping with the simplest view of the synthesis of sucrose in the plant.

If this revision of the structural formula of glucose be accepted and applied to other carbohydrates, many fundamental readjustments are rendered necessary. Thus the constitutional formulæ allocated to natural di- and tri-saccharides by one of the present authors are directly implicated, as are also those suggested for starch and cellulose by other workers. These compounds will now require to be formulated as possessing  $\delta$ -oxide rings in each hexose residue. In the case of lactose and cellobiose this change also involves a displacement of the point of attachment of the hexose chains from a position associated with the fifth carbon atom to that of the fourth.\*

Leaving out of account the stereochemical relationships, it is now possible to represent the principal disaccharides by three formulæ :

\* It is, however, possible to regard one glucose residue in each of these disaccharides as existing as a  $\gamma$ -oxide or  $\gamma$ -sugar, in which case the earlier constitution will continue to hold with respect to the position of the biase linking, but this is an unlikely contingency. That 2 : 3 : 6-trimethyl glucose can pass into a  $\gamma$ -oxide form is extremely probable, and indeed we have some evidence of this. It is important to notice, however, that the sugar 2 : 3 : 5-trimethyl glucose must now be regarded as 2 : 3 : 4-trimethyl glucose, and that normal crystalline tetramethyl glucose is now 2 : 3 : 4 : 6-tetramethyl glucose.

## EXPERIMENTAL.

*Tetramethyl δ-Gluconolactone*.—This lactone was prepared by oxidising normal crystalline tetramethyl glucose with bromine water under the usual conditions (Purdie and Irvine, J., 1903, 83, 1021). It was then dissolved in a slight deficiency of *N*/10-sodium hydroxide, and the aqueous solution evaporated at 35–40° under diminished pressure. The residue of sodium tetramethyl gluconate was triturated thrice with dry chloroform to remove traces of unoxidised sugar and other impurities and the remaining solid was filtered, washed with chloroform, dried, and weighed. An aqueous solution of the salt was then decomposed by adding the equivalent of dilute hydrochloric acid from a burette. Isolation of the purified lactone was effected by evaporation under diminished pressure, followed by extraction from the semi-solid residue with dry ether. The tetramethyl δ-gluconolactone distilled completely at about 100°/0.05 mm. and showed  $n_D$  1.4532. *Titration*. 0.1355 g. required 6.05 c.c. of 0.0965*N*-NaOH (Calc., 6.02 c.c.).

A titration was also conducted after keeping an aqueous solution of the lactone for 24 hours; it then appeared that more than 90% had been converted into the open-chain acid.

Determinations of the rotation of the lactone were recorded as follows:

In ethyl alcohol ( $c = 3.65$ ),  $[\alpha]_D + 101.1^\circ$ .

In aqueous alcohol (38% EtOH) ( $c = 1.39$ ):

Time in hours .	0.25	2	5	21	25	66	
$[\alpha]_D$ .....	+90.3°	84.0°	68.0°	40.7°	38.4°	38.4°	constant

In water ( $c = 1.37$ ) :

Time in hours .	0.1	3	5	6.5	8.25	26.25
$[\alpha]_D$ .....	+88.5°	43.2°	31.4°	25.6°	25.6°	25.6° constant

*Phenylhydrazide Derivative.*—This was obtained by heating for 3 hours at 100° phenylhydrazine (1 mol.) with the above lactone (1 mol.). The crystals which appeared on cooling were recrystallised from ether and light petroleum and melted at 109–112°. On admixture with the phenylhydrazide of the  $\gamma$ -lactone as prepared below under (A) and (B), (m. p. 130–133°) the melting point for the mixture was depressed to 102–118° (Found : C, 56.1; H, 7.6; N, 8.0.  $C_{16}H_{26}O_6N_2$  requires C, 56.1; H, 7.6; N, 8.2%).

*Tetramethyl  $\gamma$ -Gluconolactone.*—(A) In one experiment, 4.3 g. of 2:3:6-trimethyl glucose were oxidised with bromine water and the corresponding lactone was isolated in the usual way. This product was purified by extraction with light petroleum, which dissolved the lactone, leaving as residue traces of unchanged sugar. *Titration.* 0.0943 g. required 4.24 c.c. of  $N/10$ -NaOH (Calc., 4.48 c.c.) (Found : OMe, 40.9. Calc., OMe, 42.2%).

The tetramethyl gluconolactone was obtained by twice methylating the above product with Purdie's reagents and was thereafter distilled. It showed  $n_D$  1.4470 (Found : C, 51.6; H, 7.8; OMe, 53.5. Calc., C, 51.3; H, 7.7; OMe, 53.0%). *Titration.* 0.0945 g. required 3.86 c.c. of  $N/10$ -NaOH (Calc., 4.03 c.c.).

In a second experiment, using a highly purified specimen of 2:3:6-trimethyl glucose, the tetramethyl  $\gamma$ -gluconolactone distilled at 92–96°/0.02 mm. and the colourless liquid was dissolved in a slight excess of aqueous barium hydroxide, left over-night, and then heated at 70° for 1 hour. Thereafter the excess of barium hydroxide was precipitated by admitting carbon dioxide, the filtrate evaporated under diminished pressure, and the residue extracted with ether to remove impurities. Solution of the barium salt in water containing the requisite equivalent of hydrochloric acid led to the isolation of the purified  $\gamma$ -lactone, which showed  $[\alpha]_D = +49.7^\circ$  in ethyl alcohol ( $c = 2$ ), and on dilution with water (44%) this value changed in 3 hours to  $+48.9^\circ$ , and thereafter showed little change during 2 days. A titration showed that at this stage about 30% of the lactone had been converted into the acid.

*The phenylhydrazide* was prepared by adopting the same procedure as that described below. The product was washed with petroleum, and recrystallised from ether. M. p. 130–133° (Found : C, 56.05; H, 7.8; N, 8.2. Calc. for  $C_{16}H_{26}O_6N_2$ , C, 56.1; H, 7.6; N, 8.2%).

(B) The above lactone was also prepared from tetramethyl  $\gamma$ -glucose (Irvine, Fyfe, and Hogg, J., 1915, 107, 529), the precaution being taken to separate any traces of the normal sugar

by the method of hydrolysing the methylglucoside with *N*/15-hydrochloric acid, since acid of this concentration has little effect on the normal glucosides but effects the complete hydrolysis of the  $\gamma$ -form. The  $\gamma$ -sugar was oxidised with bromine water in the usual way, and the above lactone distilled as a colourless liquid, b. p.  $97^{\circ}/0.05$  mm.,  $n_D$  1.4467. In ethyl alcohol ( $c = 2.07$ ) the specific rotation was  $+53.7^{\circ}$ , and on dilution with water (44%) the reading was  $[\alpha]_D = +49.8^{\circ}$ , falling to  $48.9^{\circ}$  in 4 hours, at which value it remained constant for 2 days.

The polarimetric data were recorded for an aqueous solution of the lactone.

Time in hours ...	0.16	1.33	5.06	19.33	43.83
$[\alpha]_D$ .....	$+61.5^{\circ}$	$60.7^{\circ}$	$57.2^{\circ}$	$56.2^{\circ}$	$55.6^{\circ}$
Time in days .....	6	7	12	15	20
$[\alpha]_D$ .....	$+48^{\circ}$	$47.4^{\circ}$	$44.0^{\circ}$	$39.6^{\circ}$	$39.6^{\circ}$

*Phenylhydrazide*.—The lactone was heated during 3 hours at  $100^{\circ}$  with an equivalent proportion of phenylhydrazine. The product had crystallised during this period, and the crystals were purified from light petroleum and dry ether. M. p.  $131-134^{\circ}$ . In admixture with the specimen of the phenylhydrazide prepared as described above (A) there was no depression of the melting point (Found: C, 56.2; H, 7.8; N, 8.2%).

*Tetramethyl  $\delta$ -Galactonolactone*.—The specimen prepared by Haworth, Ruell, and Westgarth (*loc. cit.*) was purified and used in the following determinations of specific rotations in water ( $c = 0.95$ ):

Time in mins. ...	19	40	70	100	165	220	280	340
$[\alpha]_D$ .....	$+161.1^{\circ}$	$146.3^{\circ}$	$122.1^{\circ}$	$98.9^{\circ}$	$62.1^{\circ}$	$46.3^{\circ}$	$36.8^{\circ}$	$32.6^{\circ}$
Time in hours ...	7	8	10	22	46			
$[\alpha]_D$ .....	$28.4^{\circ}$	$28.2^{\circ}$	$27.4^{\circ}$	$27.2^{\circ}$	$27.2^{\circ}$			

*Trimethyl  $\gamma$ -Arabonolactone*.—The crystalline specimen used was that prepared by Baker and Haworth (*loc. cit.*). The solvent was water.

Time in days .....	0	4	10	20
$[\alpha]_D$ .....	$-42.0^{\circ}$	$33.8^{\circ}$	$26.0^{\circ}$	$25.1^{\circ}$

Other optical data employed in constructing the curves given in the introduction will be found by consulting the references quoted.

XVIII.—*Studies in Adsorption by an Optical Method.*  
*Fixation by Dispersoids of Methylene-blue within*  
*the Disperse Phase.*

By ANDOR FODOR and RASSA RIWLIN.

ADSORBENTS in a comparatively coarse state of division, and therefore readily separable from the solution, have hitherto been used in investigations on adsorption. When one comes to deal with colloidal, finely divided adsorbents—and there is no doubt that the micelle of a sol also can act as an adsorbent—the difficulty of separating the phases from one another becomes almost insurmountable. Scarcely any case of this kind has been thoroughly examined because of the experimental difficulties. Dynamic methods, which cause a displacement of the equilibrium, and ultrafiltration are useless. The applicable static methods are limited in number. Potentiometric and conductivity methods, useful as they are in the case of proteins, which adsorb relatively large quantities of electrolytes, can be employed to measure the adsorption of only a few definite ions, and the method of compensation-dialysis has many disadvantages, one of which is the disturbance due to the membrane. For these and other reasons, it seemed to the authors that an optical method would be the most suitable for measuring adsorption, and, since the polarimeter and the refractometer cannot deal with opaque or turbid liquids, it should be based upon the absorption of light.

The concentration of a dye in solution will diminish on addition of a colloidal solution, owing to adsorption of the dye by the micelle. The absorption curves of the dye solution before and after the addition will therefore not be the same; and the difference between them will be a measure of the adsorption, if other losses of light, *e.g.*, by diffusion, do not affect the result.

A suitable dye solution must comply with the following requirements: 1. It must be stable. 2. Its absorption spectrum must (a) fall within the visual region and not be too extended, and (b) be continuous and consist of one band. The curve will then have only one maximum or minimum, in the neighbourhood of which slight changes can be very conveniently measured.

*Method.*—The transmissive powers,  $T$ , of a dye solution for light of different wave-lengths were measured directly in percentages with Vierorath's improved form of the Schmidt-Haensch spectrophotometer. The transmission curve of the solution was then obtained by plotting the values of  $T$  as ordinates and wave-lengths ( $\lambda$ ) as abscissæ (Fig. 1).

The concentration of a dye solution may be determined by this method in the following way, which obviates the application of Beer's law. The absorption curves of a series of solutions of the dye of known concentrations are drawn. The minima of these curves will all lie on one and the same ordinate, *viz.*, that drawn through the wave-length corresponding to minimum transmissive power. A second graph is drawn, having the concentrations of the

FIG. 1.

solutions as abscissæ and the corresponding minimal transmissive powers as ordinates. The minimal transmissive power of the solution of unknown concentration is now determined from its transmission curve, and the corresponding abscissa in the second graph will then give the concentration.

#### EXPERIMENTAL.

*Preparation of the Dye Solutions.*—A series of solutions was prepared containing 4, 6, 8, 10, 12½, 15, 17½, 20, 25, 30, 40, and 50% \*

\* For convenience' sake, a true concentration of 0.000n% is written as n%.

of a standard solution of methylene-blue (0.1 g. in 1000 c.c. of water). Ten c.c. of each of those solutions were mixed with 10 c.c. of water, and the transmission curves of the mixtures were plotted (Fig. 1). From time to time, the transmissive powers were redetermined to ensure that they still agreed with those of the freshly prepared solutions, and therefore that the concentrations of methylene-blue were unchanged.

Methylene-blue is adsorbed by many substances, including filter-paper. The solutions, therefore, were not filtered and the parts of the vessels used that would come into contact with the liquid were specially polished.

Solutions of methylene-blue are not very stable. Under the influence of light and air they slowly lose their colour, and much more quickly in presence of alkali. The mixture of methylene-blue and a sol under investigation was therefore compared with a solution having the same hydrogen-ion concentration. Wherever possible, for the preparation of the comparison liquid the same acid or alkali was used as that present in the sol.

In many cases the sol itself was cloudy. The effect of the consequent scattering of light was ascertained in the following way. The transmissive power ( $a$ ) of a mixture of 10 c.c. of the sol with 10 c.c. of water was measured. If  $c$  is the transmissive power of the methylene-blue solution (10 c.c. of the diluted standard solution + 10 c.c. of water) and  $b$  that of the experimental mixture (10 c.c. of the diluted standard solution of methylene-blue + 10 c.c. of the sol), then, provided that there was no interference due to chemical reaction or adsorption, for each wave-length,  $ac = b$ .

If the sol transmitted light to the same extent as water,  $a = 1$ ; and to find any deviation from the 'mixture' law, it was only necessary to compare  $c$  with  $b$ .

TABLE I.

Transmissive powers of methylene-blue + silica sol.

1. *Silica Sol*.—This was prepared by Ostwald's method ("Kleines Praktikum der Kolloidchemie," 3rd ed., p. 8, expt. 23).  $a = 1$  for all wave-lengths.

The transmissive power of the reddish-violet mixture of the methylene-blue solution with the silica sol (Fig. 2, curve II) is quite different from that of its blue mixture with water (curve I); the minimum has shifted from  $\lambda 637 \mu\mu$  to  $\lambda 590 \mu\mu$  and is of about twice the magnitude. Moreover, the two transmission curves have

FIG. 2.

I, *Methylene-blue + water*. II, *Methylene-blue + silica sol*.  
 III, *Methylene-blue + silica sol + sodium hydroxide*.

different forms. These facts all indicate the production of a compound.

To prove that the effect of the sol on the methylene-blue was not due to the presence of hydrogen- or hydroxyl-ions, the transmission curves were determined of methylene-blue solutions containing these ions. It will be seen (Table II) that the addition neither of acid nor of alkali caused any considerable alteration in the position of the minimum of the curve for the methylene-blue solution during the time of observation. If the solutions were kept for some time, the minimum shifted towards the blue end of the spectrum (see last two columns). Acid was without appreciable effect

TABLE II.

Effect of acid or alkali on the transmissive powers of methylene-blue.

$\lambda$ ( $\mu$ ).	12.5% Methylene-blue.			17.5% Methylene-blue + N/10-NaOH.		
	+ Water.	+ N/10-HCl.	+ N/10-NaOH.	Soon after mixing.	After 2 hrs.	After 24 hrs.

655	32	26	35	28.5	37.5	80

on the transmissive power of the mixture of methylene-blue solution and silica sol, whilst the addition of alkali caused the point of inflexion in the region of  $\lambda = 637 \mu$  (Fig. 2, curve II) almost to disappear and the minimum to shift to  $\lambda = 564 \mu$  (curve III).

When a mixture of methylene-blue solution and silica sol was kept in an unpolished vessel, there was little if any adsorption of the dye on the walls. It seems as if the dye is so strongly held by the particles of sol that it is indifferent to any other influence.

An experiment with kaolin gave somewhat similar results: Mixtures of 10% methylene-blue solution with (a) water, (b) silica sol, and (c) 1% sodium silicate solution were each shaken with 100 mg. of kaolin, which was then allowed to settle. The supernatant liquid was (a) colourless, (b) violet-blue, (c) blue.

In another experiment, 2, 3, 5, 10, 30, and 50% solutions of methylene-blue were each mixed with 10 c.c. of silica sol and shaken with 100 mg. of kaolin. After settling, the sediment was coloured in every case, the liquors from the 2% and 3% solutions were colourless, and the others were slightly coloured.

*Sodium Silicate* (Merck's commercial solution).—When the last experiment was repeated with a 1% solution of sodium silicate instead of the silica sol, even the liquors from the 2% and 3% solutions of methylene-blue were coloured. Sodium silicate seems to retain the dye better than silica sol.

On mixing solutions of methylene-blue and sodium silicate a blue precipitate was obtained or not according as the former or the latter was in excess. A similar behaviour was not observed in the case of the silica sol.

The transmission curves of mixtures of solutions of methylene-blue and sodium silicate were determined; the solutions were of

course alkaline. As in the case of the silica sol (Fig. 2, curve II), a minimum was found at  $\lambda$  590  $\mu\mu$  (Fig. 3, curve I). On addition of insufficient hydrochloric acid for neutralisation the minimum was slightly displaced and a bend appeared in the region of  $\lambda$  637  $\mu\mu$  (curve II). When the mixture was made acid, the minimum shifted to  $\lambda$  637  $\mu\mu$ , its place being taken by a slight bend (curve III). If the

I, *Methylene-blue + sodium silicate + water.* II, *Methylene-blue + sodium silicate + hydrochloric acid (still faintly alkaline).* III, *Methylene-blue + sodium silicate + hydrochloric acid (faintly acid).*

acid was added very carefully until the mixture was neutral, the whole mass coagulated.

*Kaolin.*—A suspension of 2 g. of kaolin in 100 c.c. of water was kept for 18 hours, and the turbid liquor was then syphoned off. This liquor, containing only the finest particles of the kaolin, was used in the following experiments and was well shaken before each determination.

TABLE III.

Transmissive powers of mixtures of methylene-blue and kaolin.

The transmissive powers of the kaolin suspension (a), of the methylene-blue solution (c), and of the mixture of the two (b) were determined and b was compared with ac (Table III and Fig. 4). The b transmission curves and the calculated ac curves are almost parallel for the more concentrated solutions of methylene-blue, but diverge in the case of dilute solutions. The b curve, however, invariably lies above the corresponding ac curve, and therefore it

may be concluded that the methylene-blue is partly adsorbed by the kaolin.

#### Aluminium Hydroxide

*Sol.*—The sol was prepared by Ostwald's method (*op. cit.*, p. 12, expt. 30). A mixture of methylene-blue solution and the sol was less transparent than the corresponding mixture of methylene-blue and water. This result was due to the presence in the sol of acetate ions, which diminish the transmissive power of methylene-blue (Table IV and Fig. 5). Almost identical transmission curves were obtained for the methylene-blue solution + the aluminium hydroxide sol and methylene-blue solution + an acetate buffer the  $p_H$  of which was the same as that of the sol (3.84).\* No adsorption of methylene-blue, therefore, can be demonstrated in the case of aluminium hydroxide sol.

FIG. 5.

I, 10% methylene-blue + water. II, 10% methylene-blue + N/50-acetic acid. III, 10% methylene-blue + aluminium hydroxide sol.

*Natural Protein.*—A solution of white of egg in water (20 vols.)

\* Compare A. Fodor, "Determination of the affinity constants of weak acids and bases" ("Handbuch der biologischen Arbeitsmethoden," E. Abderhalden, p. 474).

was filtered. The filtrate was turbid, and therefore *a* had to be determined. On comparing *ac* (where *c* = transmissive power of methylene-blue + buffer solution) with *b*, no difference was observed (Table V). Natural protein, therefore, does not adsorb methylene-blue.

TABLE V.

Transmissive power of white of egg + methylene-blue (10%).

501	93.5	93	87	86	604	95	35	33	34
521	93.5	92.5	86.5	85.5	620	95	29	27.5	28.5
542	94	84.5	79.5	78	637	95.5	24	23	24
564	95	70.5	67	69.5	655	96	33.5	32	34.5

An experiment was also made with the protein at the isoelectric point. Acid was added in increasing quantities to solutions of the protein, and the concentration was thus found (*viz.*, 0.6 c.c. of *N*/10-hydrochloric acid for 10 c.c. of protein solution) at which the protein coagulated most rapidly on heating. The above experiments were repeated with such a protein mixture, but again there was no difference between *ac* and *b*.

Finally, the protein was finely dispersed by the addition of sodium hydroxide (1 c.c. of *N*/10-solution to 10 c.c. of protein solution), and the mixture with methylene-blue examined in the usual way, the comparison liquid being a solution of sodium hydroxide of the same  $p_H$  as the protein mixture. No adsorption of methylene-blue was detected.

*Casein*.—A solution of 2 g. of casein (Hammersten) in 60 c.c. of water and 2 c.c. of *N*-sodium hydroxide was diluted to 100 c.c. with water, a slight excess of hydrochloric acid added, and the solution kept for 12 hours. The precipitated casein was washed free from chloride, and dissolved in 100 c.c. of *M*/15-disodium hydrogen phosphate or *M*/15-sodium carbonate.

The  $p_H$  of the phosphate solution was 7.45. A buffer solution of the same  $p_H$  was made by mixing 84 c.c. of *M*/15-disodium hydrogen phosphate with 16 c.c. of water.

Mixtures of either solution of casein (phosphate or carbonate) with methylene-blue were examined, but no difference was found between *ac* and *b*, and therefore no adsorption occurred.

*Pure Albumin*.—A 10% solution of white of egg was mixed with an equal volume of saturated ammonium sulphate solution, the precipitated globulin removed, and the filtrate dialysed for several days until it was free from sulphate. The solution of albumin thus obtained was used in experiments with methylene-blue, but no adsorption was detected.

*Saponin*.—The transmission curve of a mixture of methylene-blue with a 10% solution of saponin (for which  $a = 1$ ) was the same as that of its mixture with water. There was, therefore, no adsorption.

Kobert (Freundlich, "Kapillarchemie," 3rd ed., 1923, p. 889) dialysed a saponin solution against a solution of methylene-blue and showed that the dye accumulated in the sol so that its concentration there exceeded that in the external solution. We tried to repeat this experiment; but the whole of the methylene-blue was adsorbed by our dialysis membrane ("Dialysierhülse" of Schleicher and Schüll) and both liquids became colourless.

*Gelatin*.—A 1% solution of gelatin, made by warming 1 g. to 70° with 100 g. of water, becomes more opalescent on standing, but if it is prepared under the proper conditions, reproducible values of its transmissive power can be obtained. The calculated and the experimental values of the transmissive power of the mixture methylene-blue + gelatin were the same. Hence gelatin does not adsorb the dye.

#### *Discussion.*

It has been shown that sols of proteins, such as casein, natural white of egg, purified albumin and gelatin, do not adsorb methylene-blue; the substances remain mutually uninfluenced. This result is very remarkable, because, in the precipitation of a solution of protein containing methylene-blue by means of electrolytes, the dye always comes down with the coagulum and colours it blue. Possibly in the latter case, the particles of protein may be completely dehydrated; and the activities of the hydrated and the dehydrated particles may be different.

Also aluminium hydroxide sol and methylene-blue in solution are without influence on each other. Flocculating aluminium hydroxide, however, may carry down methylene-blue. Since both substances are basic, the reason for the carrying down must be sought in some physical cause—an explanation which might be applicable to coagulating protein also. The conditions of this mechanical adsorption are of course not yet known. It must, however, be kept in mind that methylene-blue is mechanically retained by substances of many different kinds, *e.g.*, glass, filter-paper, different kinds of membranes, etc. The adsorption of methylene-blue by finely divided kaolin is also a mechanical one, as may be seen from the absorption curve. The experimental curve runs almost parallel to the calculated one and lies above it. Consequently the transmissive power observed is greater than that calculated, but here, unlike the case of silica sol or sodium silicate, no new absorption minimum results, so that there is no new specific absorption curve of the mixture to be observed. Indeed the calculated curve for the kaolin—

methylene-blue mixture has an absorption minimum, namely, that of pure methylene-blue, at  $\lambda = 637\mu$ , and this does not appear in the experimental curves for very low concentrations of methylene-blue (Table III). This, however, is because the kaolin adsorbs the whole of the methylene-blue.

The absorption curve of the system silica sol + methylene-blue, on the other hand, is characteristic in that it has a new absorption minimum (quite removed from that of the methylene-blue). This and the production of a violet colour, appreciable by the naked eye, indicate chemical combination between the silica and the dye.

The same violet coloration and the same absorption minimum are obtained when a dilute solution of water-glass mixed with methylene-blue is used. The same compound is produced with its own absorption minimum at  $\lambda = 590\mu$ , near which the absorption minimum of methylene-blue also is to be found.

This investigation shows that it is possible by spectrophotometric methods to determine (1) whether a dye is not adsorbed at all by colloidal adsorbents (*e.g.*, albumin, casein, gelatin,\* saponin, aluminium hydroxide sol), (2) whether a mechanical adsorption takes place, *e.g.*, kaolin suspension (*lyosorption*), or (3) whether there is chemical combination between the adsorbent and the dye, *e.g.*, water-glass solution, silica sol (*chemosorption*). (See Fodor, *Koll.-chem. Beih.*, 1923, 18, 77; "Grundlagen der Dispersoid Chemie," Dresden u. Leipzig, 1925.)

In case 1 the curves calculated from the values of  $a$  and  $c$  agree with the experimental curves.

In case 2 there is a parallel displacement upwards of the experimental curve.

In case 3 the curve has a special form with one (or perhaps several) new absorption minimum.

It is often very difficult to distinguish between chemosorption and lyosorption. In case 3, however, we believe that the appearance of a new absorption minimum indicates chemosorption. An example of the capacity of colloidal solutions to form reproducible definite stoichiometric compounds is to be found in the case of the albumin solutions investigated by Sørensen and Höyrup (*Z. physiol. Chem.*, 1918, 103, 104).

We have to thank Miss S. Rubinstein for help in the experimental part of the work.

THE HEBREW UNIVERSITY, JERUSALEM.

[Received, July 6th, 1925.]

\* Recent researches have shown that the phospho-protein sol from yeast-macerate is able to fix methylene-blue fairly strongly. The results will be published later.

# XIX.—*Substituted Dihydropentazines—A New Series of Cyclic Nitrogen Compounds.*

By FREDERICK DANIEL CHATTAWAY and GEORGE DAVID PARKES.

It has recently been shown (J., 1925, 127, 975, 1687) that when halogens react with benzaldehydephenylhydrazones substitution occurs in the hydrazine residue and in the so-called  $\omega$ -position, that is, in the  $\cdot\text{CH}\cdot$  group. This affords an easy method of obtaining in quantity many substituted hydrazones, in which the  $\omega$ -halogen is unusually reactive.

Such  $\omega$ -bromo-substituted hydrazones, for example, react with ammonia to form hydrazidines which are converted by the action of nitrous acid into tetrazoles (compare Pinner, *Ber.*, 1894, 27, 984).

Several tetrazoles, prepared by this method, which establishes their constitution, have been shown to be identical with the compounds produced by heating the corresponding hydrazone with phenyl azide (compare Dimroth, *Ber.*, 1910, 43, 2899). For example, benzaldehyde-2:4-dibromophenylhydrazone yields 1-(2:4-dibromophenyl)-4-phenyltetrazole by either method, thus:

These  $\omega$ -halogen compounds react also with hydrazine, replacing by a hydrazino-group, the  $\omega$ -halogen. For example,  $\omega$ -bromobenzaldehyde-2:4-dibromophenylhydrazone yields  $\omega$ -hydrazinobenzaldehyde-2:4-dibromophenylhydrazone\* (II):

This compound behaves as a substituted hydrazine: it forms salts with halogen acids, yields an acetyl derivative when treated with acetyl chloride, and reacts with aldehydes, forming hydrazones. It also reacts with excess of  $\omega$ -bromobenzaldehyde-2:4-dibromophenylhydrazone, forming a compound having probably the constitution (III).

\* This behaviour is in marked contrast to that of phenylhydrazine, which converts the hydrazone into a formazyl compound (compare Pechmann, *Ber.*, 1894, 27, 322).

When treated with nitrous acid these  $\omega$ -hydrazinobenzaldehyde-hydrazone are converted into dihydropentazines. Thus, for example,  $\omega$ -hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone yields 1-(2 : 4-dibromophenyl)-5-phenyl-1 : 4-dihydropentazine (IV) :

The 5-phenyldihydropentazines are crystalline, odourless, weakly basic compounds which on being rapidly heated decompose, yielding benzonitrile.

#### EXPERIMENTAL.

*Preparation of 1-(2 : 4-Dibromophenyl)-4-phenyl-1 : 2 : 3 : 5-tetrazole (I).—*(a) *From  $\omega$ -bromobenzaldehyde-2 : 4-dibromophenylhydrazone.* The hydrazone was prepared by the action of bromine upon benzaldehydephenylhydrazone and converted into the corresponding hydrazidine by boiling with an aqueous alcoholic solution of ammonia (compare Chattaway and Walker, *loc. cit.*).

A suspension of finely ground benzaldehyde-2 : 4-dibromophenylhydrazidine (5 g.) in a mixture of 20 c.c. of concentrated hydrochloric acid and 10 c.c. of water was cooled in a freezing mixture and 1 g. of solid sodium nitrite was added very gradually with constant stirring. 1-(2 : 4-Dibromophenyl)-4-phenyltetrazole separated as a slightly brown solid. It was filtered off, washed repeatedly with water, and recrystallised from boiling alcohol, in which it is moderately easily soluble and from which it separates in a felted mass of fine, white needles, m. p. 127° (Found : Br, 41.7.  $\text{C}_{13}\text{H}_8\text{N}_4\text{Br}_2$  requires Br, 41.95%).

(b) *From benzaldehyde-2 : 4-dibromophenylhydrazone and phenyl azide.* A mixture of 5 g. of benzaldehyde-2 : 4-dibromophenylhydrazone, 2 g. of phenyl azide, and a solution of 0.4 g. of sodium in 8 c.c. of alcohol was heated at 100° in a sealed tube for 15 hours. The tetrazole which separated was filtered off, washed with a little alcohol, and recrystallised several times from boiling alcohol, separating as a felted mass of fine, white needles, m. p. 127°.

This and the tetrazole prepared by method (a) were identical in every respect.

1-(2 : 4-Dibromophenyl)-4-*m*-nitrophenyl-1 : 2 : 3 : 5-tetrazole (formula corresponding with I) was prepared similarly from  $\omega$ -bromo-*m*-nitrobenzaldehyde-2 : 4-dibromophenylhydrazone. It separates from boiling alcohol, in which it is somewhat sparingly

soluble, in colourless needles, m. p.  $215^{\circ}$  (Found: C, 37.0; H, 1.7; N, 16.55; Br, 37.5.  $C_{13}H_7O_2N_5Br_2$  requires C, 36.7; H, 1.6; N, 16.5; Br, 37.65%).

*$\omega$ -Hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone* (II).—A suspension of 10 g. of finely divided  *$\omega$ -bromobenzaldehyde-2 : 4-dibromophenylhydrazone* in 50 c.c. of alcohol was added to 10 c.c. of a 50% hydrazine hydrate solution, and the mixture shaken vigorously for 15 minutes. It was then kept for 12 hours, when the whole had become a semi-solid, light brown mass. The solid was filtered off and the  *$\omega$ -hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone* separated from the hydrazine hydrobromide with which it was mixed, by heating it with 40–50 c.c. of alcohol and filtering hot. On cooling the warm alcoholic solution,  *$\omega$ -hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone* separated in almost colourless needles, m. p.  $123^{\circ}$  (decomp.) (Found: Br, 41.8.  $C_{13}H_{12}N_4Br_2$  requires Br, 41.7%).

This compound can be preserved unchanged for a considerable time in a sealed tube, although it darkens somewhat when exposed to light. When exposed to the air, it undergoes slow decomposition.

On adding excess of strong hydrochloric acid to a warm alcoholic solution of  *$\omega$ -hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone* the hydrochloride of the base separates on cooling as a colourless, microcrystalline powder, m. p.  $188^{\circ}$  (decomp.). The sulphate, obtained similarly, separates in minute, colourless plates which on heating decompose without melting.

*$\omega$ -Benzylidenehydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone*,  $C_6H_3Br_2 \cdot NH \cdot N : CPh \cdot NH \cdot N : CHPh$ , is obtained as a yellow, crystalline powder on warming together in alcoholic solution equivalent quantities of benzaldehyde and  *$\omega$ -hydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone*. It separates from boiling alcohol, in which it is moderately easily soluble, in small, yellow needles, m. p.  $126^{\circ}$  (Found: Br, 33.8.  $C_{20}H_{16}N_4Br_2$  requires Br, 33.9%).

This compound dissolves with a yellow colour in strong alcoholic potash, and in strong sulphuric acid with a brown colour which soon changes to red.

*$\omega$ -p-Nitrobenzylidenehydrazinobenzaldehyde-2 : 4-dibromophenylhydrazone*,  $C_6H_3Br_2 \cdot NH \cdot N : CPh \cdot NH \cdot N : CH \cdot C_6H_4 \cdot NO_2$ , was prepared similarly from *p*-nitrobenzaldehyde. It separates from boiling alcohol in small needles which appear dark violet by transmitted light and dark green by reflected light; m. p.  $194^{\circ}$  (Found: Br, 30.8.  $C_{20}H_{15}O_2N_5Br_2$  requires Br, 31.0%).

It dissolves in strong alcoholic potash with an intense blue colour, which fades almost immediately. With sulphuric acid a brown colour is produced which becomes violet on standing.

The action of a further quantity of  $\omega$ -bromobenzaldehyde-2:4-dibromophenylhydrazone upon  $\omega$ -hydrazinobenzaldehyde-2:4-dibromophenylhydrazone yields a compound, having in all probability the symmetrical constitution (III), *hydrazobenzaldehyde-2:4-dibromophenylhydrazone*.

This compound was obtained by boiling a solution of 2 g. of  $\omega$ -hydrazinobenzaldehyde-2:4-dibromophenylhydrazone and an equivalent quantity of  $\omega$ -bromobenzaldehyde-2:4-dibromophenylhydrazone in 20 c.c. of alcohol under reflux for 12 hours. A solid separated which was filtered off and recrystallised from boiling glacial acetic acid, in which it was fairly easily soluble and from which it separated in colourless needles, m. p.  $237^{\circ}$  (Found: Br, 43.2.  $C_{26}H_{20}N_6Br_4$  requires Br, 43.4%).

1-(2:4-Dibromophenyl)-5-phenyl-1:4-dihydropentazine (IV).—Five grams of finely divided  $\omega$ -hydrazinobenzaldehyde-2:4-dibromophenylhydrazone were added to a mixture of 25 c.c. of concentrated hydrochloric acid and 25 c.c. of water, and stirred vigorously. The hydrochloride of the base separated in the course of a few minutes as a finely divided, colourless, crystalline powder. The whole was then cooled in a freezing mixture and treated with 5 g. (a considerable excess) of sodium nitrite with constant stirring. The dihydropentazine separated as a pasty, slightly brown, semi-solid mass, which was filtered off and washed repeatedly with water. It was then washed with a little light petroleum (b. p.  $40-60^{\circ}$ ) and recrystallised from boiling alcohol, in which it is fairly easily soluble and from which it separates as a colourless, microcrystalline powder, m. p.  $172^{\circ}$  (decomp.) (Found: Br, 40.4; N, 17.6.  $C_{13}H_9N_5Br_2$  requires Br, 40.5; N, 17.7%).

When rapidly heated alone, the compound decomposes with a puff of black smoke and formation of benzonitrile. One g. of the substance was rapidly heated in a long glass tube sealed at one end. After decomposition drops of a yellow liquid condensed on the cool parts of the tube. The tube was washed out with ether, the ethereal solution filtered, and the ether evaporated. The residual drop of yellow oily liquid, which had a smell resembling that of benzonitrile, slowly dissolved when it was boiled with aqueous sodium hydroxide, ammonia being evolved; from the cooled, acidified solution, benzoic acid was obtained which separated from boiling water in white, shining flakes, m. p.  $120^{\circ}$ . The yellow oil was therefore benzonitrile.

1-(2:4-Dibromophenyl)-5-phenyldihydropentazine is a colourless, crystalline solid which exhibits slightly basic properties. It is without odour and is easily soluble in the common organic solvents. It is quite stable to air and light.

The action of nitrous acid on  $\omega$ -hydrazinobenzaldehyde-2:4-

dibromophenylhydrazone might conceivably have yielded, not the dihydropentazine, but an azide of the structure

That the compound produced has not this structure is shown by the circumstance that when heated at  $100^\circ$  for 60 hours in a sealed tube with acetone saturated with acetylene at  $0^\circ$  the whole was recovered completely unchanged. Had it possessed the azide structure it should have reacted with the acetylene, yielding 1:2:3-triazole-1-(benzaldehyde-2:4-dibromophenylhydrazone) (compare Dimroth, *Ber.*, 1910, 43, 2222). Further, as mentioned above, Pinner obtained phenyltetrazole and not benzenyliminoazide by the action of nitrous acid on benzenylhydrazidine,  $\text{NH}\cdot\text{CPh}\cdot\text{NH}\cdot\text{NH}_2$ , which is an analogous compound to the  $\omega$ -hydrazino-compound from which the new ring compound was prepared. Its behaviour, therefore, is inconsistent with an azide structure, whilst it possesses the properties which would be expected in a dihydropentazine.

The formation of this compound is of considerable interest, as it contains a type of nitrogen ring apparently hitherto undescribed.

## XX.—*Purification of Phosphoric Oxide.*

By GEORGE INGLE FINCH and REGINALD PERCY FRASER.

THE method for the purification of phosphoric oxide as devised by Finch and Peto (*J.*, 1922, 121, 692) has been employed in these laboratories for the last 4 years. In the light of the experience thus gained, several modifications in the original apparatus have been adopted which permit of the attaining of greater yields and increased rapidity of working. The modified form of apparatus consists of two iron tubes of 2-inch bore, the one 24 and the other 12 inches in length. These tubes are coaxially joined together by means of a  $2\frac{1}{4}$ -inch bore T-piece, the 1-inch long upper branch of which is machined flat and closed by the plug P, the lower surface of which is also machined. This 36-inch tube is supported in an inclined, gas-fired combustion furnace. Oxygen is led from a cylinder through glass wool into the lower end of the tube, the attachment being made by means of a length of  $\frac{1}{4}$ -inch iron tubing and a screwed adaptor. The cylinder oxygen employed in these laboratories is made by fractional distillation of liquid air and therefore needs no preliminary drying. The glass wool serves to retain dust. The upper and condensing end of the tube consists

of a  $2\frac{1}{4}$ -inch smoothly rounded, right angle bend, into the lower end of which a 2-inch length of 2-inch bore tubing is screwed. The receiver in which phosphoric oxide is condensed consists of a  $1\frac{1}{2}$  litre glass-stoppered bottle, the neck of which is just sufficiently wide to admit the 2-inch bore iron tube. The right angle bend as far as the neck of the bottle is well lagged with asbestos cloth and heated by means of a large T  clu burner in order to prevent condensation in the tube itself.

The method of operation is as follows. The main, 36-inch tube is first brought to a bright red heat. A rapid stream of oxygen (3 litres per minute) is then admitted, and 10 to 15 g. of the impure phosphoric oxide are fed in, in one lot, through the short branch of the T-piece into the main tube, whereupon the plug is immediately replaced. The viscous phosphoric acid soon formed on the

FIG. 1.

machined surfaces of the plug and T-piece forms an effective seal. Rapid volatilisation of the oxide occurs, and a dense white cloud of pure crystalline phosphoric oxide is seen to condense in the receiver. A fresh charge of impure oxide is introduced as soon as the condensation due to the previous charge subsides. Glassy phosphoric acids formed in the main tube flow down towards the oxygen inlet end. They may be removed when the tube is cold by unscrewing the  $\frac{1}{4}$ -inch adapter and hammering the tube. The necessity for this does not arise until after several pounds of oxide have been distilled. The 24-inch section of the main tube serves to preheat the oxygen and to distil the volatile portions of the viscous oxides. The distillation section of the main tube must be kept at a bright red heat, and the right angle bend and the short piece of tubing attached to it and entering the receiver must be kept at a sufficiently high temperature to prevent condensation anywhere in the iron tube itself. At a normal rate of working,

about 500 g. of oxide can be distilled in this manner in 1 hour. The yield obtained varied from 70 to more than 80%, according to the nature of the original impure oxide and the skill of the operator. Owing to the rapid rate and the high temperature (above  $800^{\circ}$ ) at which distillation occurs, a uniform crystalline product of a volume about 5 times that of the original oxide, and thus well suited for drying operations, is obtained. In order to obtain rapidly a good yield of pure product, distillation should not be commenced until the main tube is at a bright red heat with a large excess of oxygen passing through it. The receiver serves as the storage bottle, the stopper being lubricated with phosphoric oxide. The pure product obtained and stored in this manner will keep indefinitely.

The suitability of a phosphoric oxide for use in the experimental study of heterogeneous gas reactions or the attainment of a Bakerian degree of dryness depends on its vapour pressure, voluminous nature, and freedom from impurities, such as lower oxides of phosphorus and traces of organic matter. Smits and Rutgers (J., 1924, **125**, 2573) have shown that heating at temperatures above  $400^{\circ}$  yields that form of phosphoric oxide which exhibits the minimum vapour pressure. The rapid distillation carried out in the manner described above yields a crystalline product of great voluminousness. Traces of organic impurities may be detected by gently heating the moistened product in a test-tube; discoloration occurs if organic matter is present. The absence of lower oxides of phosphorus is best confirmed by the silver nitrate test described by Finch and Peto (*loc. cit.*). The mercuric chloride test also mentioned by them and advocated by Whitaker (J., 1925, **127**, 2219) has been found by us to be less sensitive than the silver nitrate test and therefore is not to be recommended.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,

## XXI.—*Production of Arsenic Subsulphide. Reduction of Certain Arsenic Compounds by Sodium Hyposulphite [Hydrosulphite].*

By WALTER FARMER and JAMES BRIERLEY FIRTH.

PRELIMINARY experiments on the reduction of certain arsenic compounds by sodium hyposulphite gave a product which was insoluble in colourless ammonium sulphide and appeared to be a subsulphide of arsenic. In the present investigation the pro-

ducts obtained by reducing various arsenic compounds in acid and in alkaline solution by sodium hyposulphite were examined.

In all the experiments the amounts of the different arsenic compounds taken were equivalent to the quantity of arsenic contained in 1 g. of pure arsenic trioxide, *i.e.*, 0.7575 g. of arsenic.

Filtration and washing of the precipitate at room temperature was a very slow process; if, however, the product was heated to boiling, the precipitate coagulated, and filtration and washing were greatly facilitated; also analysis showed that the composition of the precipitate was not affected by this treatment.

*Analysis of the Product.*—A solution of the precipitate was obtained by two distinct methods: (a) oxidation by fuming nitric acid, (b) oxidation by sodium peroxide in presence of hydrogen peroxide. Both methods were used for the precipitate obtained in each experiment and the two sets of results obtained showed satisfactory agreement. In each case, the arsenic was estimated as magnesium pyroarsenate (Levol, see Treadwell's "Analytical Chemistry," 1915, Vol. ii, pp. 206—208) and the sulphur as sulphate (Hentz and Weber; *op. cit.*, p. 469). To obtain a further check on the results, the arsenic remaining in the filtrate and washings was also estimated.

*Series I. Reduction (a) at 18°, (b) at 0° in Hydrochloric Acid of Definite Concentration by Sodium Hyposulphite in Various Concentrations.*—The requisite quantity of the arsenic compound was dissolved, if necessary by heating under reflux, in a mixture of 5 c.c. of concentrated hydrochloric acid and 45 c.c. of water. A solution of the requisite quantity of sodium hyposulphite in 50 c.c. of water was rapidly added, making the total volume 100 c.c. In all cases there was an immediate precipitation of a dark brown product, the quantity of which varied with the concentration of hyposulphite used.

Experiments carried out over periods ranging from 30 minutes to 12 hours showed that the duration of the experiment did not appear to affect the nature of the decomposition product, but only slightly increased the amount of the precipitate. In all subsequent experiments, therefore, the reaction was allowed to proceed for 12 hours, the reaction flask being well stoppered and the contents frequently shaken. After 12 hours, the reaction products were heated just to boiling point, and the precipitate was filtered off, thoroughly washed, dried at 100°, and weighed. In series (b), the solutions were cooled to 0° before mixing and the temperature of the mixed solutions was maintained at 0° for 12 hours. The results are in Table I; *w* = grams of hyposulphite in 100 c.c. of mixed solutions.

*Series II. Reduction at 18° in Oxalic Acid Solution of Definite Concentration by Various Amounts of Sodium Hyposulphite.*—This series was carried out in order (if possible) to reduce the rate of decomposition of the sodium hyposulphite in the acid solution. The requisite quantity of the arsenic compound (= 0.7575 As) was dissolved in a solution of 4.5 g. of oxalic acid in 75 c.c. of water. The hyposulphite was dissolved in 25 c.c. of water and rapidly added to the oxalic acid solution. Other details were as before. The results are in Table II.

*Series III. Reduction at 18° in Hydrochloric Acid of Various Concentrations by Sodium Hyposulphite of Definite Concentration.*—In order to ascertain the effect of acid concentration, solutions of 1 g. of arsenic trioxide in 50 c.c. of hydrochloric acid of definite strength were each treated with 25 c.c. of a solution containing 10 g. of sodium hyposulphite. With increasing concentration of acid the colour changed from dark brown to very light brown. The results are in Table IIIa. This series was repeated, a quartz vessel being used. The results are in Table IIIb.

*Series IV. Reduction in Potassium Hydroxide Solution of Definite Concentration by Sodium Hyposulphite in Various Concentrations.*—Preliminary experiments showed that no dark brown precipitates were formed at room temperature, even after 3 hours. As the temperature was being raised to the boiling point of the alkaline solution in which the reduction was taking place, there was a continuous darkening of the reaction liquid followed by the formation of a dark brown precipitate, the bulk of which increased after the liquid had reached the boiling point. The escaping vapour contained a gas having a strong garlic odour. This gas was further examined. The flask containing the reaction liquid was fitted with a small reflux condenser, to the top of which a hard glass tube was attached. The reaction liquid was boiled for 30 minutes while one part of the tube was strongly heated. A white, crystalline sublimate of arsenious oxide and a metallic mirror of arsenic formed in the cooler parts of the tube. Further, the gas produced a black deposit of metallic silver in a dilute solution of silver nitrate and reacted with iodine in solution.

The subsequent experiments were carried out at the temperature of the boiling solution. A solution of the arsenic compound in 50 c.c. of 3*N*-potassium hydroxide was treated rapidly with the required amount of sodium hyposulphite dissolved in 50 c.c. of 3*N*-potassium hydroxide. The gas evolved from the boiling mixture was passed into 25 c.c. of *N*/10-iodine solution, the evolution being complete after 20 minutes. In subsequent experiments, therefore, the reaction liquid was maintained at the boiling point for 30 minutes, and was then diluted to 200 c.c. and filtered through a tared filter; the precipitate was thoroughly washed, dried, and analysed. The iodine solution was titrated with *N*/10-thiosulphate. The results are in Table IV.

*Series V. Reduction at 18°, a Neutralisation Method being used in which the Arsenic Compound dissolved in Hydrochloric Acid of Definite Volume and Concentration is reduced by Various Amounts of Sodium Hyposulphite dissolved in Potassium Hydroxide Solution of the same Volume and Normality as the Hydrochloric Acid.*—The

hyposulphite dissolved in 50 c.c. of 1.2*N*-potassium hydroxide was rapidly added to a solution of the arsenic compound in 50 c.c. of 1.2*N*-hydrochloric acid. In all cases, there was an immediate precipitation of a dark brown substance; after 12 hours, this was filtered off, washed, dried, weighed, and analysed. The results are in Table V.

With the exception of this series (V), the results obtained with trisodium and tripotassium arsenites and arsenates were similar to those obtained with the trioxide and pentoxide respectively.

*Further Examination of the Precipitates.*—The precipitates obtained in the foregoing experiments were repeatedly digested with colourless ammonium sulphide until on acidifying the extract no precipitate of arsenic sulphide was obtained.

With the exception of those obtained in the experiments in alkaline solution, the precipitates contained 6, 12, 25, or 32% of sulphur. A few contained 40% or more, and some were of intermediate composition.

Products of similar composition gave similar results when digested with colourless ammonium sulphide. The following are typical examples. In the fifth experiment there was, after digestion, a very small, dark brown residue containing arsenic and sulphur.

The average sulphur content of the residues after extraction was 12.69% in the case of the precipitates containing initially 12.5 to 32.5% of sulphur. As  $\text{As}_2\text{S}_3$  requires S, 12.45%, the final product would appear to be this subsulphide, the slightly high value for sulphur being due to retention of a little arsenious sulphide, the removal of the last traces of which is very difficult. For those precipitates containing less than 12% of sulphur, the results were not so consistent; e.g., for the final product from arsenic trioxide treated by the neutralisation method the mean sulphur content after extraction was 4.8%, whilst the precipitates from alkaline solutions gave final products containing 2.5 to 5.35% of sulphur.

#### *Discussion and Conclusions.*

One of the products of reduction of the arsenic compounds used is a sulphide of arsenic which contains about 12.7% of sulphur and is insoluble in colourless ammonium sulphide. It agrees in composition with the subsulphide of arsenic  $\text{As}_2\text{S}_3$  and appears to be identical with the substance obtained by Scott (J., 1900, 77, 651) by treating an aqueous solution of an alkali arsenate with phosphorus trichloride and saturating the mixture with sulphur dioxide. Products containing from 2.5 to 5.35% of sulphur have also been isolated.

In moderately acid solutions trivalent arsenic compounds yield precipitates of arsenic subsulphide,  $\text{As}_2\text{S}_3$ , containing comparatively small quantities of arsenic trisulphide, whilst quinquivalent arsenic compounds yield precipitates which approximate in composition to the formula  $\text{As}_2\text{S}_3 \cdot \text{As}_2\text{S}_5$  (25.42% S). The total arsenic precipitated from the latter compounds is approximately half that from the former.

Similar results are obtained by the neutralisation method, except that the precipitates from arsenic trioxide contain 6–7%, and those from alkali arsenates 30–32%, of sulphur ( $2\text{As}_2\text{S}_3 \cdot \text{As}_2\text{S}_5$  requires S, 29.89%).

Increase in acid concentration increases the amount of arsenic precipitated as trisulphide, and in strongly acid solutions the precipitate is mainly the trisulphide.

In alkaline solution, precipitation occurs not at room temperature but at the boiling point of the mixed solutions. In the case of arsenic trioxide the products contain 4–11% of sulphur. Arsenic pentoxide gives a comparatively small precipitate. A small amount of arsenic is volatilised at the boiling point of the mixture, mainly as trioxide associated with the hydride. The total arsenic precipitated increases, but not proportionally, with the concentration of the hyposulphite.

It would appear from the results that the subsulphide is formed by reaction between the tervalent arsenic compound and the hyposulphite, whilst the trisulphide is produced by the interaction of the arsenic compounds with thiosulphate and other thio-decomposition products of the hyposulphite. A yellow precipitate of arsenic sulphide is obtained when a solution of sodium thiosulphate containing alkali arsenite is acidified with hydrochloric acid and warmed. Hence increased concentration of hydrochloric acid increases the rate of decomposition of the hyposulphite, and the quantity of subsulphide produced is diminished and that of the trisulphide increased.

In the case of quinquevalent arsenic compounds, reduction to the tervalent compound first takes place with the production of thio-decomposition products; the arsenic is subsequently precipitated, partly as subsulphide by the hyposulphite and partly as trisulphide by the thiosulphate, etc.

At 0° (Series Ib), the sulphur content is diminished owing to the diminution in the rate of decomposition of the hyposulphite.

In no case was the arsenic completely precipitated from solution, but in neutral solution, with 10 g. of hyposulphite for 1 g. of arsenic trioxide, 99.24% (Series V) was precipitated. The maximum precipitation of arsenic from quinquevalent compounds was 57.25%, obtained in the same series under similar conditions.

## XXII.—*Hydrogen Electrode Studies of the Precipitation of Basic Chromates, Borates and Carbonates.*

By HUBERT THOMAS STANLEY BRITTON.

THE work described in earlier papers (J., 1925, 127, 2110, 2120, 2142, 2148) showed that a characteristic property of a metallic hydroxide is the hydron concentration at which it separates from solution. The following electrometric titrations have therefore been carried out to see if the hydrogen-ion concentrations at which various basic precipitates are formed could in any way be correlated with the hydron concentrations at which the respective hydroxides are precipitated.

### I. *Basic Chromates.*

These titrations were made at 18° by the method used in the hydroxide investigations (*loc. cit.*) and chromic acid titration (Britton, J., 1924, 125, 1572). In Table I are the particulars of the solutions and the  $p_H$ 's at which precipitation took place.

TABLE I.

*M*/10-Potassium chromate was used in each titration except that of thorium chloride, in which case the concentration was *M*/20. The data relating to the different hydroxides were taken from the previous papers. The titration curves are given in Fig. 1, the arrows indicating the points at which precipitates first appeared.

*Mechanism of the Precipitation of Basic Chromates.*—Table I shows that in the majority of the titrations a precipitate did not form until the hydrogen-ion concentration of the solution had become that at which the hydroxide separates. In one or two cases the precipitate first formed was the hydroxide uncontaminated with any chromate. This was particularly the case with aluminium, the initial precipitate being aluminium hydroxide containing some unattacked sulphate. The chief factor controlling the concentration of hydrogen ions is the reaction whereby the acid, produced from the metallic salt by hydrolysis, and the potassium chromate generate hydrochromate ions. The dissociation of these ions is exceedingly small and is rendered still smaller by the increasing concentration of chromate ions from the added potassium chromate. The range of hydrogen-ion concentrations which can be produced in equilibria involving chromate and hydrochromate ions is  $10^{-5}$  to  $10^{-8}$ , as may be seen from the second section of the chromic acid titration curve (Britton, *loc. cit.*). For a considerable range of equilibria the hydrogen-ion concentration remains approximately  $10^{-6}$ . The reason why potassium chromate precipitates basic chromates from salt solutions lies in the inability of the hydrochromate ions to react with the metallic bases and thus maintain them in solution, except in the few instances in which insoluble normal chromates are formed. For example, consider the reactions between freshly precipitated aluminium hydroxide and the hydrochromate ions present in potassium dichromate solutions of different concentrations. It can be shown that the *p<sub>H</sub>* of *M*/10- and *M*/100-KHCrO<sub>4</sub> is 3.68 and 4.18 respectively, by assuming the salts to be completely dissociated into K<sup>+</sup> and HCrO<sub>4</sub><sup>-</sup>, and the latter ions to

be dissociated further into an equal number of hydrogen ions and chromate ions. As aluminium hydroxide is precipitated at  $p_H$  4.14, it follows that at the moment of formation of the precipitate the hydroxyl-ion concentration of the solution is  $K_w/10^{-4.14} = 10^{-10}$ . In order that the aluminium hydroxide may react with the hydrochromate ions and consequently dissolve, the hydrochromate ions

FIG. 1.

must be capable of providing sufficient hydrogen ions to form water with the hydroxyl ions in the solution, i.e., the product  $[H^+][OH^-]$  must be greater than  $K_w$ . If  $M/100$ -potassium hydrochromate solution be added to freshly precipitated aluminium hydroxide, it will set up a hydron concentration of  $10^{-4.18}$ , which, being less than the precipitation hydron concentration, will be incapable of causing solution, or, in other words,  $[H^+][OH^-]$  will become equal to  $10^{-14.18}$ ,

a value just less than  $K_w$ ,  $10^{-14.14}$ . With  $M/10$ - $\text{KHCrO}_4$ ,  $p_{\text{H}} = 3.68$ , the hydrogen-ion concentration will be less than that necessary for the precipitation of aluminium hydroxide and consequently there will be a tendency for the aluminium hydroxide to dissolve, the product being  $10^{-13.68}$ , which just exceeds the ionic product of water at  $18^\circ$ . If thorium hydroxide, however, be used, no reaction can take place, for its precipitation  $p_{\text{H}}$  being 3.5, the product of the hydroxyl-ion concentration and the hydron concentration arising from either  $M/10$ - or  $M/100$ -solution of the potassium acid chromate will be less than  $K_w$ .

The hydroxides higher in the  $p_{\text{H}}$  scale (*loc. cit.*, p. 2157) become increasingly reactive with the hydrochromate ions, though very little reaction takes place with those hydroxides which are precipitated from acid solutions. This is due to the fact that as soon as some hydrochromate ions have been converted into chromate ions, the hydrogen-ion concentration becomes considerably reduced and so prevents further reaction. As the hydron concentration thereby produced is about  $10^{-6}$ , its effect will be most marked with those hydroxides whose precipitation  $p_{\text{H}}$ 's are above 7. The reaction between those hydroxides, which are precipitated at  $p_{\text{H}}$  7 and above, and the hydrochromate radical becomes more pronounced and consequently potassium chromate causes either partial or no precipitation. Thus it is clear why potassium chromate fails to precipitate magnesium salt solutions. Magnesium hydroxide is precipitated at  $p_{\text{H}}$  10.5 and is therefore able to react with the ions produced in the second stage of the ionisation of chromic acid to an extent sufficient to prevent the attainment of the  $p_{\text{H}}$  of precipitation. Manganous hydroxide, too, is sufficiently strong ( $p_{\text{H}}$  8.4) to enter appreciably into combination with the hydrochromate radical. No precipitate is formed when potassium chromate is added to a manganous salt solution, but after some time the solution deepens in colour and eventually a brownish-black precipitate appears. This, however, is due to oxidation of the relatively large amount of manganous hydroxide present in the alkaline solution by the chromate and to some extent by the air (Gröger, *Z. anorg. Chem.*, 1905, 44, 453).

The latter precipitation reactions may also be considered from the point of view of the alkalinity of the potassium chromate solutions. By assuming complete ionisation of the various salts involved in the hydrolysis of potassium chromate solutions, it can be shown that at  $18^\circ$ ,  $[\text{H}^+] = \sqrt{K_2 K_w / C_{\text{K}_2\text{CrO}_4}}$ ,  $K_2$  of chromic acid being  $4.4 \times 10^{-7}$ . Therefore  $p_{\text{H}}$  of  $M/10$ -potassium chromate is 9.75 and of the  $M/100$ -solution, 9.25. Hence the addition of potassium chromate in either of these concentrations to mag-

nesium salt solutions cannot cause precipitation, as the reactants are incapable of attaining an alkalinity corresponding to the  $p_H$  of precipitation of magnesium hydroxide. On the other hand, it appears at first sight that if a dilute manganous salt solution contained (say)  $M/100$ -potassium chromate, the hydrogen-ion concentration which the latter would impart, *viz.*,  $10^{-9.25}$ , would be less than that at which manganous hydroxide is precipitated ( $p_H$  8.4). The reaction between manganous chloride (say) and potassium chromate involves a ready reaction between manganous hydroxide and the hydrions from the first stage of ionisation of chromic acid to form some  $Mn(HCrO_4)_2$  and also the more difficult reaction with the hydrions from the second stage. The result is that instead of the reaction being one of simple double decomposition, thus  $K_2CrO_4 + MnCl_2 = MnCrO_4 + 2KCl$ , the formation of a precipitate depends on how far the following equilibrium reaction is disturbed,  $Mn(HCrO_4)_2 + Mn(OH)_2 \rightleftharpoons 2MnCrO_4 + 2H_2O$ , which is governed, the oxidation effects which are peculiar to manganous and cobaltous hydroxides being excluded, by the two reactions (a)  $HCrO_4' + OH' \rightleftharpoons CrO_4'' + H_2O$ , and (b)  $Mn^{++} + 2OH' \rightleftharpoons Mn(OH)_2$ . Equilibrium (a) is dependent on  $K_2$  and  $K_w$ , and equilibrium (b) on  $[Mn^{++}][OH']^2$  or, more directly, the  $p_H$  of precipitation. Thus it follows that when  $M/10$ -potassium chromate is added to a manganous salt solution of the concentration used in these titrations, the  $p_H$  of the solution barely attains the precipitation  $p_H$  of manganous hydroxide and no precipitate is at first produced. More concentrated solutions of potassium chromate, however, effect partial but almost immediate precipitation of basic manganous chromate.

The behaviour of potassium chromate towards nickel and cobalt salt solutions is of interest. As shown in Table I, nickel hydroxide is precipitated at  $p_H$  6.66 and cobalt hydroxide at  $p_H$  6.81. Yet when  $M/10$ -potassium chromate is added to solutions of cobalt and nickel salts partial precipitation occurs in the former case and merely an opalescence is produced in the latter. The nickel and cobalt curves show that potassium chromate produces hydrion concentrations less than those at which the respective hydroxides are precipitated by alkali. The partial precipitation of cobalt is probably due to the tendency of cobalt hydroxide to oxidise. Gentle warming of the nickel solution is sufficient to cause precipitation.

The curves showing the course of precipitation of the basic chromates of neodymium and samarium have been included, for unlike the other metals except thorium, they form well-defined, difficultly soluble salts and thus the precipitation of one or the other

is determined by (a) the hydrogen-ion concentration and (b) the solubility of the normal chromate.

These hydrogen-ion relationships of the various hydroxides explain why solutions of potassium dichromate, in spite of their  $p_H$ 's being greater than the precipitation  $p_H$ 's of certain hydroxides, fail to cause the precipitation of basic chromates, except from zirconium salt solutions; and even in this case it is far from complete. Unless concentrated solutions be used, in which case the normal thorium chromate may be precipitated, the addition of potassium dichromate to thorium salt solutions fails to give a precipitate, although the  $p_H$  of the dichromate solution itself is greater (3.68—4.18 for solutions ranging from 0.1M to 0.01M) than the hydroxide precipitation  $p_H$ , 3.5. Potassium dichromate behaves, towards a weak base like thorium hydroxide, as a salt of a strong monobasic acid containing no reactive hydrogen atom, and on addition to a thorium salt solution merely sets up an equilibrium,  $\text{ThCl}_4 + 4\text{KHCrO}_4 \rightleftharpoons \text{Th}(\text{HCrO}_4)_4 + 4\text{KCl}$ , in which the thorium salt is largely hydrolysed, and thereby maintains a hydron concentration in the solution which is much greater than that required for the precipitation of the hydroxide. An excess of potassium dichromate will have a buffering effect on the hydrolysed chromic acid, but, as the first section of the chromic acid titration curve shows, the excess would have to be considerable before the hydrogen-ion concentration could be reduced to  $p_H$  3.5.

*Detailed Study of the Precipitation Reactions.—Thorium.* It was mentioned (J., 1923, 123, 1434) that when  $M/100$ -thorium nitrate solution was treated with  $M/20$ -potassium chromate solution in stoichiometrical amounts, precipitation was partial and the precipitate contained thoria and chromic anhydride in the molecular ratio 1:1.38. On substituting the chloride for the nitrate, no variation was found in the composition of the precipitate. Fig. 1 shows that 22.7 c.c. of  $M/20$ -potassium chromate caused the attainment of the hydroxide precipitation  $p_H$ , at which point basic thorium chromate began to be precipitated. The next 30 c.c. caused little change in  $p_H$ , but soon afterwards a rapid diminution in hydrogen-ion concentration occurred which marked the end of precipitation. On comparing the inflexion thereby produced with that in the neutralisation curve of chromic acid, it will be observed that it indicates the first half of the neutralisation of all the free chromic acid present in the solution,  $\text{KHCrO}_4$  being formed. The reaction may be regarded as two simultaneous reactions: first, the gradual hydrolysis of the thorium salt thus,  $\text{ThCl}_4 + 4\text{H}_2\text{O} \rightarrow \text{Th}(\text{OH})_4 + 4\text{HCl}$ , and, secondly,  $4\text{HCl} + 4\text{K}_2\text{CrO}_4 \rightarrow 4\text{KCl} + 4\text{KHCrO}_4$ .

As stated above, it would be expected that thorium hydroxide

would show a negligible tendency to react with the small concentrations of hydriions which arise from the dissociation of hydrochromate ions. Yet the thorium hydroxide which was precipitated contained appreciable amounts of chromic anhydride. Two reasons may be offered: (a) co-precipitation of thorium chromate, and (b) adsorption of chromic anhydride, through chemical forces at play between the weak base, thorium hydroxide, and the weak acid,  $\text{HCrO}_4'$ . The precipitates, apart from being yellow, resembled thorium hydroxide and appeared to contain no crystalline thorium chromate. Thorium chromate is much more soluble than the hydroxide, and seeing that the thorium- and chromate-ion concentrations were insufficient to produce a precipitate of the normal chromate before the hydroxide precipitation  $p_H$  was attained, it appears improbable that the basic chromate contained any normal chromate. The large chromic anhydride content of the basic precipitate was probably caused by a process akin to adsorption in which the chemical tendencies of the weak acid and the weak base played an important part.

An approximate estimate of the composition of the precipitate may be obtained from the titration curve. Precipitation was complete when 53 c.c. of  $M/20$ -potassium chromate had been added, i.e., an amount corresponding to the mid-point of the inflexion. If thorium hydroxide alone had been precipitated, then, as shown by the previous equations, 4 mols. of potassium chromate to 1 mol. of thorium chloride would have been required, or 80 c.c. in the titration; as compared with 2 mols., or 40 c.c. of  $M/20$ -potassium chromate, if the normal chromate had been formed. But actually 53 c.c. were required, and therefore by alligation the basic chromate precipitate must have contained  $27\text{Th}(\text{CrO}_4)_2, 13\text{Th}(\text{OH})_4$ , or  $\text{ThO}_2, 1.35\text{CrO}_3$ . The precipitate contained 54.55% of  $\text{ThO}_2$  and 28.47% of  $\text{CrO}_3$ , and therefore agreed with the formula  $\text{ThO}_2, 1.38\text{CrO}_3, 4.57\text{H}_2\text{O}$ , which is similar to that suggested by the curve.

*Aluminium.* Precipitation began when 5 c.c. of  $M/10$ -potassium chromate had been added, the  $p_H$  attained being that required for the precipitation of aluminium hydroxide. At first, the precipitate was white basic aluminium sulphate, but gradually became yellow and contained some chromate (compare Gröger, *Ber.*, 1902, 35, 3420). The curve shows that very little change in  $p_H$  ensued until 20 c.c. of potassium chromate had been added. The main inflexion occurred and precipitation became complete when between 32 and 35 c.c. were added. The precipitate was gelatinous and contained chromate, much of which could be removed by washing.

The experiments of Gröger on the solubility of aluminium hydroxide in chromic acid solutions throw some light on the reactivity

of the acid. He found that the number of molecules of chromic anhydride required to hold 1 mol. of alumina in solution varied from 4.46 to 5.02, and therefore concluded that both aluminium chromate and dichromate were capable of existence in solution. The explanation lies in the mode of dissociation of chromic acid. The first stage of the ionisation permits of the ready solution of aluminium hydroxide, thus  $\text{Al}(\text{OH})_3 + 3\text{H}_2\text{CrO}_4 \rightleftharpoons \text{Al}(\text{HCrO}_4)_3 + 3\text{H}_2\text{O}$ , which requires 6 mols. of  $\text{CrO}_3$  to 1 mol. of  $\text{Al}_2\text{O}_3$ , but the amount of hydrions produced in the second stage of the dissociation will depend on the concentration of chromic acid used. If it be large, the great concentration of hydrochromate ions will tend to suppress the second stage of dissociation and consequently there will be proportionally fewer hydrions available for reaction than in a more dilute solution. Hence it is clear why Gröger required variable amounts of chromic acid which corresponded to somewhat less than 6 mols.

*Chromium.* Maus (*Pogg. Annalen*, 1827, 9, 127) and later Storer and Eliot (*Proc. Amer. Acad. Arts Sci.*, 1862, 5, 192) found that brown precipitates of basic chromium chromate were produced by the action of potassium chromate on solutions of chromium salts, from which the chromic acid could be removed by repeated washing. The latter investigators stated that the abstraction did not stop when the precipitate had attained any particular composition and, from an equation based on the molecular proportion of potassium chromate which they found necessary for precipitation, concluded that  $\text{CrO}_2$ , i.e.,  $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$ , must have first been formed.

The titration curve shows that the factor which determined precipitation was the hydrogen-ion concentration, for when 26 c.c. of  $M/10$ -potassium chromate had been added and the  $p_{\text{H}}$  had become 5.2, as compared with 5.34 found for the hydroxide, the basic chromate began to separate. The amount of potassium chromate required was 2.6 mols. to 1 mol. of chromic sulphate, and thus happens to be about half the quantity (5 mols.) found by Storer and Eliot. As the point of precipitation is determined by the hydrion concentration, the amount of potassium chromate required appears to be a function of the concentration of the reactants. The  $p_{\text{H}}$  change prior to precipitation was indicated by a line which was nearly straight, comparable with the section, corresponding to the addition of the first equivalent (to 1 Cr) of sodium hydroxide, in the alkali titration curve (*loc. cit.*). The fact that 2 mols. of sodium hydroxide had to be added to 1 mol. of chromium sulphate before precipitation began was due to the peculiar property of trivalent chromium of forming "soluble basic salts," such that in a solution of the sulphate one molecule of sulphuric acid is in a state

of loose combination which may perhaps be expressed by the equilibrium  $\text{Cr}_2(\text{SO}_4)_3 + 2\text{H}_2\text{O} \rightleftharpoons (\text{OH})_2\text{Cr}_2(\text{SO}_4)_2 \dots \text{H}_2\text{SO}_4$ , the looseness of the combination being indicated by the dotted line. This molecule of sulphuric acid, on its gradual release, reacted with two molecules of potassium chromate, thus:  $\text{H}_2\text{SO}_4 + 2\text{K}_2\text{CrO}_4 = 2\text{KHCrO}_4 + \text{K}_2\text{SO}_4$ , and the remaining 0.6 mol. of potassium chromate set up an equilibrium with the hydrochromate ions so formed to produce the requisite hydron concentration for precipitation.

The precipitates formed by treating chromium sulphate solution (alum) with varying proportions of potassium chromate, corresponding to 30, 60 and 90 c.c. in the titration, were analysed. After being freed from mother-liquor by suction and a little washing by decantation, the first precipitate was green and had the composition  $\text{Cr}_2\text{O}_3, 0.079\text{CrO}_3, x\text{H}_2\text{O}$ , and was thus almost pure chromium hydroxide; the second was brown and contained more chromate,  $\text{Cr}_2\text{O}_3, 0.574\text{CrO}_3, x\text{H}_2\text{O}$ ; and the third, still more, its composition being  $\text{Cr}_2\text{O}_3, 0.871\text{CrO}_3, x\text{H}_2\text{O}$ .

*Beryllium* is another of the elements that form soluble basic salts and this property appears to be reflected in the titration curve, the  $p_{\text{H}}$  at which precipitation began not being attained until 24 c.c. of  $M/10$ -potassium chromate had been added, i.e., 1.2 mols. for 1 mol. of beryllium sulphate.

The alkali curve (*loc. cit.*) shows a characteristic inflexion during the reaction with the first equivalent of sodium hydroxide; precipitation occurred at  $p_{\text{H}}$  5.69 (given at the top of an inflexion), when 1.04 equivalents had been added. A similar inflexion occurred in the chromate titration curve and precipitation began at  $p_{\text{H}}$  5.72, indicated by a point in a similar position. The equivalent amount of potassium chromate which produced this change was 2.4 times that of the alkali and consequently the change in hydron concentration was due to reaction between a loosely bound equivalent of acid in the beryllium sulphate molecule and potassium chromate, hydrochromate ions being formed which eventually entered into equilibrium with the added chromate ions.

Bleyer and Moorman (*Z. anorg. Chem.*, 1912, 76, 70; see also Orlov, *ibid.*, 1913, 79, 365) found that the interaction of potassium chromate and beryllium sulphate in solution produced very highly basic chromate precipitates, the chromate content of which seemed to increase slightly with the amount of potassium chromate added. Thus with 2 mols. of potassium chromate to one of beryllium sulphate the precipitate contained  $\text{BeO}, 0.036\text{CrO}_3$ , and with 4 mols. of potassium chromate,  $\text{BeO}, 0.07\text{CrO}_3$ , some unattacked sulphate being present in each precipitate. Bleyer and Moorman,

having found that chromic acid solutions saturated with beryllium hydroxide contained the two in equimolecular proportions, stated that beryllium chromate existed in solution. Solutions of strong acids saturated with beryllia are invariably basic, and, as shown by the titration curve of beryllium sulphate and sodium hydroxide (*loc. cit.*), the solution had to be rendered basic to an extent shown by the formula  $\text{Be}(\text{SO}_4)_{0.5}(\text{OH})$  before precipitation commenced. Similarly, the proportions in Bleyer and Moorman's solutions show that they were basic to the same extent, *viz.*,  $\text{Be}(\text{HCrO}_4)(\text{OH})$ , chromic acid being too weak in its second stage of dissociation to react with beryllium hydroxide to any appreciable extent.

*Zinc.* Table I shows that the  $p_{\text{H}}$  of precipitation of basic zinc chromate was 5.49 and therefore a little higher than that of the hydroxide, 5.20. The rapidity with which the  $p_{\text{H}}$  changed during the addition of the first c.c. of potassium chromate rendered it difficult to ascertain with any degree of precision the exact point at which the precipitate appeared. The precipitate was basic and consequently the hydron concentration of the solution was controlled mainly by the equilibrium between the liberated hydrochromate ions and chromate ions. Gröger's analyses (*Monatsh.*, 1904, 25, 520) showed that the precipitates obtained by treating zinc sulphate solutions with potassium chromate were indefinite and contained some sulphate, but the precipitates obtained from zinc chloride solutions were free from chloride, evidently due to the greater ease with which chlorides are hydrolysed. Varying amounts of potassium chromate were retained but were removable by washing.

An insoluble normal zinc chromate has been stated to exist by Schultze (*Z. anorg. Chem.*, 1895, 10, 148) and Briggs (*ibid.*, 1908, 56, 254), but the latter's data are unconvincing. It was thought that, if a difficultly soluble chromate did exist, its solubility might be too large for it to be precipitated by double decomposition through the attainment of the  $p_{\text{H}}$  at which the basic chromate separated, but that it might be precipitated from a chromic acid solution of zinc oxide by the gradual addition of potassium chromate so that the  $p_{\text{H}}$  should be kept below that necessary for the precipitation of the basic chromate (compare Britton, J., 1924, 125, 1875). Indefinite basic chromates were always obtained; *e.g.*, one air-dried precipitate,  $\text{ZnO}, 0.605\text{CrO}_3$ , contained 55.03% ZnO and 40.90%  $\text{CrO}_3$ , and another contained 58.10% ZnO and 33.00%  $\text{CrO}_3$ , corresponding to  $\text{ZnO}, 0.462\text{CrO}_3$ .

Some criticism appears to be necessary of Gröger's conclusions (*Z. anorg. Chem.*, 1911, 70, 135) from his study of the 25°-isotherm of the system  $\text{ZnO}-\text{CrO}_3-\text{H}_2\text{O}$ , in which he claims to have established

the identity of several definite basic chromates of zinc. The "rests" were considered, without experimental proof, to be the actual solid phases alone. If the molar concentrations of Gröger's liquid phases of ZnO be plotted against those of  $\text{CrO}_3$ , it will be found that all the points lie on a continuous curve, whereas had definite basic salts been formed the curve should display a number of "breaks," indicating the univariant points.

Although Gröger's conclusions can scarcely be regarded as valid, the analyses of his liquid phases are important in that they give the solubility of zinc oxide in chromic acid solutions varying in concentration from 0.006*M* to 9.7*M*, and therefore should give some idea of the reactivity of chromic acid towards zinc oxide. The number of molecules of chromic acid,  $\text{H}_2\text{CrO}_4$ , required to dissolve one molecule of zinc oxide varied continuously with increasing concentration of acid from 1.20 to 2.03, which led Gröger to conclude that the more dilute solutions contained both zinc chromate,  $\text{ZnCrO}_4$ , and zinc dichromate,  $\text{ZnCr}_2\text{O}_7$ , whilst the highly concentrated solutions contained only zinc dichromate. The fact that approximately two molecules of chromic acid were required for the most concentrated acid solutions was due to the reaction having taken place between zinc oxide and the hydrions of the first dissociation, thus:  $\text{ZnO} + 2\text{H}_2\text{CrO}_4 \rightarrow \text{Zn}(\text{HCrO}_4)_2 + \text{H}_2\text{O}$ , the large concentration of hydrochromate ions having inhibited further ionisation and consequent reaction, whereas in the dilute solutions some of the hydrions from the second stage of ionisation became available for reaction, with the result that less than 2 mols. of chromic acid were required.

*Cobalt and Nickel.* The reactions of these two metals have already been discussed (*vide supra*).

Reference may be made to Weil's proposal (*Bull. Soc. chim.*, 1911, 9, 20) to use potassium chromate for the separation of cobalt from nickel. Although potassium chromate does not precipitate basic nickel chromate at room temperature, the titration curve shows that the hydrion concentration produced by addition of potassium chromate to a nickel salt solution is such that the basic salt is on the point of being precipitated. A method depending on such a small difference in solubility can give but a rough separation, for there will be a great tendency for the gelatinous basic cobalt chromate to carry down much nickel.

*Rare Earths.—Yttrium.* Basic yttrium chromate began to be precipitated at the same  $p_x$  as its hydroxide, but precipitation was far from complete and the precipitate was highly basic. The air-dried precipitate formed by the interaction of stoichiometrical amounts of yttrium chloride and potassium chromate (40 c.c. of

$M/10\text{-K}_2\text{CrO}_4$  in the titration) solutions contained 38.61%  $\text{Y}_2\text{O}_3$  and 22.29%  $\text{CrO}_3$ , corresponding to the formula  $\text{Y}_2\text{O}_3 \cdot 1.30\text{CrO}_3$ . The filtrate from this precipitate was treated with more potassium chromate, and the new precipitate was still more basic and contained  $\text{Y}_2\text{O}_3 \cdot 0.93\text{CrO}_3$ .

*Neodymium and Samarium.* These two elements form well-defined but comparatively insoluble chromates (Britton, J., 1924, 125, 1875); the power of these earths to unite with chromic acid in its two stages being, no doubt, due to the small solubility of the salts formed, rather than to the strength of the bases. The solubilities of praseodymium chromate and lanthanum chromate are so small that when potassium chromate is added to the respective salt solutions the conditions requisite for the precipitation of the normal chromates are obtained before the hydroxide  $p_{\text{H}}$  is reached. This is not so with neodymium and samarium chromates, for they are sufficiently soluble to allow the  $p_{\text{H}}$  at which the hydroxide is precipitated to be attained before the respective solubility products of the chromates are exceeded, and consequently basic chromate precipitates are produced. When neodymium nitrate solution was treated with potassium chromate, a flocculent precipitate was obtained which on microscopic examination was seen to contain crystalline needles similar to those of the normal chromate. The following analyses refer to precipitates so obtained: (1)  $\text{Nd}_2\text{O}_3$ , 44.13;  $\text{CrO}_3$ , 34.59%, corresponding to  $\text{Nd}_2\text{O}_3 \cdot 2.64\text{CrO}_3 \cdot 9.02\text{H}_2\text{O}$ , and (2)  $\text{Nd}_2\text{O}_3$ , 47.95;  $\text{CrO}_3$ , 31.81%, corresponding to  $\text{Nd}_2\text{O}_3 \cdot 2.23\text{CrO}_3 \cdot 7.88\text{H}_2\text{O}$ . The fact that precipitation began at  $p_{\text{H}}$  6.48 instead of at 7.0, coupled with the nature of the precipitates and the relatively high  $\text{CrO}_3$  content, indicates that the formation of these precipitates constitutes a comparatively rare example of the co-precipitation of the crystalline normal salt and an indefinite basic salt.

Samarium chromate has a greater solubility than neodymium chromate and does not appear to be precipitated with the basic chromate. As the titration curve shows, the basic chromate was precipitated at  $p_{\text{H}}$  6.55, which was somewhat lower than the hydroxide  $p_{\text{H}}$ . It was yellow and flocculent and when dried and examined under the microscope appeared to be entirely amorphous. Its separation was partial. The air-dried precipitate from the titration contained 25.1%  $\text{CrO}_3$  as compared with 37.84% in  $\text{Sa}_2(\text{CrO}_4)_3 \cdot 8\text{H}_2\text{O}$ .

## II. Basic Borates.

Electrometric titrations were carried out at 18° with 0.05M-borax solution and salt solutions, which were so chosen that the precipitation reactions could be studied over as wide a range of hydrogen-

ion concentration as possible. Details of the solutions used and the  $p_H$ 's at which precipitates first appeared are in Table II.

TABLE II.

Solution (100 c.c. .	Ppton of basic borate began.		Ppton of hydroxide began.		Ppton.
	<i>E.M.F.</i>	$p_H$ .	<i>E.M.F.</i>	$p_H$ .	
0.01 <i>M</i> -ZrCl <sub>4</sub>	0.517	4.07	0.390	1.86	Complete

The titration curves are given in Fig. 2, the arrows showing the points at which precipitation began. The top curve in the diagram represents the titration of 100 c.c. of 0.02*M*-manganous chloride with 0.1018*M*-sodium metaborate.

Table II shows that, except in the case of zirconium and thorium, addition of borax solution did not cause precipitation to begin until the  $p_H$  at which the hydroxide is precipitated had been attained. The titration curves in Fig. 2, apart from that of zinc, are similar in shape to those representing the alkali titrations. Moreover, those curves which correspond to precipitation taking place in the acid zone show that the amounts of *N*/10-borax solution which caused the solutions to become alkaline, precipitation having become complete, were approximately the same as those required in the sodium hydroxide titrations. It appears, therefore, as far as the weaker bases are concerned, that sodium pyroborate has simply a hydrolysing action in precipitating the hydroxides, and in fact behaves as if no borate were present at all. The hydroxides which were precipitated contained some unattacked acid radical of the original salt, as may be seen from the amounts of *N*/10-borax required to render the solutions neutral, if it be assumed that the borate radical did not enter into combination. Thus in the zirconium titration, 38.5 c.c. were required as compared with the theoretical amount, 40 c.c.; thorium, 38.0 instead of 40 c.c.; aluminium, 36.0 instead of 40; chromium, 55 instead of 60; and beryllium, 37.6 instead of 40 c.c.

Provided that no insoluble normal borates are formed, it follows on theoretical grounds that boric acid, HBO<sub>2</sub>, with its exceptionally small dissociation constant, is incapable of producing hydrogen-ion concentrations large enough to cause dissolution of any of the hydroxides which are precipitated at  $p_H$  less than 7. As far as the reactivity of boric acid is concerned, boric acid behaves as a mono-

basic acid. If  $5 \times 10^{-10}$  be taken as an average value of  $K = [\text{H}^+][\text{BO}_2^-]/[\text{HBO}_2]$ , it follows that in a  $M/10$ -boric acid solution the hydrogen-ion concentration is  $10^{-5.2}$ , and  $10^{-5.6}$  in a  $M/100$ -solution. The hydroxides of beryllium, zinc, chromium, aluminium,

FIG. 2.

thorium and zirconium are all precipitated at  $p_{\text{H}}$  less than 5.69, and consequently the hydron concentrations of  $M/10$ - and  $M/100$ -solutions of boric acid are too small to have any solution effect on these hydroxides. Taking the case of beryllium hydroxide, which is precipitated at the highest  $p_{\text{H}}$  of the series under consideration,

in order that the reaction  $\text{Be}(\text{OH})_2 + 2\text{HBO}_2 \longrightarrow \text{Be}(\text{BO}_2)_2 + \text{H}_2\text{O}$  may proceed, water must be formed and therefore the product of the concentration of hydroxyl ions due to beryllium hydroxide, *viz.*,  $10^{-14.14}/10^{-5.69} = 10^{-8.45}$ , and that of the hydrions from the boric acid, about  $10^{-5.2}$ , must exceed  $K_w$ . In this case it is  $10^{-13.9}$ , and only just exceeds  $K_w$ , and consequently beryllium hydroxide may perhaps be expected to exhibit the slightest tendency to dissolve. Any solution, however, would cause an increase in the concentration of  $\text{BO}_2'$  ions, which would depress the ionisation of boric acid and so prevent further solution. Boric acid does not dissolve either of these bases to any appreciable extent.

The hydrogen-ion concentrations of the solutions at the end of these titrations were such as would be given by borate mixtures comprising the total quantity of boric acid added and the alkali in excess of that required for the precipitations, and therefore confirm the view that no boric acid, or relatively little, was contained in the precipitates. Thus in the titrations of zinc, beryllium, aluminium, thorium and zirconium, it will be seen from Fig. 2 that the hydrion concentration when 60 c.c. of *N*/10-borax had been added was  $10^{-8.3}$  in each case. By subtracting the 40 c.c. of *N*/10-sodium hydroxide which were neutralised during the precipitations, it is found that the solutions contained alkali equal to 20 c.c. of *N*/10-sodium hydroxide and boric acid equal to 120 c.c. of *N*/10- $\text{HBO}_2$ , the boric acid having been one-sixth neutralised. The  $p_H$  of a 0.2*N*-solution of boric acid neutralised to the same extent is, according to Sørensen, 8.29 (Prideaux, "Theory of Indicators," 1917, p. 279), and as the variation in  $p_H$  produced by the difference in concentration of the two solutions is very small, it will be seen that the agreement is sufficiently good.

Although the changes in hydrion concentration which took place in the acid zone of the titrations are almost identical with those which were obtained when the precipitant was sodium hydroxide, in the case of the weakest two bases, zirconia and thoria, the  $p_H$ 's of precipitation do not compare favourably with the corresponding hydroxide  $p_H$ 's. Zirconium hydroxide is generally precipitated at a  $p_H$  somewhere on the very slightly inclined part of the curve. In the precipitation of zirconium chloride solution with sodium hydroxide (J., 1925, 127, 2124) the  $p_H$  was 1.86, but in the present titration the solution remained perfectly clear until the inflexion in the curve had been passed and the  $p_H$  had become 4.06; opalescence then began. This was when 3.4 atoms of chloride of the zirconium tetrachloride had been replaced by hydroxyl groups and, notwithstanding its highly basic nature, the solution had remained perfectly clear. With thorium chloride, the effect was similar; the

solution remained quite clear until 3.3 atoms of chloride had been replaced and the curve had begun to incline, the  $p_H$  being 4.70 instead of 3.51 obtained by using alkali. Hence it appears that the boric acid was having some restrictive influence on the size of the particles. It is probable that the tendency, although very slight, which boric acid may have to combine with thorium and zirconia exerts its greatest influence just at the point where the hydroxide or basic salt is about to pass into colloidal solution prior to precipitation. If this be the case, it seems reasonable that the boric acid, in trying to react with the nascent hydroxide, tended to keep it in solution by impeding the growth of the particles. Two experiments were made to determine whether the delayed precipitation from a thorium chloride solution whose  $p_H$  is that at which precipitation normally takes place is a matter of time: To thorium chloride solutions of the concentration used in the titration were added amounts of borax equal to 2 and 3 equivalents; in neither case did a precipitate separate during a period of several weeks.

In the chromium titration, the solution became green on addition of the borax and precipitation occurred when 21.9 c.c. of  $N/10$ -solution had been added, or 1.09 equivalents for each atom of chromium.

The beryllium curve again is similar to the alkali curve, and precipitation was also delayed until 21.9 c.c. (= 1.09 equivalents to 1 atom of Be) had been added.

The zinc curve shows hydrogen-ion changes which were due mainly to equilibria which must have been set up between borate ions and boric acid. The precipitation  $p_H$  was the same as that when alkali was used.

The incomplete precipitation which took place from  $M/50$ -manganous chloride solution will be understood when it is remembered that the  $p_H$  of  $N/10$ -borax itself, viz., 9.11, is only slightly greater than the  $p_H$  at which manganous hydroxide is precipitated. Table II gives two  $p_H$  values for manganous hydroxide; the one marked with an asterisk is low, probably on account of oxidation of manganous hydroxide, and the other, which is approximately correct, was extrapolated from the alkali titration curve. In the borax titration the precipitate did not appear until 20 c.c. of  $N/10$ -borax had been added and  $p_H$  8.82 attained. The precipitate was white and remained dispersed until 50 c.c. had been added, and, unlike the hydroxide, it did not immediately turn brown through oxidation. It readily did so when washed. (It is this protective action which is conferred on manganous hydroxide by union with some boric acid which makes the substance of use as a "drier")

in paints and varnishes.) The fact that it was precipitated at the hydroxide  $p_H$  suggests that the white precipitate was basic, and not manganous borate as was stated by Hartley and Ramage (J., 1893, 63, 133). Their precipitates were obtained by pouring solutions of manganous sulphate into solutions of borax until no further precipitation occurred. From widely differing estimations of the manganese content only, they concluded that they had prepared a definite borate having the formula  $MnH_4(BO_3)_2$  when dried at  $100^\circ$ , and they state that  $MnH_2B_2O_5$  and  $Mn(BO_2)_2$  were formed by dehydrating it still more. They also state that manganous borate was produced by the interaction of manganous sulphate and sodium metaborate. The precipitate produced by the action of  $N/10$ -borax on  $M/50$ -manganous chloride solution was both indefinite and basic and contained  $MnO, 1.47HBO_2$ . In the titration of  $M/50$ -manganous chloride with  $0.1018N$ -sodium metaborate, the precipitate appeared when 1 c.c. of precipitant had been added and the  $p_H$  had become 8.77. This precipitate was, like the hydroxide, quickly oxidised and was strongly basic.

Laurent (*Comp. rend. Trav. Chim.*, 1850, 6, 33) observed that manganous salt solutions were not precipitated with potassium hexaborate. It will be seen from the hydrogen-ion concentrations of the various borate "buffer" mixtures that the  $p_H$  of a boric acid solution, a third of which has been neutralised with alkali and which thus corresponds to Laurent's reagent, is about 8.7; this falls just below the  $p_H$  at which the hydroxide is precipitated. When, however, the borate solution is added to a manganous salt solution, some of the alkali is neutralised and the  $p_H$  falls a little further below 8.7.

According to Gmelin-Kraut ("Handbuch anorg. Chem.," 1908, iii, [2], p. 324), Berzelius found that when a magnesium salt had been added to a manganous salt solution, borax failed to give a precipitate. Neutral salts, such as sodium chloride, sodium sulphate, calcium chloride and potassium chloride, also produce this effect, but to a lesser extent; e.g., a solution from which precipitation had been prevented with magnesium sulphate remained clear on standing, whereas by using either potassium chloride or any of the other salts brown precipitates appeared after 12 hours. Precipitates obtained by means of borax may be forced back into solution by the addition of these salts. Since the highest  $p_H$  that could be produced by borax solutions was far removed from the precipitation  $p_H$  of manganous hydroxide, it appeared that the behaviour of these salts in preventing precipitation of basic manganous borate lay in their power to diminish the  $p_H$  below that necessary for precipitation. For example, when 10 c.c. of a satur-

ated solution of magnesium sulphate were added to 100 c.c. of  $N/10$ -borax solution whose initial  $p_H$  was 9.11, the  $p_H$  fell to 8.58; with 40 c.c.,  $p_H$  was 8.10; and with 50 c.c., 8.06. The effect of potassium chloride was not so marked. The addition of much potassium chloride to a  $N/10$ -borax solution depressed the  $p_H$  only from 9.11 to 8.82—a value, it will be noticed, corresponding to incipient precipitation.

The dotted curve shows the changes produced in hydrogen-ion concentration during the addition of  $N/10$ -borax solution to a  $M/50$ -solution of magnesium sulphate. No precipitate was obtained, for the  $p_H$  of the borax solution was below that, 10.49, requisite for the precipitation of magnesium hydroxide. Borax produces in the boiling solution a precipitate which redissolves on cooling. No precipitate was obtained with  $N/10$ -sodium metaborate solution, for although its  $p_H$  was 10.85, the  $p_H$  of the mixture became a little lower than the necessary value.

### III. Basic Carbonates.

The hydrogen electrode titration method has been applied in a study of the relationships involved in the precipitation of basic carbonates. By using a plentiful supply of hydrogen electrodes which were efficient in ordinary solutions, potential differences between them and the normal calomel electrode were obtained, in these carbonate titrations, which were readily reproducible and were unaffected by any liberated carbon dioxide. Table III gives the particulars of the several titrations, and Fig. 3 shows the titration curves, the points at which precipitation began being again denoted by arrows. The sodium carbonate was decinormal in every case except the chromium titration, where it was 0.166*N*.

TABLE III.

Solution (100 c.c.).	Ption of basic carbonate began.		Ption of hydroxide began.		Ption. Complete
	<i>E.M.F.</i>	$p_H$ .	<i>E.M.F.</i>	$p_H$ .

0.02 <i>M</i> -MgSO <sub>4</sub>	0.891	10.54	0.885	10.49	Turbidity

The titration curves are of the same type as those obtained in the preceding hydrolytic precipitation titrations, and in every case but zirconium, precipitation began at hydron concentrations equal or very nearly equal to those necessary for the corresponding

hydroxides. *N*/10-Sodium carbonate, unlike the reagents used in the previous titrations, when added to the magnesium sulphate solution, produced an alkalinity corresponding, but only just so,

Fig. 3.

to the  $p_H$  at which the hydroxide is precipitated, which did not occur until 27 c.c. had been added. The precipitate formed even after 100 c.c. of sodium carbonate had been added did not amount to more than a slight turbidity.

The stoichiometrical quantity of sodium carbonate required for simple double decomposition was equivalent to 40 c.c. of  $N/10$ -sodium carbonate, except in the case of chromium, where it was 36 c.c. The curves for zirconium, thorium, aluminium, beryllium and chromium show that the mother-liquors became alkaline when approximately theoretical quantities of sodium carbonate had been added. The hydron concentrations at the end of the titrations, although differing somewhat owing to the escape of different amounts of carbon dioxide during the precipitations, were such as would be produced by mixtures of sodium bicarbonate and carbonate (compare Prideaux, "Theory of Indicators," p. 299; Auerbach and Pick, *Arb. K. Gesundheitsamt.*, 1911, **38**, 243). The changes in hydron concentration which took place during the precipitation of the basic carbonates from solutions whose hydrogen-ion concentrations were greater than  $10^{-6}$  were scarcely at all affected by the carbon dioxide that was liberated. The carbon dioxide set free during the precipitation of basic zinc carbonate, however, had so marked an effect on the hydrogen-ion concentration that the inflexion corresponding to the formation of sodium bicarbonate from the liberated carbon dioxide and the added sodium carbonate did not occur until 54 c.c. of the latter had been added.

The curve for manganese shows that the addition of  $N/10$ -sodium carbonate, after the first 2 c.c., produced a diminution in  $p_H$ , which reached a minimum, 8.2, when 30 c.c. had been added. The precipitate appeared when 1.4 c.c. had been added and  $p_H$  8.68, i.e., nearly the hydroxide  $p_H$ , had been attained. The precipitate first formed was basic, as may be seen from the curve, which shows that more than 40 c.c. of sodium carbonate had to be added before the  $p_H$  of sodium bicarbonate was attained, viz., 8.7.\* The precipitate, although basic, did not turn brown through oxidation by the air. It is remarkable that the increase in hydron concentration which occurred during the titration did not cause the basic carbonate to re-dissolve. This, however, was a case of two precipitations, one of the basic carbonate due to the  $p_H$ 's ruling at the beginning and at the end of the reaction, and the other of the normal carbonate, which was precipitated when the hydron concentration of the solution was enhanced. Sodium bicarbonate when added to a manganous chloride solution, preferably saturated with carbon dioxide, causes the precipitation of manganous carbonate only, for it cannot produce a sufficiently low hydron concentration to enable

\* It may be calculated from Noyes's formula (*Z. physikal. Chem.*, 1893, **11**, 495), by taking  $K_1$  and  $K_2$  of carbonic acid to be  $3 \times 10^{-7}$  and  $1.3 \times 10^{-13}$ , respectively, that the  $p_H$  of dilute solutions of sodium bicarbonate is about 8.7.

the basic carbonate to separate from solution; e.g., the hydron concentration of a manganous chloride solution was gradually reduced by the addition of a solution of sodium bicarbonate until  $p_H$  was 7.6; a white precipitate of manganous carbonate then began to form. Hence, in order to ensure the precipitation of the normal carbonate, the precipitant must be incapable of causing the  $p_H$  to be attained at which the hydroxide is precipitated.

Normal zinc carbonate has been prepared. The titration curve shows that in order to precipitate this salt uncontaminated with basic carbonate a reagent must be used which, besides causing the solubility product  $[Zn^{++}][CO_3^{--}]$  to be exceeded, will maintain a hydrogen-ion concentration greater than that at which the basic carbonate would separate. Sodium bicarbonate with its  $p_H$  of 8.7 would be useless, even though the carbon dioxide which would be set free during the precipitation would tend to increase the hydron concentration. It would be necessary to have the solution saturated with carbon dioxide under a very high pressure before any addition of sodium bicarbonate. Smith (*J. Amer. Chem. Soc.*, 1918, **40**, 883) has determined the solubility of zinc carbonate in solutions of carbon dioxide under pressures ranging from 4.12 to 40.6 atmospheres. His results may be used to calculate the hydrogen-ion concentrations of the various solutions which, being in equilibrium with zinc carbonate, were just on the point of precipitating zinc carbonate, if it be assumed, as was done by Bodländer (*Z. physikal. Chem.*, 1900, **35**, 23), that metallic bases exist in carbonic acid solutions in the form of bicarbonates. If zinc oxide exists as  $Zn(HCO_3)_2$ , the concentration of  $HCO_3'$  ions is equal to twice the concentration of dissolved zinc oxide, and, the extremely small concentration of hydrions arising from carbonic acid in its second stage of dissociation being neglected, it follows that  $[H^+] = [H_2CO_3]K_1/[HCO_3'] = ([CO_2] - 2[ZnO]) \cdot 3 \times 10^{-7}/2[ZnO]$ . It was thus calculated that the  $p_H$ 's of Smith's solutions varied continuously from 4.94 to 4.33. Even when the pressure of carbon dioxide is very high, the  $p_H$  at which the normal carbonate is precipitated is not very much less than that at which the hydroxide is precipitated.

Mikusch (*Z. anorg. Chem.*, 1908, **56**, 365) determined the solubility of zinc oxide in carbon dioxide solutions in equilibrium with basic zinc carbonate. By means of the above formula, it was found that the  $p_H$ 's of his solutions lay between 6.05 and 6.15. These hydron concentrations, though somewhat higher than that at which basic zinc carbonate began to separate in the present titration, viz.,  $p_H$  5.3, happen to be those that obtained during the main course of the precipitation. As zinc carbonate exists in equilibrium with

hydrogen ions at a relatively high concentration, it follows that water will decompose zinc carbonate to give the less soluble basic carbonate.

The hydrogen-ion concentration which had to be attained in the magnesium titration before sodium carbonate produced a precipitate shows that, contrary to the statements of several workers, the precipitate was basic. The solubility product of magnesium carbonate,  $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ , at  $18^\circ$  is  $1.2 \times 10^{-4}$  (Johnson, *J. Amer. Chem. Soc.*, 1915, 37, 2014), and consequently, if complete dissociation be assumed, the solubility of magnesium carbonate is  $1.1 \times 10^{-2}$  mol. per litre. The solubility of magnesium hydroxide, obtained from the solubility product,  $2 \times 10^{-11}$ , is  $2.7 \times 10^{-4}$  mol. per litre. Hence, to precipitate the more soluble magnesium carbonate, a precipitant must be used which will supply the necessary carbonate ions without introducing the concentration of hydroxyl ions that causes the separation of magnesium hydroxide. As magnesium hydroxide is precipitated at  $p_{\text{H}}$  10.5, it is obvious that sodium bicarbonate ( $p_{\text{H}}$  8.7), even although added in large excess, cannot produce the corresponding concentration of hydrogen ions, and therefore cannot precipitate basic magnesium carbonate. It can, however, supply the carbonate ions which, provided that the magnesium salt solution is sufficiently concentrated, will cause magnesium carbonate to separate. Boussingault (*Ann. Chim. Phys.*, 1825, 29, 285) found that sodium sesquicarbonate,  $\text{Na}_2\text{CO}_3 \cdot 2\text{NaHCO}_3$ , also could be used for this purpose. The data of Auerbach and Pick (*loc. cit.*) show that the  $p_{\text{H}}$  of such a mixture, decinormal with respect to carbonic acid, is approximately 9.9, which is just a little below the value required for the precipitation of the hydroxide.

No normal carbonates of chromium, beryllium, aluminium, thorium, and zirconium are known, and, as would be expected, the precipitates they form are highly basic. The shape of the beryllium titration curve appears to be peculiar to that element, and the precipitate did not appear until 22 c.c. (= 1.1 equivs.  $\text{Na}_2\text{CO}_3$  to 1 mol.  $\text{BeSO}_4$ ) of sodium carbonate had been added. In the chromium and thorium titrations, precipitation did not begin until 20 c.c. (1.85 equivs. to 1 Cr) and 18 c.c. (1.8 equivs.), respectively, of sodium carbonate had been added. As may be seen from Table III, the precipitation which took place from thorium chloride solution with sodium carbonate was due to the attainment of the  $p_{\text{H}}$  at which the hydroxide is precipitated and therefore the precipitate was basic. Chauvenet (*Compt. rend.*, 1911, 153, 66), having found that the analysis of such a precipitate corresponded to the formula  $\text{ThO}_2 \cdot \text{CO}_2 \cdot 8\text{H}_2\text{O}$ , stated that it was

normal thorium orthocarbonate,  $\text{ThCO}_4 \cdot 8\text{H}_2\text{O}$ , a salt of a purely hypothetical acid. In the case of the zirconium titration the curious effect noted in the borate titration was again observed, opalescence not beginning until 3.4 equivalents of sodium carbonate had been added and the relatively high  $p_{\text{H}}$  of 3.95 had been attained. In the borate titration the  $p_{\text{H}}$  was 4.06, and 3.4 equivalents of borax were required. As mentioned above, this phenomenon is believed to be due to suppression of the growth of the basic particles owing to a slight solvent action of the liberated weak acid.

### *Summary.*

(1) The hydrogen-ion concentrations which govern the precipitation of basic salts containing weak acid radicals—chromates, borates, and carbonates—have been investigated.

(2) These basic precipitates are formed at the same  $p_{\text{H}}$  as the respective hydroxides; cases occurred of delayed precipitation from zirconium and thorium chloride solutions.

(3) The precipitability of the different bases as basic salts depends on the capacity of the precipitant to produce the  $p_{\text{H}}$  at which the hydroxide is precipitated. In cases where this  $p_{\text{H}}$  is only just attained, the precipitation is partial.

(4) The conditions for the precipitation of normal salts have been discussed wherever possible.

(5) The mode of dissociation of chromic acid (J., 1924, 125, 1572) has been shown to account for the action of alkali-metal chromates in precipitating basic salts.

The author's thanks are due to Professor J. C. Philip, F.R.S., for kindly granting facilities, to the Chemical Society for a grant from its Research Fund which has defrayed the cost of the rare materials, and to the Department of Scientific and Industrial Research for a personal grant.

## XXIII.—*Chloro-derivatives of m-Hydroxybenzaldehyde.*

By HERBERT HENRY HODGSON and HERBERT GREENSMITH BEARD.

THE literature of this subject describes only 6-chloro- (no m. p. recorded) and 4 : 6-dichloro-3-hydroxybenzaldehydes (Friedländer and Schenck, *Ber.*, 1914, 47, 3044), 2 : 4 : 6-trichloro-3-hydroxybenzaldehyde (Krause, *Ber.*, 1899, 32, 123), and the conversion of

*m*-hydroxybenzaldehyde into aldehydotrichloroquino-dichloride by the action of chlorine in dilute acetic acid solution (Biltz and Kammann, *Ber.*, 1901, **34**, 4118).

The chlorination and the bromination (J., 1925, **127**, 876) of *m*-hydroxybenzaldehyde proceed in general on similar lines. A noteworthy difference is the production of 2-chloro-3-hydroxybenzaldehyde and but little of the 6-chloro-isomeride by direct monochlorination, bromination under similar conditions yielding 6-bromo-3-hydroxybenzaldehyde. The proportion of the 6-chloro-isomeride increases at high temperatures. The presence of water promotes trichlorination and renders regulated chlorination very difficult.

4-Chloro-3-hydroxybenzaldehyde was obtained in good yield from the corresponding 4-nitro-compound, but, as in the case of 6-bromo-3-hydroxybenzaldehyde (*loc. cit.*, p. 878), only poor yields of 6-chloro-3-hydroxybenzaldehyde were produced by a like procedure. This compound, however, was obtained in excellent yield by converting 2-chlorobenzaldehyde quantitatively into 2-chloro-5-nitrobenzaldehyde, reducing the oxime of this, diazotising the resulting 2-chloro-5-aminobenzaldoxime, and decomposing the product.

2 : 6- and 2 : 4-Dichloro-3-hydroxybenzaldehydes were obtained by direct chlorination of 2- and 4-chloro-3-hydroxybenzaldehydes, respectively, in glacial acetic acid solution, but 6-chloro-3-hydroxybenzaldehyde yielded a mixture of dichloro-compounds from which only the 2 : 6-isomeride could be isolated. In the direct dichlorination of *m*-hydroxybenzaldehyde the main product was the 2 : 6-dichloro-compound, Friedländer and Schenck's 4 : 6-dichloro-3-hydroxybenzaldehyde (*loc. cit.*) being isolated only in small quantity. The formation of the 2 : 6-dichloro-compound from both 2- and 6-chloro-3-hydroxybenzaldehyde proves the constitution assigned to it. The presence of the 4 : 6-dichloro-compound in the product of direct dichlorination of *m*-hydroxybenzaldehyde points to chlorination of the 6-monochloro-compound partially in the 4-position. Chlorination, however, takes place preferentially in position 2, and this preference is strong support for the constitution assigned to the 2 : 4-dichloro-compound obtained quantitatively from 4-chloro-3-hydroxybenzaldehyde.

The chloro-3-hydroxybenzaldehydes all have very pronounced sternutatory properties, which are most marked in the 2 : 6-, and but slightly less so in the 2 : 4 : 6-compound. For the monochloro-3-hydroxybenzaldehydes the order is 6-, 2-, and 4-. The property is comparatively feeble in the last compound, and thus is indicated its dependence on ortho-substitution. The property vanishes on methylation, but the methoxy-compounds have now acquired a hawthorn-like odour which in turn vanishes when these are oxidised

to the benzoic acids. All these compounds attack the moistened skin, producing painful blisters.

The colours produced by the action of alcoholic potash on the *p*-nitrophenylhydrazones are all claret and conform to Chattaway and Clemo's generalisation (J., 1923, 123, 3041).

The melting points of the ethers are considerably lower than those of the hydroxy-compounds, as in the case of the bromo-compounds (*loc. cit.*, pp. 878, 879), while those of their *p*-bromophenylhydrazones exhibit noteworthy diversity.

## EXPERIMENTAL.

### *Monochloro-3-hydroxybenzaldehydes.*

*2-Chloro-3-hydroxybenzaldehyde.*—(a) *Preparation by direct chlorination.* Through a solution of *m*-hydroxybenzaldehyde (50 g.) in glacial acetic acid (160 g.) at 15°, chlorine was bubbled (rate about 3 g. per hour) until the increase in weight was 29 g. After 12 hours, the colourless crystals of *2-chloro-3-hydroxybenzaldehyde* were filtered off (22 g.) and recrystallised from dilute acetic acid; m. p. 139·5° (Found: Cl, 22·5.  $C_7H_5O_2Cl$  requires Cl, 22·6%). The crystals become pale pink on prolonged exposure to air. On removal of 80 c.c. by distillation from the filtrate, a further crop (11 g.) was obtained, m. p. 138—140° after one recrystallisation. The solvent was then completely evaporated, and the dark residue (28 g.), m. p. 80—90°, resolved into two products by partial dissolution in hot aqueous sodium carbonate (10 g. of residue, 2 g. of  $Na_2CO_3$ , 50 c.c. of  $H_2O$ ) and extraction from the cold solution with ether. The compound thus removed (3—4 g.), after two crystallisations from dilute acetic acid, had m. p. 110° and was identified as 6-chloro-3-hydroxybenzaldehyde by comparison with the synthetic product from 6-nitro-3-hydroxybenzaldehyde (see later) and with the de-alkylated product from 6-chloro-3-methoxybenzaldehyde. On acidification of the sodium carbonate solution after ether extraction, *2-chloro-3-hydroxybenzaldehyde* was precipitated; this melted at 139·5° after crystallisation from dilute acetic acid.

The quantity of sodium carbonate to be used varies slightly with each chlorination experiment, the above being a good average and arrived at by trial, *viz.*, a sequence of additions, ether extractions, etc., until only 6-chloro-3-hydroxybenzaldehyde is extracted, this being much less acidic than the *2-chloro-isomeride*.

Catalysts such as ferric chloride, quinoline, quinoline sulphate, and iodine have no effect on the chlorination, which proceeds equally well in carbon disulphide, chloroform, or carbon tetrachloride, apart from difficulties arising through the volatility of the solvent. Chlorine in solution is less efficient than flowing chlorine.

The above process was repeated, a stream of bromine being substituted for the stream of chlorine. 6-Bromo-3-hydroxybenzaldehyde was produced as in the regulated bromination previously described (*loc. cit.*, p. 876), but in improved yield.

(b) *Preparation from 2-nitro-3-hydroxybenzaldehyde.* The nitro-compound was reduced with sodium hyposulphite (*loc. cit.*), the mixture just acidified at 0° (Congo-paper) with hydrochloric acid, and sodium nitrite and hydrochloric acid were then added alternately with stirring until diazotisation was complete. The diazo-solution was decomposed with cuprous chloride in the usual way, and the product distilled with steam. The large distillate was concentrated to small bulk after addition of sodium carbonate, and acidified. The product extracted therefrom with ether had m. p. 139.5° after recrystallisation from dilute acetic acid and also when mixed with 2-chloro-3-hydroxybenzaldehyde prepared by method (a) (Found : Cl, 22.55. Calc., Cl, 22.6%).

*Evidence for its constitution.* Two g. of the presumed 2-chloro-3-hydroxybenzaldehyde obtained in (a) were treated in aqueous 20% sodium hydroxide with methyl sulphate, and the methyl ether was removed in steam and crystallised from dilute alcohol. It melted at 57°, was identical with the methyl ether of the product obtained in (b), and depressed the m. p. (52°) of 4-chloro-3-methoxybenzaldehyde. On oxidation with alkaline permanganate (*loc. cit.*, p. 880), it yielded 2-chloro-3-methoxybenzoic acid, stout, colourless rectangles, m. p. 160° (Found : Cl, 18.8.  $C_8H_7O_3Cl$  requires Cl, 19.0%). 4-Chloro-3-methoxybenzoic acid forms needles, m. p. 215–216° (Found : Cl, 18.9%).

The *acetyl* derivative, m. p. 62° (Found : Cl, 18.0.  $C_9H_7O_3Cl$  requires Cl, 17.9%), and the *benzoyl* derivative, m. p. 88° (Found : Cl, 13.5.  $C_{14}H_9O_3Cl$  requires Cl, 13.6%), both separate from alcohol in stout, rhombic crystals. The *oxime* forms colourless needles, m. p. 149°, from diluted alcohol (Found : Cl, 20.8.  $C_7H_6O_2NCl$  requires Cl, 20.7%).

The *p-nitrophenylhydrazone* crystallises in orange-red, micro-crystalline needles, m. p. 244–245°, from hot alcohol (Found : N, 14.7; Cl, 12.0.  $C_{13}H_{10}O_3N_3Cl$  requires N, 14.4; Cl, 12.2%).

The *semicarbazone* forms pale yellow needles, m. p. 236–237° (Found : Cl, 16.5.  $C_8H_8O_2N_3Cl$  requires Cl, 16.6%).

*4-Chloro-3-hydroxybenzaldehyde.*—This compound was prepared from 4-nitro-3-hydroxybenzaldehyde by method (b) above and obtained in colourless needles, m. p. 121° (Found : Cl, 22.55.  $C_7H_5O_2Cl$  requires Cl, 22.6%).

The *oxime* separates from dilute alcohol in colourless needles containing water of crystallisation. These decompose at 106–110°.

The anhydrous needles melt at 126° (Found : Cl, 20.6.  $C_7H_5O_2NCl$  requires Cl, 20.7%). The *p*-nitrophenylhydrazone separates from dilute alcohol in violet-red needles, m. p. 226–227° (Found : Cl, 11.9.  $C_{13}H_{10}O_3N_3Cl$  requires Cl, 12.2%), and the semicarbazone crystallises in pale yellow needles, m. p. 238–239° (Found : N, 20.0.  $C_8H_8O_2N_3Cl$  requires N, 19.7%).

6-Chloro-3-hydroxybenzaldehyde.—(a) *Preparation from 6-nitro-3-hydroxybenzaldehyde*. This was carried out by process (b) above. The yield was very poor. The compound crystallised from dilute acetic acid in colourless needles, m. p. 111° (Found : Cl, 22.4.  $C_7H_5O_2Cl$  requires Cl, 22.6%).

(b) *Preparation from 2-chlorobenzaldehyde. Nitration*. The chloroaldehyde (16.5 g.) was added at 0–5° during 1 hour to a solution of sodium nitrate (11 g.) in 98% sulphuric acid (200 g.). After 30 minutes, the mixture was poured on to ice, and the solid product filtered off, washed with warm dilute sodium carbonate (yield 21 g.), and recrystallised from dilute acetic acid; m. p. 78–79° (Erdmann, *Annalen*, 1893, 272, 153, gives m. p. 80°). (On oxidation with alkaline permanganate it gives 2-chloro-5-nitrobenzoic acid, m. p. 165°.) *Reduction*. This proceeds normally with sodium hyposulphite, but the resulting 2-chloro-5-aminobenzaldehyde gave only a trace of 6-chloro-3-hydroxybenzaldehyde on decomposition by the usual diazotisation-steam distillation process. The chloronitrobenzaldehyde was therefore converted into its oxime, m. p. 143°, and a solution of this (5.5 g.) in 20 c.c. of aqueous sodium hydroxide (20%) and 100 c.c. of water was added gradually to a mixture of crystallised ferrous sulphate (50 g.), 20% sodium hydroxide (70 c.c.), and water (200 c.c.). After being stirred for 1 hour, the mixture was warmed to 30–40°, filtered, and the filtrate just acidified; 2-chloro-5-aminobenzaldoxime was then precipitated. This crystallised from alcohol in colourless plates, m. p. 159–160°, which turned brown in the air (Found : Cl, 20.7.  $C_7H_7ON_2Cl$  requires Cl, 20.8%). *Diazotisation and decomposition*. The aldoxime was redissolved by the addition of concentrated hydrochloric acid (20 c.c.), diazotised at 0° (sodium nitrite, 1.75 g.), and the solution decomposed by pouring it into boiling dilute sulphuric acid (20%). The 6-chloro-3-hydroxybenzaldehyde thus formed could be removed (very slowly) in steam, but was best extracted with ether. Yield, 3 g.

The oxime separates from dilute alcohol in colourless needles containing  $1H_2O$  (Found :  $H_2O$ , 10.0.  $C_7H_6O_2NCl \cdot H_2O$  requires  $H_2O$ , 9.5%), and from absolute alcohol in anhydrous needles, m. p. 146–147° (Found : Cl, 20.6.  $C_7H_6O_2NCl$  requires Cl, 20.7%). The *p*-nitrophenylhydrazone crystallises from dilute alcohol in red

needles, m. p. 250—251° (Found : Cl, 12.0.  $C_{13}H_{10}O_3N_3Cl$  requires Cl, 12.2%).

The semicarbazone forms pale yellow needles, m. p. 236° (Found : N, 19.9.  $C_8H_8O_2N_3Cl$  requires N, 19.7%).

*Dichloro-3-hydroxybenzaldehydes.*

2 : 6-Dichloro-3-hydroxybenzaldehyde.—(a) *Preparation by chlorination of 2-chloro-3-hydroxybenzaldehyde.* A solution of 5 g. of the aldehyde in glacial acetic acid (50 c.c.) was treated at room temperature (15°) with chlorine until the weight had increased by 2.5 g. (50 minutes). The white solid that separated crystallised from water in colourless needles, m. p. 140°. These melted at 116° when mixed with 2-chloro-3-hydroxybenzaldehyde (m. p. 139.5°) (Found : Cl, 36.8.  $C_7H_4O_2Cl_2$  requires Cl, 37.1%). On concentrating the solution to 20 c.c. the bulk of the product separated. It melted at 115—118°, and at 140° after two crystallisations from water (yield 6 g.). There were no coloured by-products such as were formed during monochlorination.

(b) *Preparation from m-hydroxybenzaldehyde.* Through a solution of 20 g. of the aldehyde in glacial acetic acid (90 c.c.), chlorine was passed until the increase in weight was 22 g. After an interval the rate of absorption slackened, presumably when monochlorination had taken place. The product (15 g.) was collected after 12 hours and fractionally crystallised from water. The more sparingly soluble 2 : 6-dichloro-3-hydroxybenzaldehyde separated in stout, white, rhombic crystals (yield 12 g.), m. p. 140°, identical with those obtained in (a) (Found : Cl, 36.9%). From the concentrated mother-liquor 1.5 g. of a homogeneous substance separated in needles, m. p. 129°. This was identified with the 4 : 6-dichloro-3-hydroxybenzaldehyde of Friedländer and Schenck (*loc. cit.*) and was evidently formed from the 6-chloro-3-hydroxybenzaldehyde produced in the initial monochlorination (see above).

(c) *Preparation from 6-chloro-3-hydroxybenzaldehyde.* A solution of 2 g. of the aldehyde in glacial acetic acid (15 g.) was chlorinated for 18 minutes. Crystals (0.5 g.) of 2 : 6-dichloro-3-hydroxybenzaldehyde separated (m. p. 140°; mixed m. p. 140°). On evaporating the filtrate, a mixture of dichloro-compounds (1.5 g.), m. p. 120°, was obtained which has defied resolution (Found : Cl, 36.8. Calc., Cl, 37.1%). It is probably a mixture of the 2 : 6- and 4 : 6-isomerides. The *p*-nitrophenylhydrazone prepared from it melts at a lower temperature than that of either of these two compounds.

The oxime of 2 : 6-dichloro-3-hydroxybenzaldehyde crystallises from dilute alcohol in clusters of felted needles, m. p. 174—175° (Found : Cl, 34.2.  $C_7H_5O_2NCl_2$  requires Cl, 34.5%) and the

*p*-nitrophenylhydrazone in deep orange-red needles, m. p. 205—206° (Found : Cl, 21.6.  $C_{13}H_9O_3N_3Cl_2$  requires Cl, 21.8%).

2 : 4-Dichloro-3-hydroxybenzaldehyde.—The crystals obtained quantitatively by the direct chlorination of 4-chloro-3-hydroxybenzaldehyde as in (c) above melted at 136—140°, and at 141° after crystallisation from dilute acetic acid. Mixed with 2 : 6-dichloro-3-hydroxybenzaldehyde (m. p. 140°), they melted at 111° (Found : Cl, 36.9.  $C_7H_4O_2Cl_2$  requires Cl, 37.1%).

The *oxime* crystallises from dilute alcohol in fine needles, m. p. 188° (Found : Cl, 34.3.  $C_7H_5O_2NCl_2$  requires Cl, 34.5%), and the *p*-nitrophenylhydrazone in orange-red needles, m. p. 277—278° (decomp.) (Found : N, 13.2; Cl, 21.6.  $C_{13}H_9O_3N_3Cl_2$  requires N, 12.9; Cl, 21.8%).

#### 2 : 4 : 6-Trichloro-3-hydroxybenzaldehyde.

This is obtained normally by trichlorination in glacial acetic acid solution. The crystals separate with acetic acid of crystallisation and immediately effloresce when exposed to air. They melt at 114°, and at the same temperature after they have been crystallised from dilute acetic acid (Krause, *loc. cit.*, gives m. p. 116°).

The *sodium* salt crystallises in pure yellow needles, which are sparingly soluble in water. The *oxime* separates from dilute alcohol in needles, m. p. 174° (Krause, *loc. cit.*, gives m. p. 170°) (Found : Cl, 44.1. Calc., Cl, 44.3%).

The *p*-nitrophenylhydrazone was prepared by mixing alcoholic solutions of the components at 70° and then adding one drop of water to the cooled mixture. Crystallisation was spontaneous and the product was then almost insoluble in alcohol. It crystallises in yellow-orange, microcrystalline needles, m. p. 272—273° (decomp.) (Found : Cl, 28.9.  $C_{13}H_8O_3N_3Cl_3$  requires Cl, 29.5%).

#### Methyl Ethers of the Chloro-3-hydroxybenzaldehydes.

These were prepared from the corresponding chloro-3-hydroxy- or nitro-3-methoxy-benzaldehydes by the methods used in the case of the bromo-compounds (Hodgson and Beard, *loc. cit.*, p. 878).

The following details of the methylation are reported because their adoption greatly improves the yield : a solution of 6-nitro- or 4-nitro-3-hydroxybenzaldehyde (20 g.) in water (100 c.c.) containing sodium bicarbonate (25 g.) is boiled and methyl sulphate (25 c.c.) gradually added with vigorous shaking. The mixture is heated under reflux for 15 minutes (not longer, else the yield is diminished), and the product filtered off on cooling (yield 18.5 g.).

6-Nitro-3-methoxybenzoic acid, prepared by alkaline oxidation of the aldehyde, has m. p. 255° (Rieche, *Ber.*, 1889, 22, 2347, gives

m. p. 132—133°). It crystallises in thick, colourless prisms (Found : N, 7.0. Calc., N, 7.1%). The silver salt is a white, crystalline solid (Found : Ag, 35.2. Calc., Ag, 35.5%).

*Nitration of 3-Methoxybenzaldehyde.*—Friedländer's method (*loc. cit.*) of adding the nitric acid "*auf einmal*" proved impracticable owing to the explosive violence of the reaction.

3-Methoxybenzaldehyde (20 g.) was added drop by drop during 2 hours to a mixture of 88.1% nitric acid (94 c.c.) and water (6 c.c.) maintained below 5°. The crude product (26.5 g.) obtained on pouring the mixture on to ice was washed, dried, and dissolved in hot benzene (80 c.c.). On cooling, 2-nitro-3-methoxybenzaldehyde (12 g.) separated in crystals, m. p. 98°, and more (3 g.) was obtained on concentrating the mother-liquor. Recrystallised several times from acetic acid, it melted at 102°. The material remaining in the benzene solution, consisting mainly of 6-nitro- mixed with a little 2-nitro-3-methoxybenzaldehyde, was distilled with steam and the 6-nitro-isomeride, which is the more volatile, was thus isolated. No 4-nitro-3-methoxybenzaldehyde was detected in the mixture, for on oxidation with alkaline permanganate this yielded an acid of m. p. 250° (6-nitro-, 2-nitro-, and 4-nitro-3-methoxybenzoic acids have m. p. 255°, 251°, and 208°, respectively).

*Properties of the Chloro-3-methoxybenzaldehydes.*—These all crystallise in colourless needles from dilute alcohol, sublime readily, and are very volatile in steam.

2-Chloro-3-methoxybenzaldehyde has m. p. 56° (Found : Cl, 21.0.  $C_8H_7O_2Cl$  requires Cl, 20.8%).

The oxime crystallises from dilute alcohol in stout needles, m. p. 130.5° (Found : Cl, 18.9.  $C_8H_8O_2NCl$  requires Cl, 19.1%), the *p*-nitrophenylhydrazone from alcohol in old-gold needles, m. p. 226—227° (Found : N, 14.0; Cl, 11.9.  $C_{14}H_{12}O_3N_3Cl$  requires N, 13.7; Cl, 11.6%), and the *p*-bromophenylhydrazone from alcohol in pale yellow plates, m. p. 155—156° (Found : N, 8.3.  $C_{14}H_{12}ON_2ClBr$  requires N, 8.2%. 0.1624 G. gave 0.1592 g. of mixed silver halides. Calc., 0.1585 g.).

4-Chloro-3-methoxybenzaldehyde has m. p. 52° and acquires a beautiful silver-grey colour on keeping (Found : Cl, 20.8%).

The oxime crystallises in colourless feathery needles, m. p. 98—99° (Found : Cl, 18.9%), the *p*-nitrophenylhydrazone in old-gold needles, m. p. 251° (Found : N, 14.1%), and the *p*-bromophenylhydrazone in pale pink, feathery crystals, m. p. 134° (Found : N, 8.0%).

6-Chloro-3-methoxybenzaldehyde has m. p. 62° (Found : Cl, 21.2%) and on oxidation (*loc. cit.*, p. 880) yields 6-chloro-3-methoxybenzoic acid, which crystallises in needles, m. p. 170—171°, from dilute acetic acid (Found : Cl, 18.8. Calc., Cl, 19.0%). Peratoner

and Condorell (*Gazzetta*, 1898, **28**, i, 197) give 171° as the m. p. of the acid prepared from 6-chloro-3-methoxytoluene.

The *oxime* forms fine needles, m. p. 101·5° (Found : Cl, 19·0%), the *p*-nitrophenylhydrazone crystallises in old-gold needles, m. p. 229° (Found : N, 14·0%), and the *p*-bromophenylhydrazone in pale yellow plates, m. p. 100° (Found : N, 8·0%).

2 : 6-Dichloro-3-methoxybenzaldehyde has m. p. 102° (Found : Cl, 34·9.  $C_8H_6O_2Cl$  requires Cl, 34·6%) and on oxidation yields 2 : 6-dichloro-3-methoxybenzoic acid, which crystallises in stout needles, m. p. 149·5°, from dilute alcohol (Found : Cl, 32·0.  $C_8H_6O_3Cl_2$  requires Cl, 32·1%).

The *p*-nitrophenylhydrazone forms old-gold needles, m. p. 214—215° (Found : Cl, 20·7.  $C_{14}H_{11}O_3N_3Cl_2$  requires Cl, 20·9%).

2 : 4-Dichloro-3-methoxybenzaldehyde has m. p. 82° (Found : Cl, 35·0%) and on oxidation yields 2 : 4-dichloro-3-methoxybenzoic acid, which crystallises in colourless needles, m. p. 163° (Found : Cl, 32·0%).

The *p*-nitrophenylhydrazone forms old-gold needles, m. p. 258—260° (Found : Cl, 20·7%).

2 : 4 : 6-Trichloro-3-methoxybenzaldehyde was prepared by methylating the hydroxy-compound. It is only slowly volatile in steam and crystallises from alcohol in stout needles, m. p. 76° (Found : Cl, 44·1.  $C_8H_5O_2Cl_3$  requires Cl, 44·4%). By very slow oxidation with alkaline permanganate it is converted into 2 : 4 : 6-trichloro-3-methoxybenzoic acid, which crystallises in needles, m. p. 109° (Found : Cl, 41·6. Calc., Cl, 41·7%). Zincke (*Annalen*, 1891, **261**, 239) gives m. p. 90°.

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD.

[Received, August 17th, 1925.]

## XXIV.—The Nitration of *m*-Bromophenol.

By HERBERT HENRY HODGSON and FRANCIS HARRY MOORE.

THE systematic study of the direct nitration of *m*-bromophenol does not appear to have been undertaken, although the following derivatives have been obtained by indirect means : 3-bromo-6-nitrophenol (Laubenheimer, *Ber.*, 1876, **9**, 1155), 3-bromo-6- and -4-nitrophenols (Auwers and Deines, *Zentr.*, 1924, **II**, No. 18), and 3-bromo-4 : 6-dinitrophenol (Körner, *J.*, 1876, **1**, 2317), Tijmstra (*Rec. trav. chim.*, 1902, **21**, 292) has described 3-bromo-2 : 4 : 6-trinitrophenol.

The present investigation on the direct nitration of *m*-bromophenol was carried out on similar lines to that of *m*-chlorophenol (J., 1925, 127, 1599). 2-, 4-, and 6-Nitro-3-bromophenols, 4:6-, 2:6-, and 2:4-dinitro-3-bromophenols, and 2:4:6- and 2:5:6-trinitro-3-bromophenols have been prepared in excellent yield. Their properties are very similar to those of the corresponding chloro-compounds.

3-Bromo-2-nitrophenol forms a remarkably labile, colourless hydrate, m. p. 35°, which changes on keeping, particularly in dry air, to a bright yellow, anhydrous form of m. p. 65—67°; this reverts to the colourless hydrate in moist air. The sensitiveness of the compound is such as to make it an approximate indicator of atmospheric humidity. This behaviour of the substance led to a further examination of the previously reported, colourless 3-chloro-2-nitrophenol (*loc. cit.*, p. 1601), which was found to be likewise a hydrate, but much more stable in air than that of the bromo-compound. Our analyst reported on a sample which he had thoroughly dried, but made no comment on the change of colour. This we ascribed at that time to atmospheric ammonia.) The analytical datum, therefore, is for anhydrous 3-chloro-2-nitrophenol.

Since 3-bromo-5-nitrophenol has been described by Blanksma (*Rec. trav. chim.*, 1892, 21, 254) and Heller and Kammann (*Ber.*, 1909, 42, 2191), the anhydrous substance mentioned above must have the only remaining constitution, *viz.*, that of 3-bromo-2-nitrophenol.

The order of increasing solubility in water of the three dinitro-compounds is: 2:6-, 4:6-, and 2:4-. They form characteristic silver salts, that of 3-bromo-4:6-dinitrophenol existing in three forms (two yellow and one red); Körner's observation (*loc. cit.*) is thus confirmed and supplemented.

The orientations tentatively proposed for the dinitro-compounds follow from the modes of preparation and by analogy with the corresponding chloro-compounds (*loc. cit.*). In addition is the following evidence: (1) All three dinitro-compounds are convertible into 3-bromo-2:4:6-trinitrophenol; the two nitro-groups in each compound are therefore in the meta-position with respect to each other. (2) The constitution of 3-bromo-4:6-dinitrophenol is definitely settled by its preparation from 3-bromo-4- and -6-nitrophenols and from 1:3-dibromo-4:6-dinitrobenzene. (3) 3-Bromo-2:6- and -2:4-dinitrophenols not only differ in melting point and solubility and in the properties of their silver salts, but the former can be prepared from both 3-bromo-2- and -6-nitrophenols, whereas the 2:4-dinitro-compound is obtainable

only from a sulphonated 3-bromo-2-nitrophenol. (4) The 2:6- and 2:4-dinitro-compounds both yield 2:4-dinitro-*m*-phenylenediamine when heated in a sealed tube with ammonia, and each specimen of this compound gives 2:4-dinitroresorcinol when boiled with aqueous sodium hydroxide. The vicinal positions of the four atoms or groups in each of these two bromodinitrophenols are thus established. Also these two compounds are converted into 2:4-dinitroresorcinol by boiling alkalis.

After prolonged sulphonation followed by treatment with excess of nitric acid, *m*-bromophenol gives a trinitro-sulphonic acid; this on hydrolysis yields 3-bromo-2:5:6-trinitrophenol, which is volatile in steam.

#### EXPERIMENTAL.

Unless otherwise stated, the methods of preparation of the 3-bromonitrophenols are those of the corresponding chloro-compounds (*loc. cit.*) with appropriate modifications.

##### *Mononitration of m-Bromophenol.*

(a) *By Sodium Nitrate and Sulphuric Acid* (*loc. cit.*, p. 1600).—3-Bromo-6-nitrophenol (yield 8.9 g. from 29 g. of *m*-bromophenol) is volatile in steam and crystallises from light petroleum in yellow prisms, m. p. 42°, having a characteristic odour (Auwers and Deines, m. p. 41.5–42.5°) (Found: Br, 36.7. Calc., Br, 36.7%). The methyl ether forms colourless plates, m. p. 85.5°, the benzoate crystallises in cream-coloured needles, m. p. 104°, and the sodium salt in scarlet needles. [The corresponding derivatives of 3-chloro-6-nitrophenol form colourless plates, m. p. 72°, colourless needles, m. p. 91°, and scarlet needles, respectively.]

3-Bromo-4-nitrophenol (yield 18 g.) is non-volatile in steam and crystallises from light petroleum in yellowish-white, odourless needles, m. p. 131° (Found: Br, 36.6. Calc., Br, 36.7%). It is also formed readily by oxidation of 4-nitroso-3-bromophenol (J., 1925, 127, 2262). The methyl ether crystallises in short, colourless needles, m. p. 45°, the benzoate in cream-coloured needles, m. p. 102°, and the sodium salt in amber needles. [3-Chloro-4-nitrophenol: methyl ether, short, colourless needles, m. p. 56.5°; benzoate, colourless needles, m. p. 96°; orange sodium salt.]

(b) *By Nitric Acid in Oleum* (*loc. cit.*, p. 1600).—On dilution of the nitration mixture and hydrolysis in a current of steam, the first distillates were oily, but from the later ones almost colourless needles separated on cooling; m. p. 35° (yield 13 g. or 60%). The product at first separated from light petroleum in bright yellow,

curly needles, m. p. 65—67°, but later crystals were admixed with the colourless product, which when separated mechanically had m. p. 33°. The yellow compound dissolves in aqueous sodium hydroxide to a red solution, from which the colourless variety is precipitated on acidification in the cold.

The yellow variety is anhydrous 3-bromo-2-nitrophenol (Found : Br, 36.6.  $C_6H_4O_3NBr$  requires Br, 36.7%). It has a characteristic odour distinct from that of 3-bromo-6-nitrophenol. The sodium salt crystallises in red needles, the methyl ether from dilute alcohol in white needles, m. p. 73° (Found : Br, 34.2.  $C_7H_6O_3NBr$  requires Br, 34.4%), and the benzoate from alcohol in white, feathery needles, m. p. 133° (Found : Br, 24.7.  $C_{13}H_8O_4NBr$  requires Br, 24.8%).

The colourless variety could not be dried in sufficient quantity for analysis owing to its ready conversion into the anhydrous form and in consequence its degree of hydration has not been determined.

3-Chloro-2-nitrophenol.—The anhydrous yellow variety, after prolonged drying over concentrated sulphuric acid, melts at 45—47° (Found : Cl, 20.6.  $C_6H_4O_3NCl$  requires Cl, 20.5%).

The hydrated white variety, crystallised from light petroleum, had m. p. 37.5—38° (Found : Cl, 18.5.  $C_6H_4O_3NCl \cdot H_2O$  requires Cl, 18.5%). On desiccation over concentrated sulphuric acid, 1.2108 g. lost 0.1128 g. after 20 hours and 0.1136 g. after 24 hours. The calculated loss for 1 mol.  $H_2O$  is 0.1138 g. (*M*, cryoscopic in phenol, 99.  $C_6H_4O_3NCl$  requires *M*, 173.5; and  $C_6H_4O_3NCl \cdot H_2O$  requires *M*, 96 if the water is completely abstracted by phenol).

#### *Dinitration of m-Bromophenol.*

The mixed acid referred to below contained 98% sulphuric acid (15 vols.), 70% nitric acid (12 vols.), and water (9 vols.).

3-Bromo-4 : 6-dinitrophenol.—(a) *m*-Bromophenol (4.4 g.) was added gradually to a mixture of 90.5% nitric acid (5 c.c.) and glacial acetic acid (5 c.c.), and after 12 hours the red solution was warmed for 30 minutes on the water-bath, poured into water, and steam-distilled. A little 3-bromo-6-nitrophenol passed over, followed by the main product, which solidified in colourless crystals, m. p. 90° (yield 2 g.). Recrystallised from light petroleum, this melted at 92° (Found : N, 10.7; Br, 30.4. Calc. for  $C_6H_3O_5N_2Br$  : N, 10.6; Br, 30.4%).

(b) 3-Bromo-6- and -4-nitrophenols (2 g.) were each added gradually to the mixed acid (8 c.c.) cooled in running water, the mixture was kept 2 hours, heated at 80° for 15 minutes, diluted, and steam-distilled. The product extracted from the distillate by ether crystallised from water or light petroleum in white needles,

m. p. 92°, in both cases. The liquor in the steam flask deposited in each case, on cooling, 3-bromo-2 : 4 : 6-trinitrophenol.

(c) 1 : 3-Dibromo-4 : 6-dinitrobenzene (3 g.) was boiled for 6 hours with aqueous sodium carbonate (3 g. in 20 c.c. of water), and the solution filtered hot and made just acid. The precipitate was crystallised from water; m. p. 92°.

The identity of the products in (a), (b), and (c) was established by the melting points of their mixtures.

The *silver* salt formed as a voluminous, yellow, gelatinous precipitate when a neutral solution of the ammonium salt was treated with aqueous silver nitrate. It gradually changed to a red, crystalline variety on keeping (the transition being accelerated by rubbing with a glass rod) which was but sparingly soluble in aqueous ammonia and in the presence of which conversion into a yellow, crystalline form occurred (Found : Ag, 29.0. Calc., Ag, 29.2%).

3-Bromo-2 : 6-dinitrophenol.—(a) This was obtained from a mixture of 1 g. of 3-bromo-2-nitrophenol and 4 c.c. of mixed acid (*loc. cit.*, p. 1602). The steam-volatile product solidified as a feathery, crystalline mass, m. p. 124°, and crystallised from light petroleum in colourless needles, m. p. 131° (Found : Br, 30.6.  $C_6H_3O_5N_2Br$  requires Br, 30.4%). A non-volatile product was 3-bromo-2 : 4 : 6-trinitrophenol.

(b) 3-Bromo-6-nitrophenol (4 g.) was slowly added to 7 c.c. of oleum (27%  $SO_3$ ) with cooling. The deep red solution was kept for 3 hours at 10°, then nitrated with 0.8 c.c. of nitric acid (90.5%) in 4 c.c. of oleum (27%  $SO_3$ ), and, after 1 hour, the mixture was poured into water.

Much decomposition occurred on hydrolysis but a small quantity of 3-bromo-2 : 6-dinitrophenol was obtained, m. p. 131° (Found : Br, 30.3%).

By the same procedure 3-chloro-2 : 6-dinitrophenol was obtained from 3-chloro-6-nitrophenol.

The red, crystalline *silver* salt is fairly easily soluble in water and readily in ammonia (Found : Ag, 29.1%).

3-Bromo-2 : 4-dinitrophenol was prepared as was 3-chloro-2 : 4-dinitrophenol (*loc. cit.*, p. 1602). The steam distillate deposited 3-bromo-2 : 6-dinitrophenol (0.7 g.), which was identified by its red silver salt, m. p. 131°, and by analysis (Found : Br, 30.5%). The filtrate gave to ether 0.8 g. of a product, probably 3-bromo-2 : 4-dinitrophenol, which crystallised from water in fine, silky, cream-coloured needles, m. p. 175° (Found : Br, 30.6.  $C_6H_3O_5N_2Br$  requires Br, 30.4%).

The yellow, crystalline *silver* salt was insoluble in ammonia (Found : Ag, 29%).

Attempts to prepare 3-bromo-2 : 4-dinitrophenol from 3-bromo-4-nitrophenol were unsuccessful owing to its decomposition during the sulphonation-nitration process described under (b) above.

*Separation of a Mixture of 3-Bromo-2 : 6- and -2 : 4-dinitrophenols.*—The mixture was converted, by the method described under 3-bromo-4 : 6-dinitrophenol above, into silver salts, which were digested with cold aqueous ammonia. The red silver salt of 3-bromo-2 : 6-dinitrophenol dissolved completely, the yellow isomeride was insoluble. The pure phenols liberated by hydrochloric acid had m. p. 131° and 175°, respectively.

*Action of Ammonia on 3-Bromo-2 : 6- and -2 : 4-dinitrophenols.*—These (1.3 g.) were separately heated in a sealed tube with concentrated ammonia (5 c.c.) to 150° during 2 hours. On cooling, the products were obtained quantitatively as brownish-yellow needles (0.9 g.) in each case, m. p. 258°. Recrystallised from water or glacial acetic acid, they melted, separately or mixed, at 258°. The substance was sparingly soluble in water, alcohol, ether, or glacial acetic acid (Found : N, 28.1 and 28.5, respectively. Calc. for  $C_6H_6O_4N_4$  : N, 28.3%). Barr states (*Ber.*, 1888, **21**, 1545) that 2 : 4-dinitro-*m*-phenylenediamine melts at 250° with partial decomposition. 4 : 6-Dinitro-*m*-phenylenediamine melts at about 300° (Nietzki and Schedler, *Ber.*, 1897, **30**, 1667).

The 2 : 4-dinitroresorcinol obtained from each of these products by the action of boiling aqueous sodium hydroxide melted, alone or mixed with the other, at 146° (Beilstein gives m. p. 142°) (Found : N, 14.1 and 13.9, respectively. Calc. for  $C_6H_4O_6N_2$  : N, 14.0%). Each product gave a red, gelatinous silver salt.

Mixtures of 3-bromo-2 : 6- and -2 : 4-dinitrophenols gave 2 : 4-dinitro-*m*-phenylenediamine when heated with ammonia as above, and 2 : 4-dinitroresorcinol on subsequent boiling with aqueous sodium hydroxide. Barr's statement (*loc. cit.*) that conversion into 2 : 4-dinitroresorcinol does not occur is therefore disproved.

Finally 3-bromo-2 : 6- and -2 : 4-dinitrophenols when separately boiled with aqueous sodium hydroxide gave the same 2 : 4-dinitroresorcinol of m. p. 146° and mixed m. p. 146°.

#### *Trinitration of m-Bromophenol.*

3-Bromo-2 : 4 : 6-trinitrophenol, prepared as was the corresponding chloro-compound (*loc. cit.*, p. 1603), is non-volatile in steam and crystallises from water in characteristic clusters of colourless, leaf-like forms, m. p. 149° (Tijmstra, *loc. cit.*, gives 144° for the m. p. of the compound crystallised from acetic acid) (Found : Br, 25.8. Calc., Br, 26.0%).

The same compound was also obtained by nitrating 3-bromo-

4:6-, -2:6-, and -2:4-dinitrophenols: 0.5 g. of each was dissolved, by gentle warming, in 98% sulphuric acid (3 c.c.), and the cooled solution treated with 70% nitric acid (1 c.c.) in 98% sulphuric acid (2 c.c.). After 3 hours, the solution was warmed on the water-bath for a few minutes and poured into water. On passage of steam, no volatile product was detected, and the solution, on cooling, deposited crystals of m. p. 149°. The yellow silver salt was insoluble in ammonia.

3-Bromo-2:5:6-trinitrophenol was prepared as was the chloro-compound (*loc. cit.*, p. 1603). It is volatile in steam and crystallises from water in fern-like clusters, m. p. 146° (Found: Br, 26.0.  $C_6H_2O_7N_3Br$  requires Br, 26.0%). The yellow silver salt is soluble in water but insoluble in ammonia.

Potassium 3-bromo-2:5:6-trinitrophenol-4-sulphonate, isolated during the above preparation, gave characteristic, yellow crystals from alcohol which exploded when heated [Found: S, 6.7; Br, 17.4. Calc. for  $C_6Br(OK)(NO_2)_3 \cdot SO_3K$ : S, 6.8; Br, 17.2%].

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals used in this investigation.

## XXV.—Condensation of 3-Bromo- and 3-Nitro-4-dimethylaminobenzaldehyde with Ethyl Acetoacetate and Ammonia.

By LEONARD ERIC HINKEL and WILLIAM REES MADEL.

ORTHO- and para-substituted aromatic dialkylamines do not react normally with nitrous acid (Würster and others, *Ber.*, 1879, **12**, 1796, 1816; Niementowski, *ibid.*, 1887, **20**, 1890; Koch, *ibid.*, p. 2459; Grimaux, *Compt. rend.*, 1891, **112**, 290, 727; Friedländer, *Monatsh.*, 1898, **19**, 627). We have observed that by the action of nitrous acid the aldehydo-group in *p*-dimethylaminobenzaldehyde is replaced by a nitroso-group, and that no action occurs with the corresponding 3-bromo- and 3-nitro-derivatives. It is to be expected, therefore, that the presence of a substituent in the ortho-position with respect to the dimethylamino-group will counteract any influence which this group may have on the reactivity of the aldehydo-group.

The behaviour of 3-bromo- and 3-nitro-4-dimethylaminobenzaldehyde in Hantzsch's pyridine synthesis has therefore been investigated, since it has been shown by one of us (J., 1920, **117**, 137)

that the introduction of a *p*-dimethylamino-group into benzaldehyde exerts a marked influence upon the condensation. In this case, not only is the yield of the dihydropyridine derivative considerably reduced, but the oxidation of the latter with nitrous fumes follows an unusual course, the dimethylaminophenyl group being eliminated as *p*-nitrosodimethylaniline. The dihydropyridine derivative readily yields a methiodide and a stable hydrochloride which is insoluble in water. In the condensation with 3-bromo-4-dimethylaminobenzaldehyde the effect of the introduction of the bromine atom is strikingly shown, not only in the greatly increased yield but also in the properties and the stability of the dihydrolutidine (I).

The oxidation of this compound proceeds quite normally with nitrous fumes. The dimethylamino-group, however, no longer reacts with methyl iodide even when heated under pressure, but the compound forms a hydrochloride which is very soluble in water. In this condensation the combined effects of the bromine and the dimethylamino-group cause the aldehyde to react in a manner closely resembling that of benzaldehyde.

With 3-nitro-4-dimethylaminobenzaldehyde the condensation proceeds normally. The yield of the product is not so great as in the preceding case, nevertheless it is considerably higher than that obtained from *p*-dimethylaminobenzaldehyde (*loc. cit.*), so that the influence of the nitro-group on the dimethylamino-group, although marked, is not so great as that of bromine. The stability of the dihydrolutidine derivative appears to be between those of the compounds derived from *p*-dimethylaminobenzaldehyde and its 3-bromo-derivative, since its oxidation with nitrous fumes must be more carefully regulated in order to prevent the elimination of the nitrodimehtylaminophenyl group. As in the previous condensation, the dihydrolutidine derivative does not form a methiodide, but is soluble in dilute mineral acids.

The further study of the effect of substituents in benzaldehyde upon the course of Hantzsch's pyridine synthesis is in progress.

#### EXPERIMENTAL.

*Ethyl 4-(m-Bromo-p-dimethylaminophenyl)-2:6-dimethyl-1:4-dihydropyridine-3:5-dicarboxylate* (I).—3-Bromo-4-dimethylaminobenzaldehyde (1 mol.) dissolved in ethyl acetoacetate (2 mols.) was mixed with an alcoholic solution of ammonia (1 mol.). After remaining at the ordinary temperature for 1 hour, the mixture was heated for 7 hours in a closed flask. After removal of some of the alcohol the mixture solidified. The crude product crystallised from

alcohol in fine, yellowish-white needles (yield 82%), m. p. 133° (Found: Br, 17.5.  $C_{21}H_{27}O_4N_2Br$  requires Br, 17.7%). The ester is very soluble in dilute hydrochloric acid and is not hydrolysed even in the boiling solution.

*Ethyl 4-(m-Bromo-p-dimethylaminophenyl)-2:6-dimethylpyridine-3:5-dicarboxylate*.—Nitrous fumes were led into a thin paste of the dihydro-ester and alcohol until a clear solution was obtained. The viscous mass obtained after removal of the alcohol slowly solidified. It crystallised from aqueous alcohol in pale yellow crystals, m. p. 91° (Found: Br, 17.7.  $C_{21}H_{25}O_4N_2Br$  requires Br, 17.8%).

*Hydrolysis*. The ester (7 g.) was boiled for several hours with 30% alcoholic potassium hydroxide (50 c.c.). No potassium salt separated (compare J., 1920, 117, 140). The excess of potassium hydroxide was removed as carbonate, and the concentrated filtrate, after the addition of a small quantity of ether, deposited white crystals of the potassium salt.

*Ethyl 4-(m-Nitro-p-dimethylaminophenyl)-2:6-dimethyl-1:4-dihydropyridine-3:5-dicarboxylate*.—3-Nitro-4-dimethylaminobenzaldehyde (1 mol.), ethyl acetoacetate (2 mols.), and ammonia (1 mol. in alcohol) were heated together under the conditions previously described. After cooling, the solution was filtered from the crystals which had separated, and concentrated, a further crop being thus obtained. The product could be obtained in better yield by replacing ethyl acetoacetate and ammonia by ethyl  $\beta$ -aminocrotonate in alcoholic solution (yield 70%). The crude product crystallised from aqueous alcohol in deep yellow plates, m. p. 127° (Found: N, 10.3.  $C_{21}H_{27}O_6N_3$  requires N, 10.1%).

*Ethyl 4-(m-Nitro-p-dimethylaminophenyl)-2:6-dimethylpyridine-3:5-dicarboxylate*.—The oxidation of the dihydro-ester was carried out as previously described; the nitrous fumes were, however, led in very slowly and rise in temperature prevented by external cooling with water. As soon as the dihydro-ester had dissolved, the passage of nitrous fumes was discontinued; the solution almost immediately deposited crystals, and a further crop was obtained by concentrating the mother-liquor. The base crystallised from alcohol in large, yellow crystals, m. p. 109° (Found: C, 60.6; H, 6.1; N, 10.6.  $C_{21}H_{25}O_6N_3$  requires C, 60.7; H, 6.0; N, 10.1%).

We are indebted to Messrs. J. R. Geigy & Co. for a gift of the p-dimethylaminobenzaldehyde used in this investigation.

XXVI.—*The Oxidation of Certain Sesquiterpenes with Chromyl Chloride and Chromic Acid.*

By DAVID TEMPLETON GIBSON, JOHN MONTEATH ROBERTSON, and JAMES SWORD.

THE action of chromyl chloride on the simple terpenes, as is the case with aromatic hydrocarbons, results in the formation of compounds of the formula  $C_{10}H_{16}, 2CrO_2Cl_2$ , which on treatment with water yield mixtures of oxidation products of the terpene and, as a rule, some chlorinated compounds (J., 1922, **121**, 2717; 1924, **125**, 107). Extending this work to the sesquiterpenes cadinene,  $\beta$ -caryophyllene, and cedrene, we now find that additive products are formed just as in the former instances, but there is a greater absorption of the reagent. The additive compound  $C_{15}H_{24}, 2CrO_2Cl_2$  apparently is contaminated with  $C_{15}H_{24}, 3CrO_2Cl_2$ , or perhaps with  $C_{15}H_{22}, 2CrO_2Cl$ . The amount of oxidising reagent required in its formation indicates the former. These compounds are not so sensitive to atmospheric moisture as those obtained from the simple terpenes and aromatic hydrocarbons; but when they are decomposed by water they yield only a relatively small amount of tractable oxidation product.

Étard (*Ann. Chim. Phys.*, 1881, **22**, 218) states that the chromyl chloride additive product of toluene is decomposed by ether, ethyl chloride being evolved. We find, however, that ether carefully dried over sodium has no action whatever either on the toluene additive compound or on the new series of compounds we have prepared.

$\beta$ -Caryophyllene forms an additive compound having the approximate composition  $C_{15}H_{24}, 2\frac{1}{2}CrO_2Cl_2$ . On decomposition with water, this yields a ketone,  $C_{15}H_{24}O$  (which gave a crystalline *semicarbazone*), an *unsaturated ketone*,  $C_{15}H_{20}O_2$ , caryophyllene alcohol, and some chlorinated oxidation products, but no aldehyde.

From cedrene, an additive compound of similar composition was obtained, which on decomposition yielded a compound,  $C_{15}H_{24}O$ , which gives a *semicarbazone*, together with chlorinated products. The compound  $C_{15}H_{24}O$  does not give an acid upon further oxidation with nitric acid, and is therefore probably not an aldehyde.

When the additive compound obtained from cadinene was decomposed, in addition to a small quantity of an acid, a 10% yield of a steam-volatile, *neutral product* was obtained which did not give a crystalline semicarbazone. Owing to the difficulty of preparing this hydrocarbon, we did not consider that the yields justified the continuation of this part of the investigation, and it seemed probable

that a direct oxidation with chromic acid might lead to more valuable results.

Wallach (*Annalen*, 1887, 238, 87) found that, on oxidation with chromic acid, cadinene gave a mixture of lower fatty acids. With potassium dichromate and sulphuric acid mixture, we obtained products which were entirely acid. On careful oxidation with chromic anhydride, however, we obtained a *compound*, b. p. 180—196°/12 mm., the composition of which agrees with the formula  $C_{15}H_{24}O_2$ . No definite evidence of the presence of ketonic or hydroxyl groups could be obtained. When treated with metallic sodium, the compound polymerised. This compound closely resembles the hydroxy-ketone described by Ruzicka and Stoll (*Helv. Chim. Acta*, 1924, 7, 94).

#### EXPERIMENTAL.

In each case described below, the additive compound was prepared by allowing the reagents to react in carbon tetrachloride solution at such dilution (10%) as allowed the course of the reaction to be carefully controlled.

*Action of Chromyl Chloride on  $\beta$ -Caryophyllene.*— $\beta$ -Caryophyllene, b. p. 119°/9 mm.,  $n_D^{20}$  1.5030,  $[\alpha]_D^{25}$  — 5.2°, gave an additive product which had the approximate composition  $C_{15}H_{24} \cdot 2\frac{1}{2}CrO_2Cl_2$  and remained unaltered when different proportions of chromyl chloride were used (Found: Cr, 21.0, 20.9, 21.3.  $C_{15}H_{24} \cdot 2CrO_2Cl_2$  requires Cr, 20.0%.  $C_{15}H_{24} \cdot 3CrO_2Cl_2$  requires Cr, 23.3%). It was decomposed in the usual way. The steam-distilled oil (17 g. from 75 c.c. of caryophyllene) was fractionated at 1 mm., and a main product (10 g.), b. p. 120—140°, Cl, 5%, was collected. This fraction was practically freed from chlorine by refluxing with zinc dust in alcoholic solution for a month. The oil thus purified distilled mainly at 100—110° (A) and 110—125° (B) at 0.5 mm. (A), which was saturated, was treated (5 g.) in the usual way with semicarbazide acetate, being allowed to stand 2 months. After removal of the solvent and uncombined oil, the residue was recrystallised from methyl alcohol, and the resulting semicarbazone (1 g.), after further purification from benzene, melted at 234° (Found: C, 69.3; H, 10.0; N, 15.4.  $C_{15}H_{24}ON_3$  requires C, 69.4; H, 9.8; N, 15.2%).

The uncombined oil on evaporation deposited crystals which, after washing with ligroin, melted at 92—95° and did not depress the melting point of an authentic specimen of caryophyllene alcohol.

The higher fraction (B) gave a non-crystalline semicarbazone which, after removal of solvent and uncombined oil, was distilled in steam with oxalic acid, and the regenerated oil collected. It was

unsaturated; b. p.  $118^{\circ}/1$  mm. (Found: C, 77.8; H, 9.4.  $C_{15}H_{20}O_2$  requires C, 77.6; H, 8.9%).

*Action of Chromyl Chloride on Cedrene.*—Cedrene, b. p.  $123-125^{\circ}/8$  mm.,  $d_4^{20}$  0.9361,  $[\alpha]_D^{17} - 55.4^{\circ}$ ,  $n_D^{17}$  1.50170, gave an additive compound similar to the one described above. When it was decomposed, steam-distillation of the product gave an oil which contained chlorine (Found: Cl, 4.2%). The chlorine content was reduced to 0.5% by refluxing in alcohol with zinc dust for 8 weeks. The oil then distilled at  $93^{\circ}/0.15$  mm., and the distillate contained no chlorine;  $n_D^{15}$  1.5462 (Found: C, 81.0; H, 10.6; *M*, cryoscopic in benzene, 224, in camphor, 223.  $C_{15}H_{24}O$  requires C, 81.7; H, 11.0%; *M*, 220).

The oil gave a good yield of an amorphous semicarbazone, which was dissolved in methyl alcohol to free it from the solid condensation product which semicarbazide forms with itself, purified with animal charcoal, and added to a large excess of water. This retained the last traces of the condensation product and precipitated the *semicarbazone* as a white powder (Found: C, 70.4; H, 10.0; N, 14.4.  $C_{15}H_{27}ON_3$  requires C, 69.4; H, 9.8; N, 15.2%).

*Action of Chromyl Chloride on Cadinene.*—Cadinene, b. p.  $130-134^{\circ}/10$  mm.,  $d_4^{20}$  0.9189,  $n_D^{20}$  1.5097,  $[\alpha]_{488}^{15} - 125^{\circ}$ , regenerated from the dihydrochloride, m. p.  $118^{\circ}$ , gave an additive compound of similar composition to those described above. On decomposition, it yielded a small quantity of a non-crystalline acid, and a neutral product in about 10% yield, consisting of a steam-volatile oil, which was mixed with semicarbazide acetate, but even after prolonged treatment no crystalline semicarbazone could be obtained.

*Chromic Acid Oxidation of Cadinene.*—Chromic anhydride (70 g.) dissolved in a little water and diluted with acetic acid was slowly added with constant stirring to cadinene (50 g.) in glacial acetic acid (250 g.) during 1 hour, the temperature being kept below  $50^{\circ}$  by occasional cooling. Finally the mixture was heated on the water-bath until green, and water added. The neutral product was isolated and purified by fractional distillation at 0.5 mm. After removal of unchanged cadinene (dihydrochloride, m. p.  $118^{\circ}$ ) and a small amount of acid, a light yellow oil was obtained, b. p.  $180-196^{\circ}/12$  mm.,  $n_D^{25}$  1.5095 (Found: C, 76.6; H, 10.2.  $C_{15}H_{24}O_2$  requires C, 76.3; H, 10.2%).

This oil was unsaturated towards bromine and alkaline permanganate. It did not give a semicarbazone, neither did it react with *p*-nitrobenzoyl chloride, or with phenylcarbimide. Addition of finely divided sodium produced polymerisation.

The acid products of the oxidation were isolated and purified.

The chief product gave the following analysis: C, 59.2; H, 8.4%. The silver salt gave Ag, 35.4%.

Cadinene (10 g.) in acetic acid (50 c.c.) was treated with potassium dichromate (20 g.) and sulphuric acid (14 c.c.) in aqueous acetic acid. The reaction was similar to that described above. After a little unchanged cadinene had been removed, there resulted only an acid product which appears to be identical with the acid described above (Found: C, 59.7; H, 8.6%. Silver salt gave Ag, 35.1%).

We desire to express our thanks to Professor G. G. Henderson for the interest which he took in this work, and to the Carnegie Trust for a grant which helped to defray the expense.

UNIVERSITY OF GLASGOW.

[Received, October 7th, 1925.]

## XXVII.—*Action of Hydrogen Fluoride on Compounds of Selenium and Tellurium. Part I. Selenium Dioxide.*

By EDMUND BRYDGES RUDHALL PRIDEAUX and JOHN O'NEIL MILLOTT.

THE action of hydrofluoric acid on selenious compounds does not appear to have been studied, except perhaps with negative results, no doubt on account of the unstable and corrosive nature of the reagents and of such compounds as they might be expected to form. Hydrofluoric acid probably does not form a definite product as it does with tellurium dioxide. A solid oxyfluoride of selenium was prepared by Moissan ("Le Fluor," p. 123) by the action of fluorine on selenium, but was not analysed. In the present research anhydrous hydrogen fluoride was used.

A remark of Ditte (*Compt. rend.*, 1876, **83**, 225) bears on the present research, *viz.*, that hydrofluoric acid is energetically absorbed by selenium dioxide; the product, however, was not examined.

*Preparation of the Selenium Dioxide.*—The method used was substantially that of Divers and Haga (*J.*, 1899, **75**, 537). The selenium was dissolved in concentrated nitric acid and after several evaporations to dryness with water the product was transferred hot to a long glass tube and sublimed in a current of oxygen dried by calcium chloride and phosphoric oxide. The product was white or pink and we consider that it was dry; the test for dryness described by Prideaux and Green (*J. Physical Chem.*, 1924, **28**, 1274) was applied. The oxide, dissolved in dry alcohol, did not immediately redden litmus paper. Also a sample, heated with anhydrous copper sulphate, gave no blue colour.

*Preparation of Hydrogen Fluoride.*—Commercial sodium hydrogen

fluoride of high quality and practically dry was finely ground and strongly heated before each distillation. This was carried out in a copper apparatus. The still, still-head, and receiver were made by Mr. E. R. Walter, B.Sc.Eng., whose skill and advice have been much appreciated. The still-head was fitted with an additional tube through which a current of dry air could be blown. The straight condenser cooled by ice-water was succeeded by a spiral condenser cooled by ice and salt. After the first runnings the liquid hydrofluoric acid was colourless and immediately gelatinised filter-paper. The receiver was then screwed on. It contained a platinum crucible, in which the acid collected, and was cooled by ice or a freezing mixture. The vapour passing on was dry, as the condensed acid would retain any traces of water. It passed over the selenium dioxide, which was usually contained in a platinum bottle supplied with platinum inlet and outlet tubes. The vapour then passed through a bubble-counter containing dry chloroform, and finally through a soda-lime tube.

The hydrogen fluoride was rapidly absorbed by the selenium dioxide, which liquefied and became warm. The liquid first formed was not analysed, but it contained quite a small proportion of hydrogen fluoride, the selenium dioxide being very soluble. As the hydrogen fluoride bubbled into the liquid it was continually absorbed. The experiment was stopped usually when the liquid contained 40 to 50% of hydrogen fluoride. This does not represent the limit of absorption from the acid vapour at a pressure somewhat below one atmosphere. In one experiment, a boat gained weight until the hydrogen fluoride was 75% of the total weight.

*Properties of the Product.*—The liquids formed were colourless and mobile. They fumed strongly and at the ordinary temperature the fumes consisted of hydrogen fluoride only. No volatile selenium compound was trapped in the chloroform (or alcohol) bubble-counter. The liquid does not mix with chloroform, but forms a layer below it. It rapidly attacks copper, forming a dark substance. In absence of water it slowly attacks glass. When allowed to evaporate in a desiccator with reagents which absorb water and hydrogen fluoride, it slowly dries up to a syrup. If water is present, as it was in some of our earlier experiments, crystals of selenious acid are formed, retaining less than  $\frac{1}{2}$ % of hydrogen fluoride.

*Distillation.*—The product was distilled from the platinum bottle and condensed in a long platinum tube cooled with ice-water. Distillation began at about 65°, continued freely to about 85°, then fell off; little was obtained above 100° until much higher temperatures were reached. The distillate contained more selenium dioxide than can be accounted for by its vapour pressure, which

is 12.5 mm. at 70° and 40.6 mm. at 199° (Jannek and Meyer, *Z. anorg. Chem.*, 1913, **83**, 60). An analysis of the distillate is given in the first line of the table. The residue in the flask was analysed by the volumetric method. The distillate was treated with dry ether, which gave an immediate white precipitate. After washing with more ether, this contained 96 mol.% of selenium dioxide and 4 of hydrogen fluoride. In another experiment the residual liquid, from which much solid had been frozen, was distilled with sulphuric acid (the monohydrate). A yellow, fuming liquid came over at 120° to 130°. This reacted violently with water, giving a solution which contained both selenious and hydrofluoric acids, but no sulphuric acid.

The residue in the bottle after distillation (without sulphuric acid) contained slightly more than 5 mols. of hydrogen fluoride to 1 of selenium dioxide. This is the composition at which the vapour pressure of the hydrogen fluoride sinks to low values. At higher temperatures, the liquid would probably distil as a whole, with dissociation.

*Separation of Solid.*—Preliminary experiments showed that when the liquid was strongly cooled by alcohol-solid carbon dioxide, a white solid separated which had a composition similar to that of the liquid left after the distillation of the more volatile part. The cooling curves of this system were determined in various forms of apparatus. The arrests were variable and not well marked. This was probably due, partly to the nature of the liquid, which can be greatly supercooled, and partly to the difficulty of securing good heat transference and suitable thermal capacity in apparatus which contained so corrosive a liquid.

The freezing points were therefore determined by observation of the contents of the platinum bottle or crucible in which was placed the thermometer in a protecting tube. A portion of solution B, containing about 4.5 mols. of hydrogen fluoride to 1 of selenium dioxide, was poured into a crucible, which was cooled by direct immersion in alcohol-carbon dioxide at -70°. When crystallisation had once started, it proceeded very rapidly. The solid was allowed to melt slowly in a second crucible cooled externally. The temperature was constant at -17.5°, when about one-third was solid, and fell slowly to -18°, when about three-quarters was solid.

*Methods of Analysis.*—From what is known of the strengths of hydrofluoric and selenious acids it should be possible by a volumetric method to determine approximately the amounts of each in a mixture; the greater part of the hydrofluoric acid being titrated with the first hydron of the selenious acid with *p*-nitrophenol as indicator, and the second with an indicator of alkaline

end-point. According to the results of Wilcoox and Prideaux (J., 1925, 127, 1543) the end-point in a titration of 0.05 *N*-selenious acid is at  $p_H = 10.35$ ; the corresponding value from Blanc's second constant is 9.70 (*loc. cit.*). Our solutions were about normal, and from the equation  $2p_H = p_k + p_{kw} + \log c$ , putting  $\log c = 0$  and using our second constant  $k_2 = [H^+][\text{SeO}_3^{''}]/[\text{HSeO}_3'] = 0.87 \times 10^{-8}$ , the end-point will be at  $p_k = 11.0$ . The most suitable indicator available was thymolphthalein, the transition interval of which is 9.3 to 10.5. Titrations to a full blue should still be slightly below the correct end-point of the dibasic acid. This was confirmed with 10 c.c. of solutions of selenious acid.

1st end-point $\times 2$ .....	11.7	11.6	10.8
2nd end-point .....	11.6	11.5	10.65

Hydrofluoric acid is usually titrated with phenolphthalein on account of the lower degree of the second dissociation of  $\text{H}_2\text{F}_2$ . Titrations first with *p*-nitrophenol and then with phenolphthalein showed that most of the acid was neutralised at the change-point of the former indicator, the factor for converting the former into the latter titres being (on the average of several results) 1.03. The effect of the short titration with thymolphthalein on the total acid titre is negligible, and it is completely overcome by the more important error in the *p*-nitrophenol end-point of the mixed acids, which makes the volumetric estimation of selenious acid too high. The necessary corrections were determined by the following titrations of known mixtures.

	Acids separately.		Acids together.	
C.c. of alkali with <i>p</i> -nitrophenol	(a) 13.04	(b) 13.98	(a) 12.90	(b) 13.80
" " thymolphthalein	(a) 18.45	(b) 19.39	(a) 18.40	(b) 19.30

Thus the result of the *p*-nitrophenol titration must be multiplied by a factor, 1.01, to give the sum of the titrations of the acids separately, *i.e.*, of the hydrofluoric acid and the first hydrion of the selenious acid. This corrected titration subtracted from the total titration (with thymolphthalein) gives the amount of selenious acid. This difference, subtracted from the corrected titration with *p*-nitrophenol, gives the amount of hydrofluoric acid estimated by this indicator; and the latter, multiplied by 1.03, gives the amount of hydrofluoric acid estimated by phenolphthalein. The corrected ratios of hydrogen fluoride to selenious acid so obtained are lower than those determined gravimetrically. We have not been able to determine the reason of this discrepancy. It is possible that the hydrolysis is not quite complete, and that there is some complex formation even in aqueous solutions which diminishes the "strong acid" titration.

Selenium was determined gravimetrically by the usual method,

*i.e.*, by precipitation with sulphur dioxide from rather concentrated hydrochloric acid. In the later experiments the modification of Lenher and Kao (*J. Amer. Chem. Soc.*, 1925, 47, 772) was employed. The selenium was precipitated from dilute hydrochloric acid, filtered off as red selenium in the cold, washed successively with concentrated hydrochloric acid, water, alcohol, and ether, dried at 30—40°, then to constant weight at 120—130°. Under these conditions, no water or salts are included in the precipitate.

*Analysis.*—Attempts were made to determine the fluorine also as calcium fluoride in the presence of calcium selenite. These gave rather variable results which were low in fluorine compared with those of the two methods on which we placed most reliance. Some of the results are given in brackets under the gravimetric results in column 6 of the table, which are based on the weight of solid taken and the gravimetric selenium. Column 7 is obtained by subtracting the equivalents of selenium (gravimetric) from the total equivalents of the two acids given by the thymolphthalein titrations. The difference gives the weight of hydrogen fluoride. The sum of the selenium dioxide and the hydrogen fluoride should be equal to the weight of the solid taken. Results in which there was not a fair agreement have not been included.

Preparation A consisted of 19.43 g. of liquid which contained 69.3% HF. The molar ratio by increase of weight was 12.5:1. This was used to determine cooling curves. The first marked arrest on the cooling curve was at  $-54^{\circ}$ , the last on the heating curve, at  $-29^{\circ}$ . The liquid was then distilled up to  $+85^{\circ}$ . The analysis of the distillate is given in the table. The residue, by titration only, contained hydrogen fluoride and selenium dioxide in the ratio 4.9. Two samples of solid separated from the mother-liquor and titrated without weighing gave ratios of 4.9 and 4.93.

Preparation B weighed 21.91 g. and the molar ratio by increase of weight was 4.425. The initial arrest on the cooling curve was at  $-22.5^{\circ}$ . The solid  $B_1$  was frozen out and analysed. The residue in the bottle, which had now been reduced to 14.8 g., was poured into a crucible and the freezing point determined as described above. The remaining samples of B were then taken and analysed.

The filtration of  $B_1$  was done in the usual way, except that the crucible was surrounded by a glass tube, containing lumps of solid carbon dioxide and closed at the top by a stopper in which was a calcium chloride tube to dry the incoming air. The platinum Gooch crucible contained dried asbestos fibre, above which was a false bottom of platinum foil perforated with needle holes. The liquid which had run through the asbestos was rejected. The solid was removed quickly and weighed in a closed crucible. Sample

$B_2$  was pressed on the Gooch crucible with the false bottom but without the asbestos. It was kept cold inside another crucible in the freezing mixture. Sample  $B_3$  was washed with dry cold chloroform by decantation and dried with filter-paper until strong fuming began. Preparation  $C$ , 17.54 g., had a molar ratio of 4.62 to 1. The fractions  $C_1$  and  $C_2$  were obtained by partial freezing and decantation of the liquid part; the solid was then broken up, stirred, and dried with filter-paper.  $C_3$  was collected from the hard solid which first formed round the edge at the top.

The use of the analytical results in making the table is exemplified for sample  $C_1$ . 1.756 Grams of solid give 0.651 g. or 0.00822 gram-atom of selenium, which is equivalent to 0.915 gram of the dioxide. The difference in weight between the original substance and the dioxide, *i.e.*, 1.756—0.915, is taken as the quantity of hydrogen fluoride (gravimetric) and is 0.04205 mol. The molar ratio of hydrogen fluoride (gravimetric by difference) to selenium dioxide (gravimetric) is therefore  $0.04205/0.00822 = 5.1$ . 1.756 Grams of solid require 58.58 c.c. of 0.988 *N*-alkali, with thymolphthalein as indicator. By subtracting from the total milliequivalents of acid, *i.e.*, 57.66, the equivalents of selenious acid, *i.e.*, 0.01645, the equivalent of hydrogen fluoride is found to be 0.0412. The ratio hydrogen fluoride (volumetric by difference) to selenium dioxide (gravimetric) is 5.0.

The weight of hydrogen fluoride so found (volumetric by difference), *i.e.*, 0.824 g., when added to the selenium dioxide, 0.918 g., gives the weight of product calculated from the volumetric total acid and gravimetric selenium; *i.e.*, 1.739. These are the values in brackets in column 2.

Description of preparation and sample.	Wt. taken. Wt. calc. from analysis in brackets.	Ratio $n\text{HF}/\text{SeO}_2$ from gravimetric selenium and total wt. of sample.	Ratio $n\text{HF}/\text{SeO}_2$ from gravimetric selenium and total acid found.

*Summary and Conclusions.*

The analyses show that the solid frozen out of our liquid product contains constantly about 5 mols. of hydrogen fluoride to 1 mol. of selenium dioxide. The fluctuations are, we consider, due to inclusion of mother-liquor, to the loss of variable quantities of hydrogen fluoride, and to other difficulties inherent in the analysis of so corrosive a substance. This additive compound,  $\text{SeO}_2 \cdot 5\text{HF}$ , is in equilibrium with liquids of various compositions. It dissociates in the vapour phase, giving off small quantities of hydrogen fluoride, the vapour pressure of which is only a small fraction of that of the pure acid. At higher vapour pressures the dissociation of the vapour which contains selenium dioxide is not complete. Thus the same compound is obtained either by distillation of the excess of hydrogen fluoride or by freezing from liquids of different compositions.

The above is one of the few examples of complex formation between hydrogen fluoride and an acid anhydride. Analogous compounds with tellurous anhydride have been prepared by Metzner (*Ann. Chim. Phys.*, 1898, 15). These were prepared from aqueous hydrogen fluoride. One of them was much hydrated;  $2\text{TeF}_4 \cdot 3\text{TeO}_2 \cdot 6\text{H}_2\text{O}$ . The other, given as  $\text{TeF}_4 \cdot \text{TeO}_2 \cdot 2\text{H}_2\text{O}$ , might of course be written as  $2\text{TeO}_2 \cdot 4\text{HF}$ . We have prepared a compound somewhat similar to this from anhydrous hydrogen fluoride which we hope to describe in a later communication. The probabilities of the two formulæ are evenly balanced in the case of tellurium, but in the case of selenium we consider the latter, or additive compound, formula far more probable. The fluoride of so strongly electronegative an element is probably not formed under conditions which involve elimination of water, or at any rate, if there is some anhydrous fluoride in the presence of a large excess of hydrogen fluoride, it would be very difficult to prove its presence and isolate it. Up to the present, no fluorides or oxyfluorides of quadrivalent selenium have been described, with the important exception of the compound, afterwards claimed to be the hexafluoride, described by Lebeau (*Compt. rend.*, 1906, 144, 1042). His first preparation, the analysis of which corresponded to  $\text{SeF}_4$ , had the properties to be expected and also resembled our present compound. It was a colourless liquid, boiling at about  $+100^\circ$ , and solidifying at  $-80^\circ$ . It decomposed water, giving hydrofluoric and selenious acids in the molar ratio 4 : 1.

A comparison between the actions of hydrogen fluoride and hydrogen chloride on selenium dioxide is instructive. Hydrogen chloride also gives in the first place an additive compound, which, however, easily loses water, giving the oxychloride  $\text{SeOCl}_2$  (Lenher, *J. Amer. Chem. Soc.*, 1920, 42, 2498). Loss of water from our

compound did not take place under the conditions tried and is unlikely in the case of the compound obtained from hydrogen fluoride on account of the order of the affinities of fluorine and oxygen for hydrogen.

The apparatus required in the preparation of the hydrogen fluoride, and the platinum used in the manipulation of the products were obtained by means of a grant from the Royal Society, which is gratefully acknowledged. The selenium was kindly presented by the Baltimore Copper Company.

The thanks of one of us (J. M.) are also due to the Department of Scientific and Industrial Research for a maintenance grant.

UNIVERSITY COLLEGE, NOTTINGHAM.

## XXVIII.—*The Hydration of Strong Electrolytes, the Viscosity of their Aqueous Solutions, and the Dilution Law.*

By JAMES NETHERWOOD SUGDEN.

MANY attempts have been made to determine the hydration of strong electrolytes in aqueous solution. The results of different methods of investigation differ widely, some yielding relatively small hydration numbers, up to 20 molecules of water per molecule of a hydrated salt, whereas others give much larger values which are quoted in many text-books (e.g., Nernst's "Theoretical Chemistry," 1923, p. 450; Freundlich, "Kapillarchemie," 1923, p. 81). In consequence of this uncertainty, it has not hitherto been possible to apply a hydrate theory to those properties of salt solutions which may be expected to depend on the hydration of the solute. An attempt has been made in this paper to apply, in a quantitative way, a new hydrate theory which is put forward as a result of the experimental work outlined in subsequent sections.

### *Determination of Hydration Numbers.*

It has been shown by Frazer and Myrick (*J. Amer. Chem. Soc.*, 1916, **38**, 1907), Scatchard (*ibid.*, 1921, **43**, 2406), and Washburn (*Tech. Quart.*, 1908, **21**, 373), from the osmotic pressure, vapour pressure, and freezing-point depression respectively, that at moderate temperatures and at concentrations as high as molar, sucrose behaves as if it formed a hexahydrate in solution, and this fact forms a convenient starting point for testing other methods which are applicable both to electrolytes and to non-electrolytes. One such method was indicated by Philip (*Trans. Faraday Soc.*, 1907, **3**, 1),

who recalculated the experimental results of Knopp (*Z. physikal. Chem.*, 1904, **48**, 97), Steiner (*Wied. Ann.*, 1894, **52**, 275), and Muller (*Z. physikal. Chem.*, 1912, **81**, 483) on the solubility of gases in aqueous solutions of sucrose, potassium chloride, etc., and showed that the solubility of hydrogen, nitrogen, and oxygen in these solutions was considerably less than might be expected from their known water content. He suggested that this lowering of solubility might be accounted for by assuming that some of the water was attached to the solute as water of hydration and thereby removed from its rôle of solvent, and that the lowering of solubility afforded a direct measure of this "fixed" water. Philip and Bramley (*J.*, 1915, **107**, 377, 1831) employed the distribution method to measure this effect, while H. E. Armstrong and his collaborators (*Proc. Roy. Soc.*, 1906, **78**, A, 272; 1907, **79**, A, 576, 579, 586; 1908, **81**, A, 102; 1912, **87**, A, 582; *J.*, 1911, **99**, 349, 371), by investigating the velocity of reactions such as the inversion of sucrose and the hydrolysis of methyl acetate by dilute acids, alone and in presence of their salts, calculated the hydration of the salt by estimating the amount of water required to be added to the solution in order to restore the velocity coefficient to its original value. In view of the approximate agreement of the results obtained by these methods, it was thought desirable to make a further study of the problem by the distribution method, which is the most convenient.

The experimental conditions desirable on theoretical grounds were laid down by Philip and Bramley (*loc. cit.*), but these have been modified in that a system was sought in which the distributed solute (a) can be estimated quickly, preferably by simple titration, (b) is miscible in all proportions with both the aqueous and the non-aqueous phase, and (c) is distributed equally between the two solvent phases. Only one such system could be found, *viz.*, acetic acid distributed between water and amyl alcohol, which had been investigated by Herz and Fischer (*Ber.*, 1904, **37**, 4746; 1905, **38**, 1138). The distribution coefficient was found to vary somewhat with the source of the alcohol (usually about the figure 0.96) and to be independent of the concentration of the acetic acid when tested on the following systems: amyl alcohol and (a) water, (b) 2*N*-sodium chloride, (c) *N*-potassium nitrate, (d) 0.25 *N*-sucrose, and also of the time, showing that esterification in the alcohol phase did not take place. The objections to this system are (a) the two solvents are slightly miscible with each other, (b) some salts are not insoluble in amyl alcohol, (c) iodides are decomposed by the acetic acid and the liberated iodine dissolves in the alcohol, and (d) acetic acid cannot be estimated by titration in presence of

ammonium salts. Complete immiscibility is, however, not essential when the distribution coefficient is approximately unity, and other methods can be applied in the case of the soluble lithium, magnesium, and calcium salts and of ammonium salts.

If  $d_1$  and  $d_2$ , and  $C_1$  and  $C_2$ , are respectively the densities and distribution coefficients of water and a salt solution of normality  $n$ , the total weight of water per litre of solution is  $1000d_2 - nE$  ( $E$  being the equivalent weight of the salt). The weight of free water is taken to be  $1000d_1 \cdot C_1/C_2$  ( $d_1 = 0.99707$ ), and consequently the weight of water attached to  $n$  gram-equivalents of the salt is  $1000d_2 - nE - 1000d_1C_1/C_2$  and the apparent equivalent hydration

$$H = 1000(d_2 - C_1d_1/C_2)/18n - E/18.$$

This calculation assumes the solvents to be completely immiscible, the quantity of acetic acid (actually 1 c.c. of acid per 200 c.c. of solvents) to be negligible, and the indicating substance (acetic acid) to be insoluble in the salt whose hydration is being determined.

In Table I are the results of the first experiments, with sucrose. The apparent molecular hydration,  $H$ , increases with dilution until

TABLE I.

$n$ .	$d$ .	$C_1$ .	$C_2$ .	$H$ .	$n$ .	$d$ .	$C_1$ .	$C_2$ .	$H$ .
2N	1.2532	0.9870	2.061	2.7	N/4	1.0300	0.9227	1.019	5.0

a value of 5 to 6 molecules of water is obtained. The method of estimating  $H$  is by difference, and the experimental error increases rapidly as the fraction of "fixed" water decreases, i.e., as the dilution increases; in the case of sucrose a steady value is not indicated until a dilution is reached where the experimental error becomes appreciable, nevertheless the average value so obtained is in good agreement with that deduced from the osmotic properties of sucrose solutions.

Table II gives the results obtained for all the salts investigated, and Table IIa summarises those for the alkali metals.

In every case except the sulphates, a reasonably constant value of  $H$  was obtained, usually over the range  $N - N/10$ . The values in the column headed  $H(\text{ex.})^*$  are those which might be ascribed

\* Where the values of  $H$  over the range  $N - N/4$  are reasonably constant,  $H(\text{ex.})$  is taken as the average. Where  $H$  is large and the maximum value is not reached at normal concentration, e.g.,  $\text{LiBr}$ ,  $\text{LiBrO}_3$ , less weight is attached to this determination.

to the salt from these experimental results alone, whilst under  $H$  are the most probable values for the apparent molecular hydration. Where the values in the two columns differ, the explanation is usually to be found in the solubility of the salt in the alcohol phase; the evidence upon which the final figure is based will appear in later sections. All previous work on hydration suggests that this

quantity is not independent of the salt concentration, but the results now obtained (with the one exception) do not support this view, and, whilst it cannot be shown from them alone whether or not the constant value is retained as the dilution is still further increased, it will be convenient, for the time being, to regard these as fixed values. The sulphates are anomalous, the values of  $H$  actually decreasing on dilution. This may be due to the appearance and subsequent dissociation of intermediate ions of the type  $\text{KSO}_4$ , or to some idiosyncrasy of the sulphate ion; salts of the type  $\text{BaCl}_2$  and  $\text{Sr}(\text{NO}_3)_2$  behave in the normal way.

Potassium bromate and iodate are only sparingly soluble salts, consequently their hydration could not be determined with accuracy. Potassium nitrate and potassium chlorate both gave constant negative values for  $H$ . Analysis of the figures brings out the interesting fact that *the difference between the apparent molecular hydration of a sodium and a potassium salt is independent of the anion, hydration thus being an additive property* (Table III).

TABLE III.

	Cl.	Br.	$\text{NO}_3$ .	$\text{ClO}_3$ .	$\text{BrO}_3$ .	$\text{IO}_3$ .

Diff.	4.6	4.7	4.4	4.7	4.6	(3.6)

The average value for the Na-K difference is 4.6 mols.  $\text{H}_2\text{O}$ . The determination of the corresponding Li-Na difference presented some difficulty, due to the solubility of lithium salts in amyl alcohol. Of those examined, the iodate alone was insoluble, so the difference (2.6 mols.  $\text{H}_2\text{O}$ ) depends on only one determination; moreover, sodium iodate is a sparingly soluble salt and the most concentrated solution available was  $N/4$ , hence the value  $H = 5.1$  for this salt is not known with the usual accuracy. Nevertheless, the difference value of 2.6 is probably not greatly in error; the hydration values for the other lithium salts tabulated in column  $H$  (Table II) are obtained by adding 2.6 to the hydration number of the corresponding sodium salts.

Table IV gives a summary of the values of  $H$  for the salts of the alkaline earths. The magnesium and calcium salts dissolved in the amyl alcohol and in each case the numbers in column  $H$  (ex.) are too small, but good values were obtained for the strontium and barium salts; the chlorides and bromides are heavily hydrated and hence the maximum value is in some cases not obtained until a dilution somewhat greater than normal is reached.

Table V indicates that hydration is additive in these salts also, and Table VI that the chloride-nitrate difference is common to both series.

*Negative Hydration.*

The salts possessing negative hydration values are the chlorates and nitrates of potassium and presumably also of ammonium, rubidium, and caesium. Since, so far as the additive nature of hydration is concerned, these salts are apparently normal, it is probable that this phenomenon is not an abnormality, but merely an extreme example of some property common to all strong electrolytes. In this particular case, the negative hydration is indicated by the fact that solutions of these salts exert a greater solvent power upon acetic acid than does pure water. An obvious explanation is that some measure of combination takes place between the salt and acetic acid, but several arguments may be raised against this. One of these (and others will appear later) is that the negative hydration, or, from the point of view of this explanation, the extent of combination between the two substances is independent of the concentration of both the potassium nitrate and the acetic acid over a wide range of concentration. The increased solvent power of potassium nitrate solutions is not confined to acetic acid alone; reference to the papers of Rothmund (*Z. physikal. Chem.*, 1900, **33**, 401), Biltz (*ibid.*, 1903, **43**, 41), Bray and Winninghoff (*J. Amer. Chem. Soc.*, 1911, **33**, 1663), and Glasstone and Saunders (*J.*, 1923, **123**, 2134) shows that the property extends over a very wide range of compounds, including the particularly interesting case of lead nitrate (Glasstone and Saunders), which contains a common ion. Moreover, whereas the ordinary process

of hydration produces a concentrating effect upon other constituents of an aqueous solution, evidence is not lacking that these "negatively hydrated" salts actually produce a *diluting effect*, a property which has been noticed by Rennie, Higgin, and Cooke (J., 1908, 93, 1162), Armstrong and Watson (*Proc. Roy. Soc.*, 1907, 79, A, 586), Harned (*J. Amer. Chem. Soc.*, 1918, 40, 1461), and Walton (*Z. physikal. Chem.*, 1904, 47, 185).

Several explanations of these anomalies are to be found in the above papers, but in seeking a general interpretation which will cover these and other properties of solutions of strong electrolytes the possibility was considered that the anions and cations might react with the solvent in fundamentally different ways. All the published work on hydration of strong electrolytes agrees on two points: (1) if cations are arranged in the order of diminishing hydration, the caesium ion occupies the lowest position, and (2) if the anions are so arranged, the chloride ion occupies the position of maximum hydration; this, together with the definite proof advanced by Washburn (*J. Amer. Chem. Soc.*, 1915, 37, 694) that the least hydrated cation (caesium) carries measurably more water than the (presumably) most heavily hydrated anion (chloride), suggests at once that anions are not hydrated, but possess properties which in certain cases are sufficiently developed to over-compensate the hydration effect of the cation.

When acetic acid is in equilibrium both with water and with amyl alcohol, its activity in each phase must be the same, and (if the solution is sufficiently dilute) proportional to its mole-fraction, which in the aqueous phase is assumed to depend on the "association factor" of water. If the mole-fraction (activity) of the acetic acid in the aqueous phase is increased by the removal of water as water of hydration, some of the acid will escape into the alcohol phase until equilibrium is re-established. Alternatively, if the association factor of water is decreased by any means whatsoever, the mole-fraction of the acetic acid will decrease and can only be restored by transference of the acid from the alcohol to the water phase. The suggestion is made, therefore, that whilst cations are invariably hydrated, probably as a result of the positive field (the intensity of which decreases as the ionic radius increases) round the ion and a stray field round the water molecule, anions are not hydrated but in all cases exert (in greater or less degree) a depolymerising action on the associated solvent, resulting in a shift of the equilibrium  $(\text{H}_2\text{O})_3 \rightleftharpoons (\text{H}_2\text{O})_2 + \text{H}_2\text{O} \rightleftharpoons 3\text{H}_2\text{O}$  towards the right. The properties of solutions of strong electrolytes are thus to a large degree determined by the relative magnitudes of these two rival processes.

An action such as the above, which increases the effective mole-fraction of the water, will produce a species of water molecule which alone is found in the vapour phase; hence aqueous solutions of negatively hydrated salts should have abnormally high vapour pressures (compare Washburn, *J. Amer. Chem. Soc.*, 1910, **32**, 653, 1636; Washburn and MacInnes, *ibid.*, 1911, **33**, 1686; Bousfield, *Trans. Faraday Soc.*, 1919, **15**, 47; Glasstone and Saunders, *loc. cit.*; Sidgwick and Ewbank, *J.*, 1924, **125**, 2273).

*Hydration and the Equivalent Conductivity at Infinite Dilution.*

Kohlrausch (*Proc. Roy. Soc.*, 1903, **71**, A, 348) suggested that "about every ion moves an atmosphere of the solvent the dimensions of which are determined by the characteristics of the ion,

FIG. 1.

and the electrolytic resistance of an ion is a frictional resistance that increases with the dimension of the atmosphere"; consequently a quantitative relationship may be expected between  $\lambda_{\infty}$  and the hydration of the kations.\* In order to correlate these properties, let it be assumed that  $H$  is independent of concentration up to infinite dilution. This assumption is not unreasonable in view of the facts presented in this paper, and further, it leads to conclusions which are supported by considerations based on the constancy of  $H$  over the experimental range  $N - N/10$  only.

If the apparent molecular hydrations of the alkali chlorides are plotted against the equivalent conductivities at infinite dilution, the points lie on a smooth curve, which is slightly concave towards the origin. The shape of the curve is determined by the properties ( $\lambda_{\infty}$  and  $H$ ) of the kations, and its position on the diagram by the equivalent conductivity of the anion. In a similar diagram drawn for the salts of a common kation, the points lie irregularly

\* The hypothesis cannot be true universally if anions are not hydrated.

and can only be joined by a zig-zag line. This dissimilarity supports the hypothesis that anions and kations behave towards the solvent in different ways.

The curvature of the lines relating  $\lambda_{\infty}$  and  $H$  for the alkali metals (so far as their hydrations are known) is so slight that the purpose of the diagram is served equally well by plotting the values for the sodium and potassium salts only and joining the points by straight lines (Fig. 1). Two points of interest, which will be encountered again later, become evident: (a) the nitrates and chlorates fall on one line, and (b) the sequence of the curves for the bromates, chlorates, and iodates is unexpected.

#### *Hydration of Strong Electrolytes and the Viscosity of their Aqueous Solutions.*

Strong electrolytes may be divided into two classes according to their effect on the viscosity of water. The first (and smaller) class consists of the salts of the heavier alkali metals the aqueous solutions of which at the ordinary temperature have viscosities lower than that of the solvent. With increasing concentration, the viscosity falls at first to a minimum and then increases to a value which, in the case of very soluble salts, may exceed the viscosity of water. At higher temperatures the minimum becomes less marked and finally disappears, the solution then behaving as solutions of electrolytes of the second (and larger) class, the viscosities of which are always greater than that of water.

Many unsatisfactory and conflicting theories have been put forward to explain the negative viscosity ( $\eta/\eta_0 - 1$  being negative) of some salt solutions, *e.g.*, by Euler (*Z. physikal. Chem.*, 1898, 25, 536), Wagner (*ibid.*, 1903, 46, 871), Jones and Veazey (*Amer. Chem. J.*, 1907, 37, 405), and Taylor (*Proc. Roy. Soc. Edin.*, 1907, 28, 461).

Getman (*J. Chim. Phys.*, 1907, 5, 344; *J. Amer. Chem. Soc.*, 1908, 30, 721, 1077) ascribed negative viscosity at least partly to association of the solvent (potassium iodide in non-associated solvents having a positive viscosity), Bousfield (*J.*, 1915, 107, 1797) pointed out that "the viscosity of dilute aqueous solutions cannot be theoretically treated except in conjunction with the effect of the peculiar constitution of water," and Rabinowitsch (*J. Amer. Chem. Soc.*, 1922, 44, 954) showed, from theoretical considerations, that whilst hydration of ions can account for an increased viscosity, depolymerisation of the solvent alone supplies a rational explanation of the negative viscosity of some salt solutions.

When the kation is only slightly hydrated and the non-hydrated anion is small, or efficient in depolymerising the solvent, the effect

of the anion predominates, and the viscosity of the solution will be negative; but with increasing salt concentration, and therefore increasing depolymerisation, the average size of the water molecules becomes smaller, and hence the tendency of the kation to increase the viscosity will become more marked, eventually accounting for the minimum value and subsequent increase in the viscosity. Increase of temperature causes depolymerisation and consequently the disappearance of the minimum in the curve, the solvent functioning at higher temperatures as if it consisted only of simple molecules or complexes incapable of easy depolymerisation.

FIG. 2.

Fig. 2 shows the relation between the hydration of the alkali chlorides and the relative viscosity\* of their solutions. If the latter is greater than unity, it is at all concentrations a linear function of the apparent molecular hydration of the salt; if less than unity, this relationship holds up to approximately semi-normal concentration. The straight lines in Fig. 2 all pass through a point where  $\eta/\eta_0 = 1$  and  $H = 4.3$ . If an alkali chloride had this hydration value of 4.3, all disturbing influences would exactly compensate one another and the viscosity of its solutions at all concentrations would be the same as that of pure water. The relative viscosities of solutions of the alkali chlorides are proportional to the differences between their apparent molecular hydrations and this "zero" value, which may be denoted by  $H_0$ . The point of origin  $\eta/\eta_0 = 1$ ,  $H = 4.3$  is independent both of the concen-

\* Except where otherwise stated, the accurate viscosity measurements of Gruneisen (*Wiss. Abhandl. Physikal.-Tech. Reichsanst.*, 1905, 4, 239), and the collected data of Noyes and Falk (*J. Amer. Chem. Soc.*, 1912, 34, 463) have been used.

tration and of the nature of the kation; it is determined by the anion, of which it is a specific property. The viscosities of these solutions depend, therefore, on (a) the value of  $H_0$ , which is fixed by the anion, (b) the hydration of the salt (determined largely by the kation), and (c) the concentration of the solution.

Many empirical equations have been proposed connecting the viscosities and the concentrations of solutions of strong electrolytes. The simplest of these (Arrhenius, *Z. physikal. Chem.*, 1887, **1**, 284),

$$\log \eta/\eta_0 = \theta c \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where  $\theta$  is a constant varying from salt to salt and  $c$  is the number of gram-molecules per litre, holds with considerable accuracy over a wide range of concentrations, provided the solutions are more viscous than water, whilst for solutions of negative viscosity its application is limited to dilutions greater than semi-normal. It is obvious from Fig. 2 that the constant  $\theta$  may be expressed in terms of the apparent molecular hydration,  $H$ , and a more general constant,  $K$ :

$$\theta = K(H - H_0) \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

whence 
$$\log \eta/\eta_0 = Kc(H - H_0) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

a general equation which has the same applicability as that of Arrhenius. In Table VII,  $K$  is evaluated for the alkali chlorides, the calculated values of  $\eta/\eta_0$  being then obtained from the equation

$$\log \eta/\eta_0 = 0.01c(H - 4.3) \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

TABLE VII.

Mean value of  $K = 0.01$ .

The figures in brackets in Tables VII and VIII refer to solutions for which  $\eta/\eta_0 - 1$  is negative, and of such concentrations that equation (1) is no longer applicable.

The corresponding diagram for the alkali nitrates closely resembles that for the chlorides, except that the origin of the curves has shifted to the value  $H_0 = 0$ ; however, the value of  $K$  (0.01) is the same (within the limits of experimental error), as will be seen from Table VIII.

TABLE VIII.

LiNO <sub>3</sub> . $H = 4.4$ .				NaNO <sub>3</sub> . $H = 1.8$ .				KNO <sub>3</sub> . $H = -2.7$ .			
c.	$\eta/\eta_0$ .	$K$ .	$\eta/\eta_0$ (calc.).	$\eta/\eta_0$ .	$K$ .	$\eta/\eta_0$ (calc.).	$\eta/\eta_0$ .	$K$ .	$\eta/\eta_0$ (calc.).	$\eta/\eta_0$ .	$K$ .

The negative sign probably indicates that the iodate ion is sufficiently large of itself to increase the viscosity of water, an effect which is, of course, independent of its depolymerising action.

The values of  $H_0$  for the bromides (4.1) and chlorates (0.0) were similarly found. In the case of the bromates, owing to lack of data, new viscosity measurements were made ( $H_0 = 1.6$ ).

The values of  $H_0$  thus found are 4.3 for Cl, 4.1 for Br, 1.6 for BrO<sub>3</sub>, 0.0 for NO<sub>3</sub>, 0.0 for ClO<sub>3</sub>, and  $-5.5$  for IO<sub>3</sub>. The chlorates and nitrates form one system here as in Fig. 1 and the sequence of the curves in Fig. 1 is that of these  $H_0$  values. Fig. 3 shows the relation between the spacing of the curves in Fig. 1 as measured by the

value of  $\lambda_\infty$  at  $H = 0$ , and the values of  $H_0$ . This curve can be accurately described by the empirical equation

$$\lambda_\infty = 100 + 13.5 \times 1.327^H. \quad (6)$$

It indicates a lower limit for the position of the curves in Fig. 1, only slightly below that of the iodate curve. Moreover, the smooth curve in Fig. 3 is of some importance, for whereas the values of  $H_0$  are obtained from the viscosities of solutions over a concentration range similar to that available for the determination of hydration by the distribution method, the sequence and spacing of the curves in Fig. 1 depend on the application of these hydration values at infinite dilution. Fig. 3 therefore supplies some justification for extending the use of these hydration numbers to infinitely dilute solutions, since no serious error is thereby introduced. It must be mentioned, however, that "the viscosity concentration curve for all salts has a change of curvature at the dilute end in

FIG. 3.

the sense that the first particles of salt added have a greater effect in increasing, or a less effect in diminishing the viscosity of water than subsequent additions. The change in curvature is scarcely noticeable unless the curve is plotted on a large scale" (Applebey, J., 1910, 97, 2000; see also Grüneisen, *loc. cit.*).

Salts of the type  $\text{BaCl}_2$  can be treated in exactly the same way as those of the type  $\text{KCl}$ . By substituting the viscosity and apparent molecular hydration of barium chloride in equation (5), the value  $H_0 = 7.4$  is obtained. On the assumption that  $H_0$  is determined solely by the anion the value for a bivalent chloride might be expected to be 8.6. The agreement, therefore, is not unsatisfactory, and supports the assumption that  $K$  in equation (5) is a universal constant.\*

\* It appears not unlikely that the size of a (unhydrated) kation is less than that of an average water molecule; consequently some small part of the water of hydration may be needed to adjust this difference, whilst the remainder tends to increase the viscosity of salt solutions. Hence  $H_0$  for a bivalent chloride might be expected to be slightly less than twice the value for a univalent chloride, since, although the number of anions per molecule is doubled, that of the kations remains the same.

Having obtained  $H_0$  for these salts, it is possible to calculate, from the equation

$$\log \eta/\eta_0 = 0.01c(H - 7.4) \quad . \quad . \quad . \quad (7)$$

the values of  $H$  for magnesium chloride ( $H = 24.8$ ) and calcium chloride ( $H = 20.6$ ). Where the final value of  $H$  differs from the experimental value  $H$  (ex.), (i.e., for soluble salts), it is obtained (a) in Table IIA, from the additive property of hydration and (b) in Table IV, from this semi-empirical hydration-viscosity equation.

#### *Hydration of Strong Electrolytes and the Dilution Law.*

According to the theory here developed, the apparent molecular hydration,  $H$ , which represents the resultant of two opposing factors, viz., hydration of kations (decrease of the effective mole-fraction or activity of water) and depolymerisation by anions (increase of the effective mole-fraction or activity of water), may be applied to determine the effective mole-fraction of water and thus the corrected van 't Hoff factor,  $i$ .

Washburn (*Tech. Quart.*, 1908, 21, 373) has shown that the effective mole-fraction,  $n'$ , of the solute may be calculated from the freezing-point depression,  $\Delta t^\circ$ , by means of the equation

$$n' = 0.00969 (\Delta t - 0.00425 \Delta t^2) \quad . \quad . \quad . \quad (8)$$

This equation may be used for freezing-point depressions as large as  $7^\circ$ , and the mole-fraction is given with an accuracy equivalent to an experimental error of  $0.001^\circ$  in measuring  $\Delta t$ . Equation (8) may be equated to (a)  $ni/(ni + N)$  and (b)  $ni_c/(ni_c + N - Hn)$ , where  $n$  and  $N$  are the numbers of gram-molecules of solute and solvent, and  $i$  and  $i_c$  the uncorrected and corrected van 't Hoff factor, respectively.

van 't Hoff's factor is defined on the basis of the classical theory by the equation (for a uni-univalent salt)  $i = 1 + \alpha$ , where  $\alpha$  is the "degree of dissociation." Alternatively,  $(1 - \alpha)$  may be regarded simply as the "osmotic deficiency," i.e., the fraction by which the osmotic properties deviate from those required for an ideal solution of a completely dissociated salt. It was necessary, therefore, to review the recorded freezing-point depressions, more especially those referring to concentrated solutions where the hydration correction is considerable. Probably the most trustworthy measurements are those of Washburn and MacInnes (*loc. cit.*), who selected lithium chloride, potassium chloride, and caesium nitrate as being representative of the whole range of hydrated salts, lithium chloride being presumably the most and caesium nitrate the least heavily hydrated of the uni-univalent strong

electrolytes. In addition, the results of Noyes and Falk (*J. Amer. Chem. Soc.*, 1910, **32**, 1011), Jones and Pearce (*Amer. Chem. J.*, 1907, **38**, 683), Ponsot (*Ann. Chim. Phys.*, 1897, **10**, 79), de Coppet (*J. Physical Chem.*, 1904, **8**, 531; *Z. physikal. Chem.*, 1897, **22**, 239), Biltz (*Z. physikal. Chem.*, 1902, **40**, 185), Jahn (*ibid.*, 1904, **50**, 129; 1907, **59**, 31), Adams (*J. Amer. Chem. Soc.*, 1915, **37**,

FIG. 4.

481), Harkins and Hall (*ibid.*, 1916, **38**, 2658), Rodebush (*ibid.*, 1918, **40**, 1204), and Rivett (*Z. physikal. Chem.*, 1912, **80**, 546) have been used for the calculations, of which a selection is given in Table XI. In applying the hydration correction it was assumed that the hydration is (a) independent of the concentration and (b) has the same value at the freezing point as at 25°, the temperature at which the hydration determinations were made.

atively, if any departure from the law is involved, not one but two changes in curvature would be necessary in order that the osmotic deficiency should not have a finite value at infinite dilution.

The freezing-point measurements of Adams (*loc. cit.*) and Hovorka and Rodebush (*J. Amer. Chem. Soc.*, 1925, 47, 1614) apply to dilute solutions, and are of a high order of accuracy, the former having been used to establish the freezing-point laws of Lewis and Linhart and of Brønsted. In Table XII their values of  $\alpha_c$  are compared with the calculated values:  $s$  = g.-mol. of salt in 1000 g. of water.

The figures for potassium chloride agree (within the limits of experimental error) with one another and with the calculated values, but those for the nitrates show considerable divergences

(compare  $\text{KNO}_3$  Adams with  $\text{CsNO}_3$  Washburn) and in the most dilute solutions agree better with the calculated value for chlorides ( $K = 0.32$ ) than for nitrates ( $K = 0.52$ ).

Table XIII refers to the four remaining univalent chlorides. With the exception of sodium chloride, they all obey the law in a satisfactory way, having a common value of  $K = 0.32$ . Sodium chloride deviates somewhat, the value of  $K$  increasing with concentration for solutions above  $0.25N$ . This is unexpected, since the viscosity is normal, and lithium chloride with its greater hydration number obeys the law, as does sodium bromide (Table XIV).

Table XIV gives a representative selection of the other salts investigated, viz., sodium bromide, magnesium chloride, barium chloride, and strontium nitrate, and it will be seen that in each

case the cube root law is obeyed and applies equally well to bi-univalent salts of the type  $\text{BaCl}_2$ ,  $\text{Sr}(\text{NO}_3)_2$ , etc.

In addition to the above salts, calculations have been made for a number of others with the following results: sodium nitrate ( $K = 0.38$ ), potassium nitrate ( $K = 0.50$ ), and rubidium nitrate ( $K = 0.51$ ) obey the cube root law, with the possible deviation of potassium nitrate in dilute solution (see Table XII and comments). The small value of  $K$  for sodium nitrate should be noted. Potassium bromide gave less satisfactory results,  $K$  decreasing from 0.31 for dilute solutions to 0.24 at the eutectic (3.836-weight normal). This salt behaves as if the hydration value of 1.9 is too small; the experimental result, however, is beyond suspicion. An increase of  $H$  by one unit (which is not justified on any other grounds) would give a constant value of  $K$  at all concentrations.

Calcium chloride ( $K = 0.47$ ), strontium chloride ( $K = 0.48$ ), cobalt chloride ( $K = 0.45$ ), and copper chloride ( $K = 0.52$ ) are all satisfactory. With barium nitrate ( $K = 0.80$ ), the constant tends to rise slightly, and with lead nitrate ( $K = 0.93$ ) to fall slightly, both in dilute solution; but this is thought to be due to possible small errors in the freezing-point measurements. Copper bromide gives a small but constant value ( $K = 0.31$ ), whilst barium bromide resembles the potassium salt, the values of  $K$  decreasing from 0.44 to 0.36.

Thus far, the results for twenty-two salts have either been given in detail or commented upon, and considerable evidence has been adduced in favour of the cube root law. In only three of the above cases do deviations occur, *viz.*, sodium chloride and potassium and barium bromides, but five other salts were found not to obey the law. These are the nitrates of lithium, magnesium, calcium, copper, and cobalt, for which  $K$  decreases continuously with increasing concentration: *e.g.*, magnesium nitrate  $n = 0.05$ ,  $K = 0.46$ ;  $n = 1.0423$ ,  $K = 0.13$ ; calcium nitrate  $n = 0.05$ ,  $K = 0.58$ ;  $n = 1.05$ ,  $K = 0.42$ ; lithium nitrate  $n = 0.04$ ,  $K = 0.52$ ;  $n = 1.016$ ,  $K = 0.24$ . These salts all contain heavily hydrated cations, and anions which are very active in dissociating the solvent. Although the hydration numbers of these salts are relatively small, since they represent the *difference* between two competing processes, they do not afford a measure of the great disturbance suffered in these cases by the solution.

The apparent molecular hydration of magnesium nitrate is  $12.8 \text{ H}_2\text{O}$ ; in a molar solution of this salt, not less than half the solvent is attached to the magnesium ions and the activity of the remainder is increased by 50% by the nitrate ions. It is doubtful, therefore, whether the use of a *constant* hydration correction is

permissible, even if Washburn's equation is applicable to cases where the solvent equilibrium is so violently disturbed. Where the absolute hydration correction is small (potassium chloride) the cube root law is followed with great exactness, even for dilute solutions, and it appears probable that an ideal strong electrolyte (anion inert, kation not hydrated) would obey the law over the whole concentration range.

*The Hydration Theory and the Conductivity Ratio.*

According to the theory of complete dissociation, the conductivity ratio  $\lambda_v/\lambda_{\infty}$  must be regarded solely as a ratio of mobilities, the mobility of the ions decreasing as the concentration increases, and this decrease is probably to a large degree due to the decreasing distance between the charged ions. If no other influence intervened, it is to be expected that the conductivity ratio would depend only on the type of salt and be independent of the ion carrying the charge. We know, however, that the so-called "dissociating power" of a solvent depends on the magnitude of its dielectric constant, whilst the latter is related to the molecular association of the solvent. The hydration theory suggested in this paper postulates a continuous decrease in the association of the solvent, and consequently a decrease in the dielectric constant, with increasing salt concentration, whilst the efficiency of the depolymerisation process varies with different anions. The conductivity ratio, therefore, should not only decrease as the concentration of salt increases, but it should do so at rates which depend on the sequence of the hydration numbers (see p. 186). For the potassium salts at semi-normal concentration at 18°, the order of the conductivity ratios is that required by the hypothesis, viz., KCl, 0.779; KBr, 0.766; KClO<sub>3</sub>, 0.703; KNO<sub>3</sub>, 0.688.

EXPERIMENTAL.

The amyl alcohol was washed with dilute sulphuric acid and with water, dried over potassium carbonate, and distilled, the fraction boiling at 128—132° being collected. The distribution coefficients were determined by shaking together 100 c.c. of the alcohol, 100 c.c. of the solution to be examined, and 1 c.c. of purified acetic acid at 25° until equilibrium was established. After the two phases had separated completely, the alcoholic layer was drawn off rapidly and the acid content determined by titration with N/20-barium hydroxide and phenolphthalein. Owing to the different nature of the two solvents it was found advisable to wash out the pipette with either 20 c.c. of water or 20 c.c. of purified ethyl alcohol, according as the aqueous or non-aqueous

phase was being examined. In the latter case, the ethyl alcohol brought the amyl alcohol into complete solution and so facilitated the titration. It was necessary to carry out blank experiments on each batch of amyl alcohol, owing to slight variations of the coefficient with different samples (presumably due to differences in the proportion of the isomerides present). The average value of the coefficient alcohol to water was 0.96.

The viscosity measurements were carried out in an Ostwald viscosimeter at 20°, and whilst no outstanding accuracy is claimed for these results, all ordinary precautions were observed.

### *Summary.*

The hydration of sucrose and some strong electrolytes has been determined from the distribution of acetic acid between their aqueous solutions and amyl alcohol. The results indicate that the hydration is (over the concentration range examined) independent of dilution and is an additive property which may have either a positive or a negative value.

A modified hydration theory is suggested according to which only kations are hydrated whilst anions depolymerise the solvent molecules. The first process tends to decrease and the second to increase the activity of the water. Hydration is therefore a composite effect, the salts having negative hydration numbers being those in which the influence of the anion predominates. Solutions of such salts have abnormally high vapour pressures.

The hydration theory has been correlated with viscosity phenomena and a semi-empirical equation established by means of which hydration values can be calculated from viscosity data.

A hydration correction has been applied to calculations of the "degree of dissociation" of strong electrolytes from freezing-point measurements, and evidence is adduced in favour of a cube root dilution law  $(1 - \alpha) = K\sqrt[3]{n}$ . Many salts have been shown to obey the law with great exactness, and those which do not do so are extreme cases in which the application of the correction is least certain.

Corroborative evidence for the new theory has been obtained from a consideration of the conductivity ratios of a number of strong electrolytes.

The author wishes to thank Messrs. Brunner Mond & Co. for a grant from their research fund which defrayed part of the cost of the investigation.

XXIX.—*Action of Acetylene Tetrabromide on Organic Bases.*

By JAMES DAVIDSON FULTON.

THE present investigation, in which the reagents were allowed to react in the absence of a solvent, was suggested by the action of nicotine on acetylene tetrabromide. The rotation of the solution changed rapidly from negative to positive and the solution became hot and coloured; after a few days a solid separated, whilst some oily matter remained. The latter, usually small in amount, was discarded in this and subsequent experiments.

The interaction of aniline and acetylene tetrabromide at the ordinary temperature was investigated by Sabanejev (*Annalen*, 1875, 178, 125), who obtained a number of products including acetylenetriphenyltriamine,  $C_{20}H_{17}N_3$ . Schoop (*Ber.*, 1880, 13, 2196) obtained octamethyltetra-aminotetraphenylethane by heating dimethylaniline with acetylene tetrabromide for 8 days. Elbs and Neumann (*J. pr. Chem.*, 1898, 58, 250) failed to substantiate all the findings of Sabanejev. In the above cases, the hydrobromide of the base also was obtained. Dehn (*J. Amer. Chem. Soc.*, 1912, 34, 286) has shown that the reaction of bases and acetylene tetrabromide in dry ether furnishes the hydrobromide and tribromoethylene quantitatively and that sunlight accelerates the reaction.

In the present instance, in the case of tertiary bases additive compounds of the hydrobromide with acetylene tetrabromide were obtained. The influence of sunlight on their formation was not marked. Abnormal bromoaurates were obtained from nicotine and quinoline.

## EXPERIMENTAL.

Acetylene tetrabromide (usually 2 or 3 mols.) was added to the base (1 mol.) in the cold. Solid hydrobromides were immediately precipitated from primary and secondary amines. With tertiary bases, a solid separated after a day or two. In the case of  $\alpha$ -picoline, although reaction was apparent, no crystals appeared for weeks until the mixture was cooled in liquid air and again left. The solid product was filtered off, freed from oily matter, and crystallised from alcohol. The well-crystallised substances thus obtained were all soluble in cold methyl or ethyl alcohol and very soluble in the hot solvent; repeated crystallisation brought about a partial change to the hydrobromide. A single crystallisation from acetone or chloroform effects this change almost completely. The compounds are slightly or not at all soluble in other common organic solvents. The total bromine and the ionisable bromine were estimated.

Water decomposes these compounds. Acetylene tetrabromide is liberated, and the supernatant aqueous solution contains the hydrobromide of the base, which was recognised, in the case of pyridine and quinoline, by analysis and melting point.

The bromoaurates separated when hot alcoholic solutions of the additive compounds, to which auric bromide in alcohol had been added, were allowed to cool.

*Nicotine*:  $C_{10}H_{14}N_2 \cdot 2HBr \cdot 2C_2H_2Br_4$ , needles, or rhombs by slow crystallisation, m. p. 178—180° (decomp.), softening at 140° (Found: total Br, 79.0; Br', 15.9. Calc., 78.7 and 15.7%, respectively).  $[\alpha]_{D}^{25} + 3.21^\circ$  in alcohol ( $c = 5.6025$ ).

The bromoaurate,  $C_{10}H_{14}N_2 \cdot 2HBr \cdot AuBr_3$ , forms dark red crystals, m. p. 183°, which are soluble in alcohol and slightly soluble in water (Found: Au, 26.05. Calc., Au, 25.9%).

A more stable, less soluble compound,  $[\alpha]_{D}^{25} + 6.96^\circ$  in alcohol ( $c = 5.6025$ ), m. p. 182—183° (decomp.), giving the same bromoaurate (Found: Au, 26.0%), was obtained by repeated crystallisation of the above and also from 1 mol. of the base and 1 mol. of acetylene tetrabromide [Found: total Br, 64.4; Br', 32.3. ( $C_{10}H_{14}N_2 \cdot 2HBr$ ) $_2 \cdot C_2H_2Br_4$  requires Br, 64.4; Br', 32.2%].

*Pyridine*:  $C_5H_5N \cdot HBr \cdot C_2H_2Br_4$ , colourless crystals, m. p. 108—109° (Found: total Br, 79.15; Br', 16.05. Calc., Br, 79.05; Br', 15.8%).

The bromoaurate forms brownish-red crystals, m. p. 318—319° (Found: Au, 33.0.  $C_5H_5N \cdot HBr \cdot AuBr_3$  requires Au, 33.0%).

*Quinoline*: The product was washed with a little alcohol and ether. It softened at 115° and melted at 136° [Found: total Br, 62.4; Br', 21.2. ( $C_9H_7N \cdot HBr$ ) $_2 \cdot C_2H_2Br_4$  requires Br, 62.7; Br', 20.9%]. This substance is analogous to the lead compound, ( $C_9H_7N \cdot HBr$ ) $_2 \cdot PbBr_4$  (Classen and Zahorski, *Z. angew. Chem.*, 1891, 4, 107).

The bromoaurate forms dark red crystals, m. p. 171—172°, which are soluble in alcohol and slightly soluble in water [Found: Au, 23.0. ( $C_9H_7N \cdot HBr$ ) $_2 \cdot AuBr_3$  requires Au, 23.0%]. It is analogous to Fenner and Tafel's chloro-compound (*Ber.*, 1899, 32, 3227).

isoQuinoline gave mostly its hydrobromide, m. p. 207° (Found: Br, 38.0. Calc., Br, 38.1%). The additive compound, m. p. 155—156°, was almost colourless and not quite pure [Found: total Br, 61.4; Br', 22.5. ( $C_9H_7N \cdot HBr$ ) $_2 \cdot C_2H_2Br_4$  requires Br, 62.7; Br', 20.9%].

The bromoaurate, obtained from the hydrobromide in dark red crystals, m. p. 223°, was normal (Found: Au, 30.25. Calc. for  $C_9H_7N \cdot HBr \cdot AuBr_3$ , Au, 30.5%).

*Lucidine*, b. p. 153—156° (regarded as 2:4-dimethylpyridine):

Colourless crystals, m. p. 135—140° [Found: total Br, 66·7; Br', 22·3.  $(C_7H_9N, HBr)_2, C_2H_2Br_4$  requires Br, 66·5; Br', 22·2%].

$\alpha$ -Picoline:  $C_6H_7N, HBr, C_2H_2Br_4$ , colourless needles, m. p. 104—105° (Found: total Br, 76·8; Br', 15·4. Calc., Br, 76·9; Br', 15·4%).

Interaction of acetylene tetrabromide and piperidine, coniine, homopiperonylamine, menthylamine, hexamethylenetetramine, and phenylhydrazine gave rise to the hydrobromide only. Antipyrine dissolved in hot acetylene tetrabromide crystallised unchanged on cooling. Pyrrole also did not react.

I desire to thank Professor T. S. Patterson for his interest in this work and for facilities to carry it out.

THE UNIVERSITY, GLASGOW.

### XXX.—*Heterogeneous Equilibria between the Sulphates and Nitrates of Sodium and Potassium and their Aqueous Solutions. Part I. The Ternary Systems.*

By MOHAMMED ABDUL HAMID.

DURING the course of an investigation of the quaternary system  $H_2O-Na_2SO_4-NaNO_3-K_2SO_4-KNO_3$  at 25° and 90°, it became necessary to investigate and revise some of the ternary systems involved. The subject of the present paper is to record the data so obtained and to sum up briefly all other information available about the isothermal relations in the four ternary systems which form the basis of the above quaternary system. In the isotherms at 90°, only the invariant points have been determined. The solubilities of single salts have been selected from Seidell's "Solubilities of Inorganic and Organic Substances." The vapour phase is always assumed to be absent and the whole subject is treated from the point of view of condensed systems at atmospheric pressure.

#### EXPERIMENTAL.

All the salts used were carefully purified by repeated crystallisation and their purity was checked by a number of analyses before use. For the determination of solubility, various complexes were vigorously stirred up to equilibrium in wide tubes immersed in water- and oil-thermostats kept constant within 0·02° at 25° and within 0·2° at 90°. The usual time given was about 40 hours at 25° and about 10 hours at 90°. The compositions of the solutions when equilibrium was established were determined by withdrawing

portions of them by means of pipettes heated previously to the temperatures of the baths, filtering, and weighing in stoppered bottles and analysing the solutions. The moist residue was weighed separately and analysed. The potassium ion was determined by the cobaltinitrite method, sulphate weighed as barium sulphate, and nitrate estimated by a modified method of Schlösing. All these methods were checked beforehand by a large number of estimations in mixtures of sodium sulphate, sodium nitrate, potassium sulphate, and potassium nitrate of known compositions. The amounts of sodium and water were determined by difference. In

FIG. 1.

some cases all the salts were converted into the chlorides and the analytical results checked in this way.

The thermometers were all compared with those standardised at the National Physical Laboratory, Teddington.

*The System Water-Potassium Sulphate-Potassium Nitrate.*—This belongs to the simplest type of ternary system, neither double salts nor salt hydrates occurring in it. The system at 25° is represented graphically in Fig. 1, and the experimental data for the two temperatures are in Table I.

The system water-sodium nitrate-potassium nitrate has been worked out by Reinders (*Proc. K. Akad. Wetensch. Amsterdam*, 1914, **16**, 1935) at 25°. The compositions of the binary and ternary invariant solutions at 90° are in Table II.

The system water-potassium sulphate-sodium sulphate is complicated by the existence of a double sulphate of sodium and potassium known as the mineral glaserite. As to the composition of this compound, there have been controversies from time to time. Its correct composition was first reported by Penny (*Phil. Mag.*, 1855, 10, 401), who assigned the formula  $3K_2SO_4 \cdot Na_2SO_4$  to it and after whom it is sometimes called Penny's double salt. Penny's results were corroborated by some authors, whilst several double sulphates of sodium and potassium of different compositions were subsequently described by various investigators. A complete literature on this subject can be found in a paper by Retgers (*Z. physikal. Chem.*, 1890, 6, 205). van 't Hoff and Barschall (*Berlin. Sitzungsber.*, 1903, 359; *Z. physikal. Chem.*, 1906, 56, 212) put forward the view that glaserite is an extreme limit of a series of solid solutions saturated with potassium sulphate having the composition  $K_3Na(SO_4)_2$ . Nacken (*Berlin. Sitzungsber.*, 1910, 1016) has confirmed the existence of the double salt  $K_3Na(SO_4)_2$  and has found that it dissolves sodium sulphate as a solid solution up to a certain extent. His results have been confirmed recently by Okada (*Mem. Coll. Sci.*, 1914, 1, 95). Whereas Nacken assumes that the solubility of sodium sulphate in glaserite increases with temperature, Okada has shown that it increases to a temperature of 60°, where it reaches a maximum, and above that temperature the field of solid solutions becomes narrower again. The system  $H_2O-K_2SO_4-Na_2SO_4$  at 25° and 90° is shown in Figs. 2 and 3

respectively. The data for this system at these two temperatures are in Table III.

TABLE III.

FIG. 2.

FIG. 3.

The points H and G (Figs. 2 and 3) represent the compositions of pure Glauber's salt and pure glaserite, respectively. The point G' (Fig. 2) represents the composition of the solid solution containing the maximum amount of sodium sulphate which glaserite can dissolve at 25°. Similarly the point G'' (Fig. 3) represents the composition of the solid solution which is formed by dissolving the maximum amount of sodium sulphate in glaserite at 90°. The compositions of G, G', and G'' are given in Table IV, both in terms of weight (*w*) and molar (*m*) percentages.

TABLE IV.

Temp. 25° :	Comp. of G.		Comp. of G'.		Diff.
	$\text{K}_2\text{SO}_4$ .	$\text{Na}_2\text{SO}_4$ .	$\text{K}_2\text{SO}_4$ .	$\text{Na}_2\text{SO}_4$ .	
<i>m</i> .....	75.0	25.0	71.7	28.3	3.3
<i>w</i> .....	78.6	21.4	75.7	24.3	2.9
Temp. 90° :	Comp. of G.		Comp. of G''.		Diff.
	$\text{K}_2\text{SO}_4$ .	$\text{Na}_2\text{SO}_4$ .	$\text{K}_2\text{SO}_4$ .	$\text{Na}_2\text{SO}_4$ .	
.....	75.0	25.0	70.5	29.5	4.5
.....	78.6	21.4	74.6	25.4	4.0

The above values of  $G'$  are taken from Nacken and Okada and those of  $G''$  interpolated from Okada's results. It will be seen from the isotherms at  $25^\circ$  and  $90^\circ$  (Figs. 2 and 3) that the solutions  $l$  and  $l_1$  are in equilibrium with Glauber's salt and  $G'$  in one case, and with sodium sulphate and  $G''$  in the other. The solutions all along the curves  $lk$  and  $l_1k_1$  are in equilibrium with solid solutions whose compositions vary between  $G$  and  $G'$  in one case and between  $G$  and  $G''$  in the other. It may be mentioned that glaserite is not known to form any solid solutions with potassium sulphate.

FIG. 4.

*The System Water-Sodium Sulphate-Sodium Nitrate.*—This system has been very recently worked out by Massink (*Z. physikal. Chem.*, 1917, 92, 364) at a number of temperatures. In addition to a hydrated double salt of the formula  $\text{Na}_2\text{SO}_4 \cdot \text{NaNO}_3 \cdot \text{H}_2\text{O}$ , commonly known in Chile as the mineral darapskite, Massink describes an anhydrous double salt of the formula  $3\text{NaNO}_3 \cdot 4\text{Na}_2\text{SO}_4$  at  $25^\circ$ . No evidence of this double salt could be obtained at this temperature. The only double salt that exists at  $25^\circ$  is the hydrated double salt, darapskite, which breaks up at higher temperatures, and at  $90^\circ$  the only stable solid phases in the system are the two anhydrous

salts, sodium sulphate and sodium nitrate. The system at 25° is shown in Fig. 4, and the data for this system at the two temperatures are in Table V.

TABLE V.

Composition by weight percentage.

Solution.			Rest.		
Temp.	% $\text{Na}_2\text{SO}_4$ .	% $\text{NaNO}_3$ .	% $\text{Na}_2\text{SO}_4$ .	% $\text{NaNO}_3$ .	Solid phases.

"	15.43	24.06	34.43	18.40	$\text{Na}_2\text{SO}_4$
"	14.15	25.96	39.87	20.45	$\text{Na}_2\text{SO}_4 + \text{D}_1$
"	11.88	28.46	30.00	31.05	$\text{D}_1$
"	9.04	32.68	27.44	33.46	"
"	5.42	39.71	29.39	37.52	"
"	3.01	45.87	24.63	62.90	$\text{D}_1 + \text{NaNO}_3$
"	0	47.69	—	—	$\text{NaNO}_3$
90°	29.90	0	—	—	$\text{Na}_2\text{SO}_4$
"	2.53	58.66	—	—	$\text{Na}_2\text{SO}_4 + \text{NaNO}_3$
"	61.65	0	—	—	$\text{NaNO}_3$

Composition of  $\text{D}_1 = \text{Na}_2\text{SO}_4$ , 57.96%;  $\text{NaNO}_3$ , 34.68%;  $\text{H}_2\text{O}$ , 7.36%.

The points H and  $\text{D}_1$  (Fig. 4) represent the compositions of pure Glauber's salt and pure darapskite, respectively. The point  $\text{D}_2$  (Fig. 4) represents the composition of the supposed anhydrous double salt of Massink and the point  $d$  his supposed ternary isothermal invariant point at which, according to him, the solution is in equilibrium with darapskite and the anhydrous double salt  $\text{D}_2$ . Not only has this solution been found to be saturated with darapskite alone, but on isothermal evaporation of unsaturated solutions at 25° which theoretically ought to have deposited the anhydrous double salt  $\text{D}_2$ , if it could exist, darapskite has been found to be precipitated as the first solid. Thus an unsaturated solution of the composition  $i$  (Fig. 4) on evaporation at 25°, according to Massink, should deposit the anhydrous double salt  $\text{D}_2$  as the first solid and should continue to do so until the point  $d$  is reached. This it does not do. Instead, however, it deposits darapskite, which comes down in very fine, needle-shaped crystals, readily distinguishable with the naked eye. Besides the double salt  $\text{D}_2$ , Massink (*loc. cit.*) describes another anhydrous double salt of the formula  $3\text{NaNO}_3 \cdot 2\text{Na}_2\text{SO}_4$  at 35°. It may be noted that he has determined the compositions of these two anhydrous double salts from one or two analyses of the solution and the wet residue in each case, which in themselves are not sufficient. The improbability of the existence of these two anhydrous double salts in this system is further manifest from the following considerations. It has been

alleged by Massink himself that these two anhydrous double salts do not exist at lower temperatures. According to him, the transition temperatures which mark the lower stability limits to the existence of the two anhydrous double salts lie somewhere between  $20^{\circ}$  and  $35^{\circ}$ . Further, it has been shown by Schreinemakers (*Z. physikal. Chem.*, 1909, **65**, 553) that if two anhydrous salts can form an anhydrous double salt at a certain temperature in the binary system, formed by these two salts, they will do so at the same temperature in all ternary systems formed by the addition of any liquid component to the above binary system, and the solubility curves of the two salts will be interrupted by that of the double salt in all these systems at this temperature. The converse of this principle has been very recently applied by Freeth (*J. Physical Chem.*, 1925, **29**, 1497) in the deduction of the type of a two-component system by the addition of a third component, from which it follows that if above a certain temperature in the ternary system  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3$  the solubility curves of sodium sulphate and sodium nitrate are interrupted by that of an anhydrous double salt, this will be the case also in the binary system  $\text{Na}_2\text{SO}_4-\text{NaNO}_3$ . Since the solution does not participate in the formation of the anhydrous double salt, the transition temperature of this binary compound is independent of the number of components of the system, *i.e.*, it is the same in all systems whether binary, ternary, or quaternary. It is clear, therefore, that at temperatures above  $35^{\circ}$  the two anhydrous double salts of Massink, if they can exist at all, must be formed in the ternary system  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3$ , as also in the binary system  $\text{Na}_2\text{SO}_4-\text{NaNO}_3$ . From an investigation of the quaternary system  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3-\text{K}_2\text{SO}_4-\text{KNO}_3$  at  $90^{\circ}$  the author has been led to the conclusion that no such double salts exist in the ternary system  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3$  at this temperature, the only solid phases being the two anhydrous salts, sodium sulphate and sodium nitrate. This is in complete accord with the very recent investigations of Perman and Harrison (*J.*, 1924, **125**, 365) of the binary system  $\text{Na}_2\text{SO}_4-\text{NaNO}_3$ .

The author wishes to express his thanks to Professor F. G. Donnan, F.R.S., for his kind help and interest during the course of this investigation.

THE WILLIAM RAMSAY INORGANIC AND  
PHYSICAL CHEMISTRY LABORATORIES,

UNIVERSITY COLLEGE, LONDON. [Received, December 1st, 1925.]

XXXI.—*Heterogeneous Equilibria between the Sulphates and Nitrates of Sodium and Potassium and their Aqueous Solutions. Part II. The Quaternary System  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3-\text{K}_2\text{SO}_4-\text{KNO}_3$ .*

By MOHAMMED ABDUL HAMID.

BEYOND the observations of some early investigators of the slow dissolution of potassium nitrate in saturated sodium sulphate solutions with the precipitation of sodium or potassium sulphate after a long time and of the ease with which sodium nitrate dissolves in solutions of potassium sulphate, no attempt seems ever to have been made to study the equilibria involved in the reciprocal salt transformation

The quaternary system formed by the addition of water to the two salt pairs,  $\text{Na}_2\text{SO}_4-\text{KNO}_3$  and  $\text{NaNO}_3-\text{K}_2\text{SO}_4$  presents certain features of interest and is of special importance in the determination of the most suitable conditions for the separation of the nitrates of sodium and potassium from the sulphates of these metals, with which they are found contaminated in nature in various parts of the world.\*

The various binary and ternary systems which form the basis of the above quaternary system have been described in Part I (preceding paper). All the binary and ternary compounds which occur in the ternary systems occupy definite saturation surfaces in the quaternary system. In addition to these binary and ternary compounds at  $25^\circ$ , a compound occurs in the quaternary system, the composition of which it has not been found possible so far to determine. It occupies a definite saturation surface in the quaternary system, and further evidence on which the conclusion of its existence is based will be found in the following pages. The isotherm at  $90^\circ$  does not contain the saturation surface of this compound. There is therefore no doubt that it splits up at some temperature below  $90^\circ$  into its simple constituents.

*Graphical Representation.*—In order to represent graphically the experimental results, Schreinemaker's pyramidal method of representation (*Z. physikal. Chem.*, 1909, 69, 557) has been used. Use has also been made of the various projection methods (*ibid.*, 1907,

59, 663) for the confirmation of solid phases by the "rest method" in certain parts of the system. It may be pointed out that by the term, orthogonal projection, is meant a projection made on to the

ground plane by means of parallel lines perpendicular to the base of the pyramid.

The experimental and analytical methods used were the same as described in Part I. The data for the system  $\text{H}_2\text{O}-\text{NaNO}_3-\text{KNO}_3$  at  $25^\circ$  are taken from Reinders (*Proc. K. Akad. Wetensch. Amsterdam*, 1914, 16, 106).

*The Isotherm at  $25^\circ$ .*—The compositions of the binary, ternary and quaternary solutions saturated at this temperature are expressed in g.-mols. of the various salts per 100 g. of the solution in Table I. The molecular formulæ of sodium and potassium nitrates have been doubled in order to give them equal replacing powers with sodium and potassium sulphates.

*The Orthogonal Projection.*—For the further discussion of the system, we shall use the orthogonal projection which is shown in Figs. 1 and 2. The apex, W, of the pyramid which represents pure water projects to the point *w* in these figures. The four ternary isotherms which form the boundary of the quaternary isotherm are shown in this projection separately in Fig. 1. As has been pointed out in Part I, the point *l* represents a ternary isothermal invariant solution which is in equilibrium not with Glauber's salt and glaserite, but with Glauber's salt and a solid solution of glaserite and sodium sulphate of the composition  $\text{K}_2\text{SO}_4 = 78.6\%$ ,  $\text{Na}_2\text{SO}_4 = 21.4\%$ . This introduces no new complication in the quaternary system provided there is always an excess of sodium sulphate present in the solid phase to form the solid solution of glaserite and sodium sulphate of the above composition. Strictly speaking, therefore, where glaserite is mentioned as a solid phase along with sodium sulphate, its composition is given by the above value. The difference between the composition of glaserite and that of its solid solution is not, however, very large and for all practical purposes glaserite may be assumed to be of the constant composition  $\text{K}_3\text{Na}(\text{SO}_4)_2$ . It may be seen that the line joining the point representing the composition of pure glaserite to the origin (apex in the space model) cuts the saturation curve of potassium sulphate and not that of glaserite. Glaserite is therefore decomposed by water and the ternary invariant solution *l* is incongruently saturated.

In order to show the positions of the quaternary saturation surfaces of Glauber's salt and sodium sulphate and the quaternary isothermal invariant point *m* more clearly in the projection, the ternary saturation curve *ab* of Glauber's salt in the system  $\text{H}_2\text{O}-\text{Na}_2\text{SO}_4-\text{NaNO}_3$  is drawn as a straight line in Fig. 2, although the actual form of the curve is that shown in Fig. 1.

The darapskite field is enclosed by the curves *ce*, *er*, *rp*, *pn*, and *en*. Here again the line joining the point representing the com-

position of pure darapskite to the origin passes through the Glauber's salt and glaserite fields and not through that of darapskite. Darapskite also is therefore decomposed by water.

FIG. 1.

FIG. 2.

The quaternary saturation curves *er*, *rs*, and *sg* mark the inner boundary limit of the sodium nitrate field. The composition of the solution containing the maximum amount of potassium nitrate, which the ternary invariant solution *e* in contact with darapskite

and sodium nitrate can dissolve, is given by the point *s*. The same quaternary solution *s* is obtained when an excess of either sodium or potassium sulphate is added to the ternary invariant solution *g* in contact with excess of solid sodium and potassium nitrates.

The point *v* (Fig. 2) represents a quaternary invariant solution in equilibrium with three solid phases, potassium sulphate, glaserite and potassium nitrate. The composition of this solution, as will be seen from the position of the point *v* in Fig. 2, cannot be represented in terms of the solid phases with which it is in equilibrium. This solution is therefore incongruently saturated.

On the addition of sodium nitrate to the solution *v* in contact with glaserite, potassium sulphate and potassium nitrate, the following reaction occurs :

This reaction does not affect the composition of the quaternary invariant solution *v*, so long as there is any solid potassium sulphate present in contact with the solution. When so much of the sodium nitrate has been added that the whole of the solid potassium sulphate which was present in contact with the solution *v* is converted into glaserite and potassium nitrate, it disappears as a solid phase and the system acquires a degree of freedom. The point representing the compositions of the monovariant quaternary solutions then traverses the curve *vg* on the additions of increasing quantities of sodium nitrate to the solution *v*. The two solid phases in equilibrium with all quaternary solutions, the compositions of which are represented by points on the curve *vg* between the points *v* and *g*, are glaserite and potassium nitrate. When so much of the sodium nitrate has been added that the composition of the quaternary solution is represented by the point *g*, a distinct halt occurs in the movement of the point representing the compositions of the quaternary solutions, and further additions of sodium nitrate do not change the composition of the solution *g*, so long as there is sufficient glaserite present in contact with it. It is the persistence of the constant composition of the solution at *g* in contact with solid glaserite and potassium nitrate with increasingly small additions of sodium nitrate that leaves no doubt as to *g* being an invariant point.

The above facts combined with the positions of the curves *np* and *pq* all point to the existence of a new solid phase in the quaternary system. Before describing the various attempts that have been made to determine the nature of this new solid phase, we shall summarise the meanings of the various curves and surfaces in the

quaternary isotherm at 25°. The letter T stands for the new solid phase.

The saturation curves and surfaces intersect in points representing solutions which are saturated with three solids. These quaternary invariant points are *m*, *n*, *p*, *q*, *r*, *s*, and *v*. The actual compositions of these solutions as well as the solids with which they are in equilibrium will be found in Table I.

*The Nature of the Phase T.*—The improbability of the existence of any compound other than darapskite of sodium sulphate and sodium nitrate has been pointed out in Part I. The positions of the various quaternary invariant points and those of the quaternary saturation curves and the existence of the enclosed area *rpqs* in Fig. 2 point clearly to the formation of a definite compound in the quaternary system. That this is essentially a quaternary compound, a triple or a tetragenic double salt, is indisputable. Attempts to isolate it by the evaporation of unsaturated solutions have proved fruitless. It will be seen by reference to Fig. 2 that points in the area *rpqs* represent solutions which are saturated with one solid only, viz., the compound T. The points representing the compositions of unsaturated solutions which will deposit this compound on isothermal evaporation as the first solid also project on to this area in the orthogonal projection. The compositions of all such unsaturated solutions which will deposit T as the first solid on evaporation cannot be read directly from this projection. Jänecke's method of representation ("Gessättigte Salzlösungen") is of inestimable value

for this purpose. A part of the Jänecke diagram is shown in Fig. 3. The proportions of dry salts contained by an unsaturated solution which will deposit T as the first solid on evaporation can be read from this figure at a glance. To hasten the process of evaporation, such mixtures of dry salts were dissolved in excess of water and the unsaturated solutions evaporated at higher temperatures to such an extent that when cooled to  $25^\circ$  they were expected to deposit T as the first solid. This method of procedure unfortunately suffers from the serious defect that the solubility of sodium sulphate in solutions of potassium and sodium nitrates decreases with rise of temperature and consequently sodium sulphate is deposited at

FIG. 3.

higher temperatures from solutions which are not saturated at  $25^\circ$  with respect to this salt. This fact makes it very difficult to adjust the whole course of evaporation in such a way that when the hot solution is cooled to  $25^\circ$  it should deposit T. Actually all such attempts have resulted in solutions, the compositions of which lie very near to the point *s* (Fig. 2), which is undoubtedly the crystallisation end-point of the system. In the isothermal evaporation at  $25^\circ$ , the solution remains supersaturated for a considerably long time. In all these cases of evaporation it has been found that crystallisation starts after the process of evaporation has been carried too far. This tendency to form supersaturated solutions has been noticed by van 't Hoff in many cases, particularly those of kieserite, leonite and kainite ( $\text{MgSO}_4 \cdot \text{KCl} \cdot 3\text{H}_2\text{O}$ ) ("Zur Bildung der organischen Salzablagerungen," 1905, 1, 28). The present case seems analogous to these and requires similar handling which

necessitates the measurements of the vapour pressure of the hydrated double salt, darapskite, as well as those of the saturated solutions at this temperature (*op. cit.*).

*The Isotherm at 90°.*—The isotherm at 90° is not so complicated as that at 25°. The only double salt that occurs in the system at this temperature is glaserite. All others seem to break down at temperatures below 90°. In the ternary systems, only the invariant points have been determined, and although the ternary curves have

FIG. 4.

not been followed completely, it is probable that in most cases they are not very different from straight lines. Furthermore, as the quaternary curve  $l_1x$  is practically a straight line, there is no doubt that the hydrated double salt, darapskite, in the ternary system  $H_2O-Na_2SO_4-NaNO_3$  and the compound T in the quaternary system split up into the simple salts at temperatures lower than 90°. The isotherm is shown in Fig. 4 as the orthogonal projection of the space model, and the data for the system at this temperature are in Table II in terms of molar percentages.

THE WILLIAM RAMSAY INORGANIC AND  
PHYSICAL CHEMISTRY LABORATORIES,

UNIVERSITY COLLEGE, LONDON. [Received, December 1st, 1925.]

### XXXII.—*Preparation, Hydrolysis and Reduction of the Fluoro-, Chloro-, and Bromo-benzyl Bromides.*

By JOHN BALDWIN SHOESMITH and ROBERT HENRY SLATER.

IN previous communications (J., 1922, 121, 1392; 1923, 123, 2828; 1924, 125, 1312, 2278) an account was given of the manner in which the reactivity of halogen atoms in various halogenated benzenoid derivatives is influenced by oxygen and by the hydrogen of a methyl group. The investigations have been continued with a view to discovering the effect of fluorine, chlorine, and bromine in such compounds. From the point of view of the principle of induced alternate polarities the halogens, except fluorine, appear to act as weakly negative "key-atoms" (as pointed out by Lapworth, *Mem. Manchester Phil. Soc.*, 1920, 64, No. 3). The present investigation has shown that (1) fluorine is capable of inducing differences of reactivity very similar to, but smaller than those met with in the cases of the methoxybenzyl bromides (J., 1922, 121, 1392) and the  $\alpha$ -bromoxylenes (J., 1924, 125, 2278) and (2) chlorine and bromine induce still smaller differences, and the chloro- and bromo-benzyl bromides provide the first examples encountered in this series, in

which a change of reagent does not cause a change in the order of reactivity.

The order of ease with which the bromides lose their bromine as bromidion in solution in aqueous alcohol is: (1) *p*-fluorobenzyl bromide > benzyl bromide > *o*-fluoro- > *m*-fluoro-; (2) benzyl bromide > *p*-chloro- > *o*-chloro- > *m*-chloro-; (3) benzyl bromide > *p*-bromo- > *o*-bromo- > *m*-bromo-. The order of ease of reduction by hydriodic acid is: (1) *o*-fluoro- > *m*-fluoro- > benzyl bromide > *p*-fluoro-; (2) *o*-chloro- > *p*-chloro- > *m*-chloro- > benzyl bromide; and (3) *o*-bromo- > *p*-bromo- > *m*-bromo- > benzyl bromide. The differences of ease of hydrolysis are quite marked. Those of ease of reduction are small, but several repetitions of the experiments led to the same order of reactivity and, as is seen from the above, the order of ease of reduction of the chloro- and bromo-compounds is not analogous to that discovered in the cases of the methoxybenzyl bromides, the *o*-bromoxylenes, and the fluorobenzyl bromides.

A series of experiments was undertaken to see if this non-reversal of the order of reactivity is due to any of the following causes: (a) removal of halogen from the nucleus, (b) liberation of iodine as follows: (1)  $\text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Br} + \text{HI} \rightarrow \text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{I} + \text{HBr}$ . (2)  $2\text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{I} \rightarrow \text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{C}_6\text{H}_4\text{R}$  (compare Silberrad, J., 1924, 125, 2196), and (c) the more rapid formation of the iodide in the case of the para-isomerides and subsequent reduction of the iodides by hydriodic acid. The bromides were reduced for a long time, but the slight elimination of nuclear halogen then noted was not sufficient to reverse the discovered order of reactivity when correction was made for it. Reaction (2) is a photochemical one and does not take place in a dark thermostat such as was used in these experiments. In order to test (c), the bromobenzyl iodides were prepared; they were reduced by hydriodic acid at the same rate as the corresponding bromides. Thus it appears as if the conversion of the bromide into iodide is due to a mass-action effect and, owing to the concentration of hydriodic acid used, goes almost equally rapidly in all cases. Some of the iodides lose iodine more rapidly than their isomerides, and when a change in order of reactivity with change of reagent takes place alternating polar influences are very strong, *e.g.*, in the methoxybenzyl bromides.

An approximate estimate of the magnitude of the three influences which affect the reactivity of the bromine atom in the bromides, namely, the general (represented by *g*), the alternating (represented by *a*), and the so-called steric influence (represented by *s*), may be arrived at from considerations similar to those put forward by Flürscheim (J., 1909, 95, 726). A comparison by means of reaction velocities, which is the most satisfactory method, is impossible,

because only during the hydrolysis of *o*- and *m*-fluorobenzyl bromides and also of the isomeric nitrobenzyl bromides (Shoesmith and Hetherington, J., 1924, 125, 1316) were the reactions slow enough to give monomolecular velocity coefficients. The reduction of the bromides, moreover, is not the simple bimolecular reaction investigated by West in the case of bromomalonyl compounds (J., 1924, 125, 710). The reciprocals of the times taken for half-completion of the reaction in the various cases may be used to obtain the necessary comparison.

If  $K_o$ ,  $K_m$ ,  $K_p$  and  $K_u$  represent the reciprocals of the times taken for half-completion of the reactions for the ortho-, meta-, para- and unsubstituted compounds, respectively, the manner in which the velocities of the reactions are affected by the three influences mentioned above may be expressed by the following equations: \*

$$\log_{10} K_o = \log_{10} K_u + g + a + s.$$

$$\log_{10} K_m = \log_{10} K_u + g - a.$$

$$\log_{10} K_p = \log_{10} K_u + g + a,$$

and hence

$$g = \frac{1}{2}(\log_{10} K_m + \log_{10} K_p - 2 \log_{10} K_u),$$

$$a = \frac{1}{2}(\log_{10} K_p - \log_{10} K_m),$$

and  $s = \log_{10} K_o - \log_{10} K_p.$

Obtained from graphs plotted from observations recorded in this and previous communications, the reciprocals of the various times taken for half-hydrolysis (*x*) and half-reduction (*y*) at the temperatures stated are summarised in Table I, on which the following remarks are based:

*The general effect.* The order in which the atoms or groups affect the reactivity of the bromine (*a*) towards hydrolysing agents in a general way is OMe, Me, F, Cl, Br, CO<sub>2</sub>H, NO<sub>2</sub>, ranging from the strongly enhancing methoxy-group to the strongly retarding nitro-group, and (*b*) towards hydrogen iodide is OMe and Me, Cl, Br, CO<sub>2</sub>H, and F. In the latter case, only the methoxy- and the methyl-group have an appreciable general influence on the reduction velocity. The strong general influence of the methoxy-group is noteworthy.

*The alternating effect.* The order in which alternation towards hydrolysing agents is produced is similar to that given above (*a*); in this case, however, the magnitudes of the effect may be compared. The order is OMe > F > Me > Cl > Br > CO<sub>2</sub>H > NO<sub>2</sub>. The differences observed in the first five cases, *i.e.*, negative groups, have positive values, whilst in the last two, *i.e.*, positive groups, they have negative values. For reduction, the order is OMe and Me > CO<sub>2</sub>H > F, Cl,

\* Logarithms are used in order that the expressions shall finally involve a product or a quotient as the case may be.

\* The extraordinary rapidity with which *p*-methoxybenzyl bromide is hydrolysed in aqueous alcoholic solution suggests that this figure should be much greater and hence *g* and *a* for hydrolysis approach those for reduction, *i.e.*, ∞

†  $\omega$ -Bromo-*o*-xylene is definitely but very slowly reduced at 25°. A definite value for  $K_o(g)$  cannot be given, but *s* (red.) must be large on account of the stability of  $\alpha$ -iodo-*p*-xylene at 25° in presence of hydrogen iodide.

and Br. Here the differences in the cases of the OMe, Me and F compounds have positive values and in the other cases negative values. According to the principle of induced alternate polarities the sign of the difference is determined by the positive or negative character of the substituents, and the reduction of the chloro- and bromo-benzyl bromides is the only case so far met with in this series in which the sign of the difference is other than was expected.

*The steric effect.* The values obtained for  $s$  show that this effect in some cases diminishes and in other cases increases the reactivity, the former being observed in the hydrolyses, the latter in the reductions. Therefore the retarding of the reactions cannot be due to steric hindrance as normally conceived, and the results justify the conclusion that there is a disturbing factor governing the reactivity of ortho-compounds (see Lapworth and Shoesmith, J., 1922, 121, 1394).

The influence of atoms or groups of atoms having the same electronic shell may be compared also, since the manner in which the methyl and the methoxy-group and the fluorine atom each affect the reactivity of the bromine atom of the  $-C_6H_4 \cdot CH_2Br$  group has been investigated. The order of potency is  $OMe > Me > F$ , except in the case of alternation of hydrolysis, for which the order is  $OMe > F > Me$ .

#### EXPERIMENTAL.

*Preparation of the Isomeric Chlorobenzyl Bromides.*—The most reliable method of preparing the ortho- and para-isomerides is indicated by the scheme :

The appropriate chlorotoluene, mixed with 5% of its weight of phosphorus pentachloride, was chlorinated at 160° until the required increase in weight had taken place. The oil thus obtained was boiled with twice its bulk of 98% formic acid ( $d$  1.20) for  $\frac{1}{2}$  hour, the mixture poured into an excess of cold water, and the oil separated, dissolved in ether, washed twice with water, and once with aqueous sodium hydroxide. The aldehyde was precipitated as the bisulphite compound, which was carefully washed with ether, dissolved in water, and the pure aldehyde liberated by the addition of excess of sodium carbonate. It was converted into the alcohol (*o*., m. p. 70°; *p*., m. p. 72°) by treatment with 25% alcoholic potassium hydroxide, and this into the bromide by means of hydrogen bromide in benzene solution.

*o*-Chlorobenzyl Bromide is an oil, b. p.  $102^{\circ}/9$  mm. (Found: Br, 39.05.  $C_7H_5ClBr$  requires Br, 38.9%). *p*-Chlorobenzyl bromide has m. p.  $51^{\circ}$  (compare Jackson and Field, *Ber.*, 1878, 11, 905) (Found: Br, 38.7%).

*m*-Chlorobenzyl Bromide.—*m*-Nitrobenzaldehyde was converted into *m*-chlorobenzaldehyde (Erdmann and Schwechten, *Annalen*, 1890, 260, 59), b. p.  $213$ — $214^{\circ}$ , and this was reduced to the alcohol in alcoholic potassium hydroxide. The alcohol had b. p.  $242^{\circ}$ , not  $234^{\circ}$  as stated by Mettler (*Ber.*, 1905, 38, 1749), and from it *m*-chlorobenzyl bromide, an oil of b. p.  $109^{\circ}/10$  mm. (Found: Br, 38.8%), was obtained as before.

*The Isomeric Bromobenzyl Bromides.*—Each of these compounds was prepared by passing a stream of air through a weighed quantity of bromine into the appropriate, boiling bromotoluene. The product was distilled under diminished pressure, the portion passing over between  $120^{\circ}$  and  $140^{\circ}/12$ — $16$  mm. being collected, cooled, and when solid recrystallised from alcohol. The bromides thus obtained had m. p.'s: *o*-,  $31^{\circ}$ ; *m*-,  $40^{\circ}$ ; and *p*-,  $63^{\circ}$  [Found: hydrolysable Br, (*o*-) 32.1, (*m*-) 31.8, (*p*-) 31.8. Calc. for  $C_7H_7Br_2$ , hydrolysable Br, 32.0%] (compare Jackson, *Ber.*, 1876, 9, 932).

The *isomeric bromobenzyl iodides* were prepared by boiling aqueous acetone solutions of the corresponding bromides with rather more than the calculated quantity of potassium iodide for  $\frac{1}{2}$  hour. The mixture was then poured into water, and the iodide recrystallised from light petroleum. *o*-Bromobenzyl iodide crystallises in shining, white needles, m. p.  $47^{\circ}$  (Found: I, 42.75.  $C_7H_5BrI$  requires I, 42.7%). *m*-Bromobenzyl iodide crystallises in white, six-sided prisms, m. p.  $42^{\circ}$  (Found: I, 42.8%). *p*-Bromobenzyl iodide crystallises in white needles, m. p.  $73^{\circ}$  (Hantzsch and Schultze, *Ber.*, 1896, 29, 2253, give  $80$ — $81^{\circ}$ ) (Found: I, 42.9%).

[With R. H. SLATER.]

*Preparation of the Isomeric Fluorotoluenes.*—A solution of the requisite toluidine (25 g.) in a mixture of 30 c.c. of concentrated sulphuric acid and 80 c.c. of water was cooled to  $-5^{\circ}$  and diazotised with 20 g. of sodium nitrite dissolved in 50 c.c. of water, the temperature being kept below  $5^{\circ}$ . The solution of the diazotised base was added to about 400 c.c. of commercial hydrofluoric acid (50—60%) in a 1,500 c.c. brazed spun-copper flask surrounded by ice, after which the flask was fitted, by means of a cork, with a copper reflux condenser and very carefully warmed on a water-bath for about an hour (alternatively, the mixture may be left at room temperature for about 16 hours). The condenser was then reversed and the flask heated directly. The mixture of fluorotoluene, hydrofluoric acid,

and cresol that distilled was collected in a copper beaker containing 300 c.c. of 30% aqueous sodium hydroxide solution surrounded by a good freezing mixture. When all the fluorotoluene had distilled, the alkaline mixture in the beaker was extracted thrice with ether, the combined extracts were de-emulsified by saturated ammonium sulphate solution and dried over anhydrous sodium sulphate, and the ether was evaporated. In each case the fluorotoluene distilled at 113–118° and the yield was 15–16 g. (65%) (compare Holleman and Beekman, *Rec. trav. chim.*, 1904, 23, 238).

*Preparation of the Isomeric Fluorobenzyl Bromides.*—Each fluorotoluene (80 g. in four lots) was brominated by volatilising bromine (30 g.) in a slow stream of dry air and passing the vapour into the boiling fluorotoluene (20 g.); by using small quantities nuclear substitution was avoided. The brominated oil was boiled with formic acid (*d* 1.20; *ca.* 2 vols.) for 6 hours, fluorobenzotribromide and fluorobenzylidene bromide being thus converted into fluorobenzoic acid and fluorobenzaldehyde, respectively, and some of the fluorobenzyl bromide into fluorobenzyl alcohol. The mixture was poured into a large excess of water, and the oil was separated, and washed in ethereal solution with 10% aqueous sodium hydroxide until free from fluorobenzoic and formic acids. After complete removal of the fluorobenzaldehyde with freshly prepared sodium bisulphite solution—the aldehydes and the benzyl bromides form constant-boiling mixtures—the ethereal solution was dried over anhydrous sodium sulphate, and the ether distilled. The residual oil was saturated in benzene solution with dry hydrogen bromide to convert any fluorobenzyl alcohol into the bromide, and after the removal of the benzene the fluorobenzyl bromide was fractionally distilled in a vacuum in the apparatus described by Widmer (*Helv. Chim. Acta*, 1924, 7, 52). *o*-Fluorobenzyl bromide had b. p. 84–85°/15 mm.; *m*-fluorobenzyl bromide, 77°/12 mm.; and *p*-fluorobenzyl bromide, 85°/15 mm. [Found: Br, 42.4 (*o*-); 42.0 (*m*-); 42.1 (*p*-).  $C_7H_5FBr$  requires Br, 42.3%].

*Hydrolysis of the Bromides.*—Twenty c.c. of a standard solution (105 c.c.) of the bromide in absolute alcohol were placed in a standard 25 c.c. flask, 5 c.c. of water added, and the volume was made exactly 25 c.c. by adding absolute alcohol. The whole was thoroughly mixed, immersed in the vapour of boiling carbon tetrachloride for a definite time, and then poured into a large volume of water. The liberated hydrobromic acid was titrated directly with standard aqueous sodium hydroxide and methyl-red. The results are in Table II, where *w* represents the total weight of benzyl bromide used, *x* the percentage changed, and *t* the time of hydrolysis in hours.

TABLE II.

*Reduction of the Bromides.*—Reduction at 25° under the conditions described by Lapworth and Shoesmith and by Shoesmith and Slater (*loc. cit.*) being so slow that satisfactory results could not be obtained, the bromides were reduced in a thermostat at 101°. Ten c.c. of a standard solution of the bromide in 50 c.c. of glacial acetic acid were placed in the 25 c.c. standard flask, 10 c.c. of freshly distilled hydriodic acid ( $d$  1.680) added, the volume was made up to 25 c.c. with glacial acetic acid, and the whole thoroughly mixed, and kept in the thermostat for a definite time. The percentage reduction was then estimated as in previous cases.

The concentration of the hydriodic acid and the amount of iodine in it both influence the rate of reduction, and therefore a series of reductions was carried out on the same day with the same hydriodic acid. The results are in Table IV,  $t$  and  $\alpha$  having the same significance as before.

\* At all temperatures, in aqueous alcoholic solution, *p*-methoxybenzyl bromide is completely, and the *o*-compound almost completely, hydrolysed in 2½ minutes.

TABLE IV.

*p*-Chlorobenzyl iodide (m. p.  $65^\circ$ ) was isolated from the reaction of *p*-chlorobenzyl bromide and hydrogen iodide in glacial acetic acid at  $25^\circ$  (compare Shoesmith and Slater, *loc. cit.*), but, owing to the dilution at which the reductions had to be carried out, end-products in the other cases could not be separated. The figures obtained, however, show that the reaction in the cases of the meta- and para-isomerides was quite normal in that it first involved conversion of the bromide into iodide and subsequent reduction of this to the halogenated toluene.

The iodobenzyl bromides have not been examined, since in a former communication we showed that hydrogen iodide reduces iodo-toluene to toluene.

The authors gratefully acknowledge the many valuable suggestions made by Dr. W. O. Kermack, especially with regard to the formulæ on pp. 216, and the receipt of a grant from the Earl of Moray Research Fund. They also thank the Trustees of the Carnegie Trust for the Universities of Scotland for a scholarship which enabled one of them (R. H. S.) to take part in this research.

### XXXIII.—*Cyclic Organo-metallic Compounds. Part I.* *Compounds of Tellurium.*

By HARRY DUGALD KEITH DREW.

THE present work has for its object the investigation of cyclic organo-metallic compounds (*i.e.*, compounds in which a metallic atom is united directly to carbon atoms, taking part therewith in ring formation), few of which have hitherto been synthesised.

Tellurium tetrachloride and diphenyl ether slowly but almost completely condense when heated together in chloroform solution. Hydrogen chloride is evolved and a yellow telluritrichloride is formed in which the group  $-\text{TeCl}_3$  has replaced a hydrogen atom of one of the aromatic nuclei. This substance is *p*-phenoxyphenyl-telluritrichloride (I),  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{TeCl}_3$ , since on reduction with aqueous potassium metabisulphite it becomes transformed to a purplish-red, crystalline substance, *pp'*-diphenoxydiphenyl ditelluride (II),  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{Te}:\text{Te}\cdot\text{C}_6\text{H}_4\cdot\text{OPh}$ , which shows a normal molecular weight in freezing benzene.

The formation of these substances demonstrates that the tellurium atom can be caused to enter an aromatic nucleus without the aid of Grignard reagents (compare Morgan and Drew, J., 1925, 127, 2307). That the group  $-\text{TeCl}_3$  enters the aromatic nucleus almost exclusively in one position was shown by the absence of an isomeric telluritrichloride from the by-products of this condensation and by the homogeneity of the ditelluride resulting upon reduction.

The telluritrichloride (I) melts at  $156^\circ$ , but if it is heated to about  $200^\circ$  a further (intramolecular) condensation occurs; a molecule of hydrogen chloride is evolved, and a colourless, crystalline, cyclic compound, 10:10-dichlorophenoxytellurine (III), is produced. That this substance contains the tellurium atom in a di-ortho-position relatively to the oxygen atom is indicated both from stereochemical considerations and by the existence of structurally analogous compounds of sulphur (IV) and of arsenic (V), of which the constitutions must be regarded as established (compare, for

example, Turner and Sheppard, J., 1925, 127, 544). Additional evidence upon this point is afforded by the ready reduction of the telluridichloride (III) to a yellow, crystalline, cyclic substance, phenoxytellurine (VI), of such marked chemical and physical stability

that there seems no doubt as to the nature of its tricyclic structure. This substance, which shows a normal molecular weight in freezing benzene, resembles somewhat closely the colourless sulphur analogue, phenoxthin or phenothioxin (IV; Mauthner, *Ber.*, 1906, 39, 1344), in both physical and chemical properties. It has, for example, a delicate floral odour suggesting rose-water, whereas phenoxthin is described as having a geraniol smell; and both substances develop intense colorations with concentrated sulphuric acid. Phenoxtellurine readily adds on bromine or iodine in chloroform solution, yielding primrose-yellow 10 : 10-dibromophenoxtellurine and red 10 : 10-di-iodophenoxtellurine, respectively; while the action of warm nitric acid converts it into colourless phenoxtellurine 10 : 10-dinitrate.

The formation of a cyclic tellurium compound from the telluritrichloride (I) suggests that the latter must in reality be the *o*-compound (VII). Since, however, it has been shown (Morgan and Drew, *loc. cit.*) that in the analogous condensation with phenetole the group  $-\text{TeCl}_3$  takes up exclusively a para-position with respect to ethoxyl, a para-orientation with respect to the phenoxy-group in the present case also would be anticipated. There remains thus the probability that the telluritrichloride is actually the *p*-compound (I), and that, on being heated above its melting point, it suffers a preliminary isomeric change into the *o*-compound (VII), which can then undergo the inner condensation :—

In an endeavour to test this possibility, the action of concentrated nitric acid upon the ditelluride (II) was tried. The telluritritrate,  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{Te}(\text{NO}_3)_3$ , was first produced and then the tellurium atom displaced, *pp'*-dinitrodiphenyl ether (m. p.  $143^\circ$ ) being formed; no *o*-nitro-compound was isolated. Of the two obvious mechanisms of displacement of the tellurium atom, *viz.*,

(1)  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{Te}(\text{NO}_3)_3 + \text{HO}\cdot\text{NO}_2 = \text{Te}(\text{NO}_3)_3\cdot\text{OH} + \text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$ ,  
and (2)  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{Te}(\text{NO}_3)_3 + \text{H}\cdot\text{NO}_3 = \text{Te}(\text{NO}_3)_4 + \text{PhO}\cdot\text{C}_6\text{H}_5$ ,  
the more probable would appear to be (1); and, if this is the case, the production of a *p*-nitro-compound of diphenyl ether proves the structure of the telluritrichloride and of the ditelluride derived from it. The possibility of mechanism (2), in which diphenyl ether is first liberated and then nitrated, cannot, however, be ignored with safety.

On the whole, the weight of evidence seems to be in favour of the para-structure; and accordingly it is considered best to adopt, for the present, the formulæ I and II for the telluritrichloride and ditelluride respectively, and to assume the transformation of the *p*-telluritrichloride into its *o*-isomeride as an intermediate step in the synthesis of the cyclic dichloride (III).

The best method of preparing 10:10-dichlorophenoxtellurine, giving a yield of 50%, is to heat at about 200° a mixture of tellurium tetrachloride and diphenyl ether in molecular proportions. The reaction proceeds in two stages, marked evolution of hydrogen chloride occurring first near 120° and then again near 200°. These stages apparently represent respectively the formation of the telluritrichloride and its transformation to the cyclic telluridichloride. The hypothetical preliminary isomeric change of the *p*- to the *o*-telluritrichloride must then occur between the temperature of the melting point of the telluritrichloride and the higher temperature, *i.e.*, between about 160° and 200°, a separate experiment having shown that the presence of chloroform in the preliminary stages of the above reaction had no effect upon the nature of the ultimate product.

Accordingly, an attempt was made to isolate the *o*-telluritrichloride by heating the supposed *p*-telluritrichloride to about 160° in an atmosphere of nitrogen. From the glassy product, which was a complex mixture containing a proportion of regenerated tellurium tetrachloride, a substance was obtained which had the properties of a telluritrichloride and yet was not identical with the initial material. This compound, which crystallised from benzene in almost colourless, pearly flakes decomposing at 125°, was possibly the *o*-telluritrichloride (VII), since it was easily reduced to a red substance possessing the characteristics of a ditelluride. Neither of these compounds was obtained in a pure condition, however, and their identity with the above structures has not been definitely established.

A colourless non-cyclic telluridichloride occurs as a by-product in the condensation of tellurium tetrachloride and diphenyl ether in chloroform solution; and this substance results also when the telluritrichloride (I) is heated with an excess of diphenyl ether at about 160°, hydrogen chloride being set free. This telluridichloride must therefore be *pp*-diphenoxydiphenyltelluridichloride (VIII),  $\text{PhO}\cdot\text{C}_6\text{H}_4\cdot\text{TeCl}_2\cdot\text{C}_6\text{H}_4\cdot\text{OPh}$ .

Here again the di-para-orientation is considered the more probable, since the substance is formed in small amount even at the low temperature of a condensation in chloroform. Owing, however, to the uncertainty attaching to the conditions under which the hypothetical

change of the tellurium atom from the *p*- to the *o*-position occurs, a di-ortho-, or even a para-ortho-structure is not definitely excluded.

The non-cyclic telluridichloride (VIII) was unchanged by the action of heat at 210°, and its formation was therefore unconnected with the production of the cyclic telluridichloride (III). It was of interest, therefore, to find that the latter was the main product of the action of heat at 200° upon a mixture of tellurium tetrachloride and a large excess (3½ mols.) of diphenyl ether, for this result seems to supply further evidence in favour of the hypothetical isomeric change of the *p*- to the *o*-telluritrichloride; since, in the absence of this transformation, it would be expected that the whole of the telluritrichloride would be changed at 200° into the non-cyclic telluridichloride (VIII), a reaction which is fairly rapid even at 160°. The production of the *o*-telluritrichloride must therefore accelerate rapidly at temperatures approaching 200°.

Leaving aside the question of orientation, we have thus the following series of changes which have been realised experimentally, with the temperatures at which the reactions are appreciably rapid :—

It is probable that *pp'*-diphenoxydiphenyltelluridichloride (VIII) is always formed, at least in minor quantities, when tellurium tetrachloride and diphenyl ether are heated together; but this telluridichloride is not readily separated from the resinous or colloidal by-products associated with it in the reaction-mixture.

Attempts are being made to clear up the uncertainty which exists regarding the orientations of the foregoing substances; and, in addition, the author is investigating the analogues and derivatives of phenoxytellurine and similar compounds containing other metals and metalloids.

#### EXPERIMENTAL.

*Condensation of Tellurium Tetrachloride with Diphenyl Ether in presence of Chloroform.*—Four experiments were carried out, with proportions of diphenyl ether ranging from 1 to 1½ mols. per mol. of tellurium tetrachloride and with amounts of chloroform varying between 0.6 and 2 c.c. per g. of the tetrachloride; the times of heating were between 8 and 26 hours. The optimum experiment only will be described in detail: 23.8 g. of tellurium tetrachloride, 18.7 g.

( $1\frac{1}{2}$  mols.) of diphenyl ether, and 15 c.c. of dry chloroform were heated under reflux during 26 hours, moist air being excluded. Hydrogen chloride was evolved and all the tellurium tetrachloride dissolved in about  $1\frac{1}{2}$  hours. The yellow trichloride that was gradually deposited from the intensely orange-brown solution was recrystallised from boiling dried chloroform; the mother-liquor on concentration to a syrup gave further crops of trichloride, which were recrystallised as before (total yield, 31.5 g. or 90%). The final syrup, on long standing in a desiccator, gave the dichloride (0.5 g.) in large, colourless prisms, which were recrystallised from ethyl alcohol or acetone. In this and in other experiments the separating trichloride was practically pure. Portions of it were subjected to careful fractionation from boiling dry chloroform, in an attempt to detect the presence of a possible isomeric trichloride. The melting points and mixed melting points of the recrystallised first and final fractions were always practically identical. Slight differences sometimes observed were traced to the presence of small amounts of the dichloride.

*p*-Phenoxyphenyltelluritrichloride (I) separates from its yellow solution in chloroform or carbon tetrachloride in opaque, nodular rosettes of very small, pale yellow needles. The rosettes crumble, on drying, to a creamy yellow, crystalline powder. The substance melts at  $156$ — $157^{\circ}$  to a transparent, yellow liquid, but never quite sharply, usually softening from about  $154^{\circ}$ , behaviour which suggests a partial change near the melting point. The compound is almost insoluble in light petroleum, sparingly soluble in hot carbon tetrachloride, but more soluble in hot chloroform or benzene. It is readily hydroxylated by water or hydroxylic organic solvents (Found: C, 35.6; H, 2.3; Cl, 26.6.  $C_{12}H_9OCl_3Te$  requires C, 35.75; H, 2.25; Cl, 26.4%).

pp'-Diphenoxydiphenyltelluridichloride (VIII), a by-product in the foregoing condensation, was best prepared by heating 3.9 g. (1 mol.) of the above trichloride and 1.7 g. (1 mol.) of diphenyl ether together at  $140$ — $165^{\circ}$  during 6 hours, moist air being excluded and a slow current of nitrogen maintained in the apparatus. Hydrogen chloride was evolved even at  $145^{\circ}$ . The hard, semi-crystalline mass was extracted with ether, the ether removed, and the resulting semi-solid triturated successively with light petroleum and ethyl alcohol, and filtered. There remained 2.8 g. of crude dichloride containing an amorphous impurity, readily soluble in chloroform, benzene or acetone, from which it was found difficult to free the dichloride. Purification was finally effected by fractional solution in cold benzene, followed by crystallisation of the least soluble fraction from benzene-light petroleum (b. p.  $40$ — $60^{\circ}$ ).

When two molecular proportions of diphenyl ether were employed and the heating was conducted during 10 hours at 115–150°, a similar product (1.1 g. from 1.5 g. of trichloride) was obtained, which yielded the dichloride on purification by means of carbon tetrachloride and ether. When quite pure, the dichloride separated from boiling methyl or ethyl alcohol in transparent, colourless, prismatic needles, which became slightly pink on keeping. The solutions in hot alcohol of impure specimens always became cloudy, on cooling, before crystallisation set in. The dichloride melted without decomposition at 157–158°, and depressed the almost identical melting point of the trichloride to about 120°. It was much more easily soluble than the trichloride in organic solvents, being readily soluble in cold benzene, chloroform or ether; but it was insoluble in light petroleum, and only moderately easily soluble in hot ethyl alcohol. The halogen atoms were firmly bound in this substance, which remained unaffected by cold aqueous potash, although it was decomposed by the boiling reagent with liberation of diphenyl ether (Found: Cl, 13.15.  $C_{24}H_{18}O_2Cl_2Te$  requires Cl, 13.2%).

When this dichloride was heated at 210° during an hour, it remained unchanged, no trace of diphenyl ether or of cyclic telluridichloride being produced.

*pp'-Diphenoxydiphenyl Ditelluride (II).*—The trichloride (7 g.) was reduced with 50 c.c. of ice-cold water and 11.6 g. (3 mols.) of powdered potassium metabisulphite, which was slowly added during  $\frac{3}{4}$  hour, the mixture being stirred mechanically. Sulphur dioxide was evolved, and a soft red mass produced. The reduction was completed by grinding the whole in a glass mortar during a further  $\frac{1}{2}$  hour. The deep purple, crystalline product was filtered off, washed with water, and dried in a vacuum; the yield of crude product (5.3 g.) was quantitative. The substance was then rapidly crystallised from hot light petroleum (b. p. 40–60°) saturated with sulphur dioxide, two crystallisations producing the analytically pure ditelluride. Careful examination of the mother-liquors failed to reveal the presence of an isomeride.

*pp'-Diphenoxydiphenyl ditelluride* separates from petroleum or alcohol in clusters of minute, bronzed, brownish-violet or purplish-red needles, which dissolve in organic solvents to dark red solutions. It commences to soften at 85° and melts to a deep red liquid at 87–88°. It is easily soluble in benzene, chloroform, carbon tetrachloride, ether, or acetone, only moderately easily soluble in light petroleum or alcohol, and insoluble in water [Found: C, 48.55; H, 3.05; Te, 43.1; *M*, cryoscopic in benzene, 579 ( $c = 1.39$ ), 595 ( $c = 2.04$ ).  $C_{24}H_{18}O_2Te_2$  requires C, 48.55; H, 3.05; Te, 43.0%; *M*, 593].

Great difficulty was at first experienced in purifying this substance sufficiently for analysis. Although it crystallised well from ethyl or methyl alcohol and from acetone or ether, the crystals were persistently low in carbon content (Found: C, 47·6, 47·6, 47·5, 48·05; H, 3·1, 3·2, 3·1, 3·15%). Finally the impurity was isolated: it consisted of a white, amorphous oxide, which was slowly reduced by aqueous potassium metabisulphite or aqueous sulphur dioxide to the ditelluride. In solution the ditelluride slowly precipitates this oxide when exposed to the air. With bromine in cold chloroform solution the ditelluride reacts to form a yellow *bromide* melting near 180° and readily soluble in hot chloroform. This substance is probably the analogue of the trichloride, since it is again reduced to the ditelluride by aqueous alkali bisulphites. With warm concentrated nitric acid the ditelluride yields ultimately *pp'*-dinitrodiphenyl ether (needles from alcohol; m. p. 142—143°).

*Preparation of 10 : 10-Dichlorophenoxytellurine.*—(1) *Action of heat on p-phenoxyphenyltelluritrichloride.* The trichloride (1·4 g.) was heated gradually during 4½ hours, from 150° to 210°; hydrogen chloride was slowly evolved. The cooled melt was extracted with ether; a substance sensitive to moisture (probably tellurium tetrachloride) was then found to be present. The residue from the ether extraction, on crystallisation from boiling toluene, yielded 0·4 g. (or 33%) of the pure cyclic telluridichloride, identical with the following product in (2).

When the trichloride (5·6 g.) was heated at a lower temperature (150—160°) during 2 hours in a current of nitrogen, a lesser proportion of hydrogen chloride was evolved. On cooling, the melt solidified to a brown glass, which was powdered and dissolved in hot dry chloroform. The solution, kept out of contact with moist air, deposited pale pinkish-white micro-needles (0·5 g.) of a telluritrichloride (probably corresponding with formula VII) which, however, still contained traces of tellurium tetrachloride (Found: Cl, 27·3; whereas formula VII requires Cl, 26·4%). Recrystallised from hot benzene, the compound formed a voluminous mass of almost colourless, nacreous flakes, decomposing near 125° with darkening and evolution of hydrogen chloride. It was readily reduced by aqueous potassium metabisulphite to a red substance (probably the ditelluride), which was soluble in benzene but easily oxidised by the air, while in solution, to a less soluble substance.

The main product of the above reaction was a glutinous mixture containing free tellurium tetrachloride.

(2) *Action of heat upon an equimolecular mixture of tellurium tetrachloride and diphenyl ether.* Six experiments under varying condi-

tions were carried out, but the yield of cyclic dichloride seemed almost constant (about 50%). The following is a typical experiment: Tellurium tetrachloride (11.1 g.) and diphenyl ether (7.0 g.) were heated together in a flask with a long air-condenser, carrying a moisture guard-tube, a slow current of nitrogen being bubbled through the melt (this was not essential, however). The temperature was raised slowly from 100° to 240° over a period of 13 hours, when hydrogen chloride was evolved, mainly during two maximal phases, the first occurring near 120° and the second near 200°. The melt gradually thickened and after about 8 hours partly solidified even at 190°, but remelted as the temperature rose. The cooled melt finally set to a crystalline cake, which was ground to a loose brown powder. The powder was stirred with ether, filtered off, dissolved in acetone, and filtered from 0.8 g. of free tellurium. Evaporation of the acetone left 9.4 g. of the fairly pure cyclic dichloride (62%); but, on further purification of the product in a Soxhlet apparatus with toluene, the yield fell to 48%.

Keeping the temperature below 220°, reducing the time of heating to 5 hours, adding a little chloroform at the commencement of heating, and other similar modifications produced no important variation in the yield.

The material obtained by evaporating the ethereal extracts of the product contained free diphenyl ether or chlorinated diphenyl ether, as well as soluble tellurium compounds which could not be isolated from the viscous residues.

10 : 10-Dichlorophenoxtellurine (III) crystallises from boiling toluene in colourless, nacreous platelets, which melt without decomposition at 265° to a transparent, yellow liquid. At 100° the crystalline solid is yellow, but reverts to the colourless form on cooling. It is extremely stable to heat and can be vaporised without undergoing much decomposition; is almost insoluble in ether or petroleum, sparingly soluble in chloroform or ethyl alcohol, rather more soluble in benzene or toluene, and easily soluble in acetone. It is slowly hydrolysed by boiling water, a white oxide resulting. Boiling aqueous potash detaches the tellurium atom and generates diphenyl ether. The solution in cold concentrated sulphuric acid is yellow (Found: C, 39.8; H, 2.2; Cl, 19.3.  $C_{12}H_8OCl_2Te$  requires C, 39.3; H, 2.2; Cl, 19.35%).

*Phenoxtellurine* (VI).—The powdered dichloride (4 g.) was reduced at 0° with 25 c.c. of water and 4.8 g. (2 mols.) of potassium metabisulphite, slowly added with stirring, when sulphur dioxide was evolved. The yellow product was ground beneath the liquid in a glass mortar during an hour to complete the reduction, and the solid was then filtered off, washed with water, and dried. The

yield (3.2 g.) was nearly theoretical. The product was recrystallised from light petroleum (b. p. 40—60°).

*Phenoxtellurine* separates from hot petroleum in long, spear-like needles and from the cold solvent in large, transparent prisms, both forms being lemon-yellow to orange in colour, melting without decomposition at 78—79°, and having a delicate floral odour. The compound is very stable to heat and can be vaporised unchanged. It is insoluble in water, but easily soluble in ethyl alcohol, ether, benzene, or carbon tetrachloride to yellow solutions. It dissolves in cold concentrated sulphuric acid to a deep purplish-red solution, and is stable towards hot concentrated hydrochloric acid or dilute aqueous caustic soda [Found: C, 48.7; H, 2.9; Te, 43.4; *M*, cryoscopic in benzene, 287 ( $c = 1.25$ ), 294 ( $c = 2.18$ ).  $C_{12}H_8OTe$  requires C, 48.7; H, 2.7; Te, 43.1%; *M*, 295.5].

Warm concentrated nitric acid does not immediately cause nuclear nitration of phenoxtellurine, but produces the 10:10-dinitrate, which forms colourless needles decomposing near 258°. Bromine and iodine in chloroform solution readily yield respectively the 10:10-dibromide, bright yellow spangles from chloroform or primrose-yellow prisms from toluene (decomposing at 290°), and the 10:10-di-iodide, red spangles (decomposing indefinitely, mainly near 270°).

*Action of Heat upon Mixtures of Tellurium Tetrachloride and Diphenyl Ether in Various Proportions.*—(1) When it was attempted to introduce two  $-TeCl_3$  groups into the molecule of diphenyl ether by using 2 mols. of tellurium tetrachloride to 1 mol. of the aromatic ether and heating at 120° during 6 hours, only the telluritrichloride was obtained, part of the tellurium tetrachloride remaining unaltered.

(2) Tellurium tetrachloride and 2 mols. of diphenyl ether, heated at 110° to 180° during 8 hours, yielded only a mixture of a trichloride and the cyclic dichloride.

(3) Tellurium tetrachloride (1 mol.) and diphenyl ether ( $3\frac{1}{2}$  mols.), heated at 110° to 210° during 16 hours, gave a yield of 42% of 10:10-dichlorophenoxtellurine, showing that the tendency towards formation of this cyclic dichloride is maintained even in presence of a large excess of diphenyl ether.

The author's thanks are due to Professor Morgan for his kind interest in the work and for his gift of certain research chemicals.

XXXIV.—*The Quaternary Salts of Benzoxazoles.*

By LESLIE MARSHALL CLARK.

SINCE the pseudo-bases of the quaternary salts of substituted benzthiazoles have been shown to be *o*-acylmethylaminothiophenols (Mills, Clark, and Aeschlimann, J., 1923, **123**, 2354; Clark, J., 1925, **127**, 973), the corresponding benzoxazole compounds have now been investigated so that a comparison may be made between the properties of these analogous ring systems.

Benzoxazole methiodide was first prepared by Fischer (*J. pr. Chem.*, 1906, **73**, 435), who showed that when the salt was heated with hydrochloric acid, *o*-methylaminophenol was formed, whilst treatment with hot alkalis caused profound decomposition.

It has now been found that benzoxazole methiodide, on being dissolved in water, gives a solution, acid to litmus, from which, after addition of one equivalent of caustic alkali, *o*-formylmethylaminophenol can be obtained. In the same way, 1-methylbenzoxazole methiodide\* and 1-phenylbenzoxazole methiodide readily hydrolyse in aqueous solution to *o*-acetylmethylaminophenol and *o*-benzoylmethylaminophenol, respectively, with the liberation of one equivalent of acid.

The reaction is therefore to be represented by the equation

No such effect is apparent in these quaternary salts as was observed by Skraup (*Annalen*, 1919, **419**, 80), who found that in the 1-substituted benzoxazole bases resistance of the oxazole ring to fission increases with increasing volume of the substituent radical.

Attempts to reverse the hydrolysis were made by passing dry hydrogen iodide through a solution of *o*-benzoylmethylaminophenol in dry ether and by dissolving *o*-acetylmethylaminophenol in excess of concentrated perchloric acid. The hydriodide of the acylmethylaminophenol separated in the first case, but no 1-phenylbenzoxazole methiodide was obtained, and in the second the only substance isolated was the unchanged phenol.

There appeared to be some possibility that the complete scheme

\* Since this paper was prepared for publication, König and Meier (*J. pr. Chem.*, 1925, **109**, 324) have shown that 1-methylbenzoxazole methiodide on hydrolysis with water gives *o*-acetylmethylaminophenol.

for the action of alkalis on substituted benzoxazole quaternary salts might be represented thus:

Were this the case, methylation might be expected to yield a derivative of each of the compounds I and II. On treating an aqueous solution of 1-phenylbenzoxazole methiodide with a slight excess of sodium hydroxide and methyl sulphate, only *o*-benzoylmethylaminoanisole could be isolated, whose identity was established by synthesis in the following stages:

Under these conditions, therefore, no evidence for the presence of the carbinol base (I) is obtained. Although there is thus a measure of similarity between benzoxazonium and benzthiazolonium salts in their reactions with alkalis, two important differences must be noticed:

(a) Benzoxazonium salts are hydrolysed by water alone, whereas benzthiazolonium salts are stable in aqueous solution.

(b) In consequence of this behaviour, benzoxazole quaternary salts cannot be obtained by treatment of the *o*-acylmethylaminophenols with acids, whereas benzthiazole methiodide is readily recovered from the sodium salt of formylmethylaminothiophenol (Mills, Clark, and Aeschlimann, *loc. cit.*).

## EXPERIMENTAL.

*Benzoxazole Methiodide.*—Benzoxazole was prepared by Ladenburg's method (*Ber.*, 1876, 9, 1924) by heating together *o*-aminophenol and formic acid. Fischer (*loc. cit.*) obtained the methiodide by heating the base with excess of methyl iodide at 100° for 3 hours, and describes it as yellow, shining needles, m. p. 182° (decomp.). In this investigation, the two substances were combined at temperatures varying from 50° to 100°; the product was similar in colour to Fischer's but melted at 202° (decomp.). The purest material was obtained by heating the base with 10% excess of methyl iodide at 60° for 8 hours and extracting the crushed product with dry ether (Found: C, 37.1, 37.25; H, 3.0, 3.1; N, 5.2; I, 48.8. Calc., C, 36.8; H, 3.1; N, 5.4; I, 48.6%).

*Action of Potassium Hydroxide on Benzoxazole Methiodide.*—From mixed aqueous solutions of the methiodide (10 g.) and potassium hydroxide (rather more than 1 equiv.), *o*-formylmethylaminophenol crystallised on cooling, and a further crop was

obtained by passing carbon dioxide through the mother-liquor. It crystallised from benzene in colourless needles (yield, 5 g.), m. p. 103—104° (Found: C, 63.6; H, 5.8; N, 9.0. Calc., C, 63.6; H, 6.0; N, 9.3%).

The *formyl* compound (1 g.) was heated for 1 hour with concentrated hydrochloric acid (7.5 c.c.) and water (4 c.c.), the solution made slightly alkaline with sodium hydroxide, and the alkali neutralised with carbon dioxide; 0.7 g. of almost colourless, shining flakes of *o*-methylaminophenol was obtained, m. p. 95—96° (Lees and Shedden, J., 1903, 83, 756, give m. p. 96—97° and Fischer, *loc. cit.*, gives m. p. 86—87°).

For further characterisation of the product, a nitroso-derivative was prepared by Dieppolder's method (*Ber.*, 1899, 32, 3519) from this compound, and from an authentic specimen of *o*-methylaminophenol. Both nitroso-derivatives and their mixture crystallised from alcohol in colourless, glistening plates, m. p. 125—126° (decomp.) (Found: N, 18.0. Calc., N, 18.4%).

*1-Methylbenzoxazole Methiodide.*—1-Methylbenzoxazole, prepared by Ladenburg's method (*Ber.*, 1876, 9, 1524), was heated (13.5 g.) with methyl iodide (17 g.) for 8 hours at 100°. The yellow mass was extracted with dry ether and crystallised from acetone in colourless needles, which became light brown unless rapidly dried; m. p. 196° (decomp.) (Found: C, 39.5; H, 3.6; I, 46.1. Calc., for  $C_9H_{10}ONI$ , C, 39.3; H, 3.6; I, 46.2%).

*1-Methylbenzoxazole Methopерchlorate.*—The methiodide was dissolved in a little cold water and treated with excess of a saturated solution of sodium perchlorate. A mass of colourless plates was immediately precipitated, m. p. 165—170°. Recrystallisation from water lowered the melting point to 150—160°, evidently causing decomposition. A portion of the crude perchlorate was extracted with ether, whereby the hydrolysis product, *o*-acetylmethylaminophenol, m. p. 150°, was removed. The purified *perchlorate* had m. p. 173°, unchanged by crystallisation from acetone-ether (Found: N, 6.0.  $C_9H_{10}O_5NCl$  requires N, 5.7%).

The salt (0.8 g.) was heated in aqueous solution for 1½ hours; colourless needles of *o*-acetylmethylaminophenol, m. p. 151°, crystallised on cooling (Found: N, 8.8. Calc., N, 8.5%).

1-Methylbenzoxazole methiodide in aqueous solution at laboratory temperature was hydrolysed incompletely after 8 hours and completely after 66 hours.

*Action of Potassium Hydroxide on 1-Methylbenzoxazole Methiodide.*—The reaction was carried out in the same way as for benzoxazole methiodide. The yield of *o*-acetylaminophenol, m. p. 151°, from 7 g. of salt was 2.1 g.

*Action of Silver Oxide on 1-Methylbenzoxazole Methiodide.*—The salt (1 g.) was dissolved in acetone (300 c.c.) and silver oxide freshly prepared from silver nitrate (3 g.) was added. Silver iodide was formed and after being shaken for 1 hour the acetone solution was evaporated: the residue was crystallised from benzene-light petroleum, colourless needles of *o*-acetylmethylaminophenol, m. p.  $151^{\circ}$ , being obtained.

*1-Phenylbenzoxazole Methiodide.*—1-Phenylbenzoxazole, prepared by Skraup's method (*loc. cit.*), was heated (3.8 g.) with methyl iodide (9 g.) at  $100^{\circ}$  for 36 hours. The product was extracted with dry ether and cautiously crystallised from absolute alcohol. The *methiodide* (yield 4.8 g.) separated in almost colourless needles, m. p.  $196^{\circ}$  (decomp.), which became brown on exposure to light (Found: C, 49.9; H, 3.6; I, 37.3.  $C_{14}H_{12}ONI$  requires C, 49.9; H, 3.6; I, 37.6%).

*Action of Water on 1-Phenylbenzoxazole Methiodide.*—When the salt (3.37 g.) was dissolved in warm water (100 c.c.), a colourless, crystalline substance immediately began to separate. The acid solution on titration with sodium hydroxide and phenolphthalein required 10.4 c.c. of *N*-NaOH (Calc. for 1 equiv. of NaOH, 10.0 c.c.).

The solid crystallised from aqueous alcohol in plates, m. p.  $163$ — $164^{\circ}$ , and was recognised as *o*-benzoylmethylaminophenol by analysis as well as by the method of preparation. Ransom (*Amer. Chem. J.*, 1900, 23, 34) gives m. p.  $162$ — $163^{\circ}$  (Found: C, 74.1; H, 5.6; N, 6.4. Calc., C, 74.0; H, 5.7; N, 6.2%).

The *urethane* was prepared by heating *o*-benzoylmethylaminophenol (1 g.) for 3 hours with phenylcarbimide (0.6 g.). The product was extracted with ether and crystallised from alcohol in colourless plates, m. p.  $144^{\circ}$  (Found: C, 73.3; H, 5.1; N, 8.2.  $C_{21}H_{18}O_3N_2$  requires C, 72.8; H, 5.2; N, 8.1%).

*o-Benzoylmethylaminoanisole.*—*o*-Methylaminoanisole, prepared by the usual reactions from *o*-nitroanisole, was benzoylated with benzoyl chloride and sodium hydroxide. The product crystallised from aqueous alcohol in small, colourless prisms, m. p.  $115^{\circ}$  (Found: C, 74.4; H, 6.1; N, 5.7.  $C_{15}H_{15}O_2N$  requires C, 74.7; H, 6.2; N, 5.8%).

When 1-phenylbenzoxazole methiodide (1.5 g.) was shaken with sodium hydroxide and methyl sulphate in slight excess, a paste formed which was crystallised from aqueous alcohol. It melted at  $115^{\circ}$ , and did not depress the melting point of *o*-benzoylmethylaminoanisole prepared as described above (Found: N, 5.8%).

XXXV.—*Reactions of the meso-Hydroxyanthrones.*

By MARCUS AURELIUS MATTHEWS.

THE reduction of 10-hydroxyanthrone\* by zinc dust and glacial acetic acid leads to anthrone, probably through addition of hydrogen to the carbonyl group and subsequent loss of water across the ring (K. H. Meyer, *Annalen*, 1911, 379, 37).

Anthrone itself on reduction with zinc and hydrochloric acid in glacial acetic acid undergoes the pinacol condensation (Barnett and Matthews, J., 1923, 123, 380), and it has now been found that under similar conditions 10-hydroxyanthrone also undergoes the pinacol condensation, although the reduction goes further and leads to *dihydrodianthranyl*, which may be (I) or (II) or a tautomeric mixture of these. The powerful blue fluorescence renders (II) the more probable, but the existence of fluorescence cannot be taken as definite proof of the presence of a "bridge" (compare Padova, *Ann. Chim.*, 1910, 19, 358, 435; Jüngermann, *Ber.*, 1905, 38, 2868).

The reduction of 10-hydroxyanthrone (III) to dihydrodianthranyl cannot take place through preliminary formation of anthrone, for, as already shown (Barnett and Matthews, *loc. cit.*), the reduction of this gives only dianthranyl and  $\alpha$ -anthrapinacolin. Further, neither dianthranyl nor dianthranol is attacked under the experimental conditions employed, although dianthranol is reduced to dihydrodianthranyl by tin and hydrochloric acid. It therefore follows that in the reduction of 10-hydroxyanthrone with zinc and hydrochloric acid attack first takes place at the carbonyl group, involving the formation of a pinacol (IV), and that further reduction of the pinacol must be due to ready attack of the "nascent" dianthranol molecule (V) formed by loss of water across the rings.

\* All the anthrone formulæ given in this paper are numbered with the carbonyl group in position 9.

10-Hydroxy-10-phenylanthrone differs from 10-hydroxyanthrone in giving on reduction a dianthranyl and not a dihydrodianthranyl derivative. Here the mechanism of the reaction probably consists in preliminary reduction to phenylanthrone, from which diphenyl-dianthranyl is very readily produced (Barnett and Cook, J., 1923, 123, 2631).

The zinc-hydrochloric acid reduction of the two  $\alpha$ -chloro-10-hydroxyanthrones gave compounds for which analytical figures corresponding to the  $\alpha$ -chloroanthrones were obtained. The compounds were not the  $\alpha$ -chloroanthrones, but each passed into the corresponding  $\alpha$ -chloroanthrone on treatment with alcoholic sodium hydroxide. These compounds are at present under investigation and their structure will be discussed in a future communication.

Further information on the mechanism of reduction of a hydroxyanthrone was obtained by comparing the behaviour of 10-hydroxyanthrone itself towards acids and towards reducing agents with that of the two  $\alpha$ -chloro-10-hydroxyanthrones:

	10-Hydroxy-anthrone gives	4-Chloro-10-hydroxyanthrone gives	1-Chloro-10-hydroxyanthrone gives
With HBr	10-Bromoanthrone	4-Chloro-10-bromoanthrone	1-Chloro-10-bromoanthrone
HCl	10-Chloroanthrone	4 : 10-Dichloroanthrone	1-Chloroanthraquinone and 1-chloroanthrone
HI (1 or 2 mols.)	Anthraquinone and anthrone	1-Chloroanthraquinone and 4-chloroanthrone	4 : 4'-Dichloro-9 : 9'-dianthrone, 1-chloroanthrone, and a trace of 1-chloroanthraquinone
Sn and HCl	Anthrone and a small amount of dihydrodianthranyl	4-Chloroanthrone	4 : 4'-Dichloro-9 : 9'-dianthrone
H <sub>2</sub> SO <sub>4</sub>	Anthraquinone and anthrone	1-Chloroanthraquinone and 4-chloroanthrone	1-Chloroanthraquinone and 1-chloroanthrone
Al and H <sub>2</sub> SO <sub>4</sub>	Anthrone	4-Chloroanthrone	1-Chloroanthrone.

10-Chloroanthrone is an extremely stable substance and is readily prepared in good yield by the direct chlorination of anthrone, although Goldmann (*Ber.*, 1887, 20, 2436; 1888, 21, 1176) failed to obtain it by this method. It is best identified in the form of

the *pyridinium* salt,  $\text{OH} \cdot \text{C} \begin{array}{c} \nearrow \text{C}_6\text{H}_4 \\ \searrow \text{C}_6\text{H}_4 \end{array} \text{C} \cdot \text{C}_5\text{H}_5\text{NCl}$  (VI) or

The direct chlorination of 4-chloroanthrone gave 4 : 10-dichloro-

anthrone, whereas from 1-chloroanthrone the only product obtained was 4:4'-dichloro-9:9'-dianthrone, the 1:10-dichloroanthrone apparently being very unstable. It was not possible to prepare the last compound by the action of hydrogen chloride on the corresponding hydroxyanthrone, a disproportioning taking place with the production of the corresponding anthraquinone and anthrone. Other acids cause a disproportioning of the hydroxyanthrones, the mechanism of which has been discussed by Scholl (*Ber.*, 1923, 56, 1065).

Hydroxyanthrone is readily converted into anthraquinol by boiling water in absence of air, this being the best method for preparing anthraquinol.

Nitration of dihydrodianthranyl leads to a *nitrodihydrodianthranyl*, a reaction which favours formula (II) without, however, excluding formula (I). The nitration is not preceded by oxidation as in the case of dihydroanthracene (Meisenheimer, *Annalen*, 1902, 323, 205; 1904, 330, 133), or of dichlorodihydrodianthranyl (Barnett and Matthews, *J.*, 1923, 123, 2549), the product isolated in the latter case being dichlorodinitrodianthranyl.

Dihydrodianthranyl reacts slowly with excess of bromine in carbon disulphide solution with the production of *dibromodihydrodianthranyl*.

Dianthrane is converted by hydriodic acid in glacial acetic acid exclusively into anthrone and by tin and hydrochloric acid into a mixture of anthrone and dihydrodianthranyl. In these reactions it is improbable that anthrone is produced by the direct reduction of dianthrane and it seems almost certain that reduction is preceded by ketonisation to dianthrone, which is then reduced to anthrone. The suggestion was at first put forward (Barnett and Matthews, *J.*, 1923, 123, 380) that the reduction of dianthrone (VIII) to anthrone (X) was due to the instability of the dianthranyl ring system, reduction taking place at the bond joining the two *meso*-carbon atoms. Further work has rendered this view improbable, for if the single bond which joins the two anthracene ring systems in dianthrone shows this lack of stability, the corresponding double

bond in dianthraquinone should be even more susceptible to reduction. This, however, is not the case, dianthraquinone on reduction

giving dianthranol and not dianthrone. It therefore seems probable that hydrogen adds on to the carbonyl groups in dianthrone instead of to the single bond joining the two anthracene ring systems. In order to satisfy the requisite valencies, the "bridge" bond must be established with necessary rupture of the bond joining the two anthracene ring systems; the anthranol thus produced being at once ketonised to anthrone (X).

A similar explanation suffices to account for the reduction of 4:4'-dichloro-9:9'-dianthrone to the corresponding anthrone.

#### EXPERIMENTAL.

*Dihydrodianthranyl* (I or II).—To 20 g. of 10-hydroxyanthrone in 100 c.c. of boiling glacial acetic acid, 20 g. of zinc dust and 50 c.c. of concentrated hydrochloric acid were added simultaneously in small amounts. The addition of these two reagents must be simultaneous, since excess of hydrochloric acid causes decomposition of the hydroxyanthrone and excess of zinc dust brings about reduction to anthrone (Meyer, *loc. cit.*). After refluxing for 5 minutes the solid was separated from the hot solution. It crystallised from pyridine as an additive compound in greenish-yellow, flat needles, which lost pyridine on drying in the steam-oven for 3 days. The product (6 g.) became yellowish-grey and melted at 298–300° to a black liquid. In this state, it is pure enough for most purposes. For analysis it was recrystallised four times from benzene (Found: C, 94.5; H, 5.7.  $C_{28}H_{20}$  requires C, 94.4; H, 5.6%).

Dihydrodianthranyl exhibits an intense violet-blue fluorescence in organic solvents. It is easily soluble in chloroform, but less so in carbon disulphide, pyridine, acetone, or ether.

*Dibromodihydrodianthranyl*.—Excess of bromine (1 c.c.) was added to a cold solution of dihydrodianthranyl in carbon disulphide. After 12 hours, most of the carbon disulphide was distilled off, ether added, and the resulting solid recrystallised twice from small quantities of pyridine and dried in the steam-oven (Found: C, 65.4; H, 3.6; Br, 31.1.  $C_{28}H_{18}Br_2$  requires C, 65.4; H, 3.5; Br, 31.1%).

*Dibromodihydrodianthranyl* forms yellow crystals which do not melt at 320° and darken on exposure to light. Its solutions exhibit a blue fluorescence.

*Nitrodihydrodianthranyl*.—Excess of nitric acid (*d* 1.42; 2 c.c.) was added to 1.5 g. of finely powdered dihydrodianthranyl suspended in 50 c.c. of cold glacial acetic acid. After 12 hours, the solid was collected, washed with acetic acid, and dried in the steam-oven. The same compound was also obtained when the nitration was carried out at 80–100° and only one molecule of nitric acid

used. For analysis, it was recrystallised twice from glacial acetic acid, in which it was very sparingly soluble, separating in golden-yellow needles which melted and decomposed at  $305^{\circ}$  and darkened on exposure to light (Found: C, 83.6; H, 4.9.  $C_{28}H_{18}O_2N$  requires C, 83.8; H, 4.7%).

*Dichlorodinitrodianthranyl*.—Dichlorodihydrodianthranyl\* (Barnett and Matthews, J., 1923, 123, 2549) in cold glacial acetic acid suspension was resistant to nitric acid, but oxidation and nitration took place when 3 g. of the finely powdered material were suspended in 30 c.c. of glacial acetic acid, 2 c.c. of nitric acid ( $d$  1.42) added, and the whole slowly heated to the b. p. After cooling, the orange-red solid was collected, washed with acetic acid and ether, and recrystallised twice from small quantities of pyridine-alcohol. It then formed orange-red needles which became dark red on exposure to light and did not melt at  $330^{\circ}$  (Found: C, 65.5; H, 3.5; Cl, 13.8.  $C_{28}H_{14}O_4N_2Cl_2$  requires C, 65.5; H, 2.7; Cl, 13.8%).

*Reduction of 10-Hydroxy-10-phenylanthrone*.—To 2.3 g. of hydroxy-phenylanthrone and 25 c.c. of boiling glacial acetic acid, 2 g. of zinc dust and 4 c.c. of concentrated hydrochloric acid were added simultaneously, and the whole was boiled under reflux for 5 minutes. After cooling, the solid was collected and the excess of zinc removed by digestion with dilute hydrochloric acid. The resulting diphenyl-dianthranyl (1.5 g.) was identified by analysis (C, 94.9; H, 5.2. Calc., C, 94.9; H, 5.1%) and by direct comparison with an authentic sample.

*Reduction of Dianthranol*.—(a) To 3 g. of dianthranol and 5 g. of zinc dust in 40 c.c. of boiling glacial acetic acid, 8 c.c. of concentrated hydrochloric acid were added during  $2\frac{1}{2}$  hours, and the boiling was continued for a further  $\frac{1}{2}$  hour. The yellow solid which separated from the filtered solution on cooling consisted mainly of unchanged dianthranol.

(b) Finely powdered dianthranol (3 g.) and zinc dust (12 g.) were heated on the water-bath with 50 c.c. of ammonia ( $d$  0.880) and 50 c.c. of water for 3 days with occasional additions of more ammonia, sodium hydroxide, and zinc dust. The hot solution was filtered, the zinc dust extracted with dilute hydrochloric acid, and the residue recrystallised from pyridine; 0.6 g. of anthracene (m. p.  $217^{\circ}$ ) was thus obtained.

(c) Dianthranol (1 g.) was boiled under reflux for 5 minutes with 20 c.c. of glacial acetic acid and 2 c.c. (2 mols.) of hydriodic acid ( $d$  1.7), and the whole then diluted with hot water to incipient crystallisation. The dark crystals which separated on cooling were

\* The m. p. of this compound, owing to a misprint, was given in the paper cited as  $288^{\circ}$  instead of  $268^{\circ}$ .

boiled with potassium iodide solution, and 0.9 g. of anthrone obtained. Dianthrone under similar conditions also gave anthrone.

(d) Dianthranol (5 g.), tin (8 g.), and glacial acetic acid (80 c.c.) were boiled under reflux and concentrated hydrochloric acid (15 c.c.) was added during 1 hour. After boiling for a further  $\frac{1}{2}$  hour, the hot solution was filtered. The dihydrodianthranyl which separated on cooling was recrystallised from benzene (yield 0.8 g.). The acetic liquors on dilution with water gave anthrone, which was recrystallised from glacial acetic acid and converted into anthranyl acetate.

The products in (b), (c), and (d) were each identified by comparison with an authentic specimen.

*Reduction of Dianthraquinone.*—Dianthraquinone (0.5 g.) and zinc dust (2 g.) were suspended in boiling glacial acetic acid (10 c.c.), and concentrated hydrochloric acid (3 c.c.) was added during 20 minutes. After filtration, dilute hydrochloric acid was added and the solid recrystallised from acetone. It was identified as dianthranol by its complete solubility in cold aqueous sodium hydroxide and by the preparation of dianthranyl diacetate.

*1-Chloro-9-anthranyl Acetate.*—A mixture of 5 g. of 1-chloro-9-anthrone, 30 c.c. of pyridine, and 7 c.c. of acetic anhydride was heated on the boiling water-bath for 15 minutes and then poured into boiling water. The solid after recrystallisation from alcohol formed long, yellow needles, m. p. 110—112° (yield 4.8 g.). Its alcoholic solutions exhibit a blue fluorescence (Found: Cl, 13.2.  $C_{16}H_{11}O_2Cl$  requires Cl, 13.1%).

*4-Chloro-9-anthranyl Acetate.*—A similar mixture containing 4-chloro-9-anthrone\* was heated for 10 minutes, the subsequent procedure being as above. The product formed almost colourless needles, m. p. 124—126° (yield 4.6 g.) (Found: Cl, 13.2%). Its solution in alcohol had a blue fluorescence.

*1-Chloro-10-bromoanthrone.*—Bromine (4 c.c.; 1 mol.) was added to 18 g. of finely powdered 1-chloroanthrone suspended in 50 c.c. of carbon disulphide. The solid (22.5 g.), after being washed with carbon disulphide and ether, was pure enough for most purposes, but for analysis a sample was recrystallised twice from chloroform, in which it was moderately soluble, separating in faintly yellow crystals, m. p. 165° (decomp.), which darkened on exposure to light (Found: Cl + Br, 37.75.  $C_{14}H_8OClBr$  requires Cl + Br, 37.6%).

*1-Chloro-10-hydroxyanthrone.*—The above bromo-compound (22 g.) was boiled under reflux with 240 c.c. of acetone and 160 c.c. of water

\* In preparing this compound by Barnett and Matthews's method (*J.*, 1923, 123, 2549) the reduction must not be too prolonged, since it has been found that 4-chloro-9-anthrone—unlike anthrone itself—slowly undergoes the pinacol condensation with tin and hydrochloric acid with the production of dichlorodihydrodianthranyl.

until an almost clear solution was obtained (about 5 minutes), the filtered solution was cooled in ice, and 160 c.c. of water were added slowly.\* The resulting solid was recrystallised three times from benzene and then formed fine, white needles, m. p. 144—145°, which dissolved in boiling aqueous sodium hydroxide to form a deep red solution (Found: Cl, 14.6.  $C_{14}H_9O_2Cl$  requires Cl, 14.5%).

*4-Chloro-10-hydroxyanthrone*.—4-Chloro-10-bromoanthrone (5 g.) was refluxed with 120 c.c. of acetone and 80 c.c. of water for 15 minutes, the filtered solution cooled in ice, and cautiously diluted with 100 c.c. of water. The yellow solid (2.5 g.) was washed with water, dried in a vacuum desiccator, and twice recrystallised from benzene; it then formed faintly yellow crystals, m. p. 144—145°. It is not altered in m. p. by mixing with 1-chloro-10-hydroxyanthrone (Found: Cl, 14.5%).

*10-Chloroanthrone*.—(a) Dry hydrogen chloride was passed for 10 minutes through a suspension of 5 g. of finely powdered 10-hydroxyanthrone in 40 c.c. of toluene, a yellow precipitate forming. After dilution with light petroleum, the solid was collected and recrystallised from benzene, from which it separated with benzene of crystallisation, which was lost on drying in the steam-oven (Found: Cl, 15.5.  $C_{14}H_9OCl$  requires Cl, 15.5%).

*10-Chloroanthrone* forms colourless needles which melt and evolve gas at 225°. It is very much more stable than the corresponding bromo-compound and can be recrystallised from boiling xylene. It is stable towards boiling dilute solutions of alkali hydroxides, but dissolves in their alcoholic solution with a yellow colour. It is hydrolysed, but very much more slowly than 10-bromoanthrone, to 10-hydroxyanthrone by boiling with aqueous acetone.

(b) Finely powdered 10-hydroxyanthrone (1 g.) was boiled with 50 c.c. of concentrated hydrochloric acid for  $\frac{1}{2}$  hour. The product was recrystallised from xylene and identified by its conversion into anthronylpyridinium chloride (see below).

(c) Very finely powdered anthrone (40 g.) was added to 180 c.c. of a solution of chlorine in carbon tetrachloride (9.5% weight-volume). The reaction was extremely sluggish, but took place rapidly with evolution of heat on the addition of a trace of iodine, so that cooling with water became necessary. When it was complete (about 10 minutes) the whole was cooled in ice, and the solid, after being washed with carbon tetrachloride and ether, was dried in the steam-oven. The yield was 33 g. and the product pure enough for most purposes without further treatment. It was identified by its conversion into anthronylpyridinium chloride.

In this and the succeeding preparation the addition of water must be made cautiously, otherwise the product separates as an oil.

10-Hydroxyanthranyl-9-pyridinium Chloride (VI) or Anthronyl-pyridinium Chloride (VII).—Chloroanthrone (2 g.) was heated with 15 c.c. of pyridine on the water-bath for 15 minutes, the crystals were washed with ether and then twice recrystallised from very dilute hydrochloric acid; orange-red needles, m. p.  $204^{\circ}$  (decomp.), were obtained (Found: Cl, 11.0.  $C_{19}H_{14}ONCl, H_2O$  requires Cl, 10.9%).

This chloride is easily identified by its reactions, which are similar to those of the corresponding bromide (Barnett, Cook, and Grainger, J., 1922, **121**, 2059).

4 : 10-Dichloroanthrone.—(a) Dry hydrogen chloride was passed for 10 minutes through 3 g. of finely powdered 4-chloro-10-hydroxyanthrone suspended in 20 c.c. of benzene; the solid slowly dissolved and crystals began to separate. After addition of light petroleum, these were collected and twice recrystallised from small quantities of chloroform and light petroleum, faintly yellow crystals being obtained, m. p.  $127-128^{\circ}$  (Found: Cl, 26.9.  $C_{14}H_8OCl_2$  requires Cl, 27.0%).

1-Chloro-10-hydroxyanthrone, when treated with hydrogen chloride under identical conditions, gave a mixture of 1-chloro-anthraquinone and 1-chloro-9-anthrone.

(b) A solution of chlorine in carbon tetrachloride (10 c.c.; 9.5% weight-volume) was added to finely powdered 4-chloro-9-anthrone (3 g.) suspended in 10 c.c. of carbon tetrachloride. No reaction took place until a crystal of iodine was added; hydrogen chloride was then slowly evolved and the solid dissolved. After concentration to small bulk, light petroleum was added and the solid recrystallised from a small quantity of chloroform-light petroleum. It was identified as 4 : 10-dichloroanthrone by the method of mixed melting points.

1-Chloro-9-anthrone, when treated under identical conditions, gave 4 : 4'-dichloro-9 : 9'-dianthrone as the sole product.

*Anthraquinol*.—Finely powdered 10-hydroxyanthrone (3 g.) was boiled with 100 c.c. of air-free water in an atmosphere of carbon dioxide for 20 minutes. The precipitate was identified as anthraquinol by its complete solubility in cold aqueous sodium hydroxide, by its facile oxidation to anthraquinone, and by the preparation of anthraquinyl diacetate. If the boiling with water is continued for a longer time, the product will be contaminated with some anthraquinone.

The action of acids and reducing agents on 10-hydroxyanthrone and on the two  $\alpha$ -chlorohydroxyanthrones, the results of which are given in the theoretical part of this paper, were carried out as follows :

*Hydrobromic acid.* The conditions were similar to those already described in the case of hydrochloric acid.

*Hydriodic acid.* The hydroxyanthrone (1 g.) was dissolved in boiling glacial acetic acid (10 c.c.), 1 or 2 mols. of hydriodic acid (*d* 1.7) were added, the whole was boiled for 1 minute in an atmosphere of carbon dioxide, and the solution then diluted with water.

*Tin and hydrochloric acid.* The hydroxyanthrone (1 g.), glacial acetic acid (10 c.c.), and tin (2 g.) were boiled under reflux, and concentrated hydrochloric acid (2 c.c.) was added during 5 minutes. The dianthrone or dihydrodianthranyl was filtered from the boiling solution. The filtrate on cooling deposited the anthrone.

*Sulphuric acid.* The hydroxyanthrone was dissolved in a small quantity of concentrated sulphuric acid in an atmosphere of carbon dioxide, kept in the cold for 15 minutes, and the product precipitated by pouring into ice-water.

*Aluminium and sulphuric acid.* The hydroxyanthrone (1 g.) was dissolved in concentrated sulphuric acid (11 c.c.), and aluminium powder (0.25 g.) added with cooling. A series of colour changes took place, the end of the reaction being determined by frothing and by the changing of the dark colour of the solution to light yellow or green (about  $\frac{3}{4}$  hour). The product was precipitated by pouring into ice-water and purified by recrystallisation.

The identification of the compounds formed in the above reactions was effected usually by means of direct comparison with authentic samples. 1-Chloro- and 4-chloro-9-anthrone were differentiated by the preparation of the respective anthranyl acetates. When an anthrone occurred together with an anthraquinone, separation was not practicable by means of fractional crystallisation. The anthraquinone was detected by the anthraquinol test. The anthrone was detected by dissolving some of the mixture in boiling alcoholic sodium hydroxide and adding a drop of chloroform: if anthrone is present, a green colour is produced (compare Padova, *Compt. rend.*, 1909, 148, 290); if 1-chloro-9-anthrone is present, a green colour will also develop; but if 4-chloro-9-anthrone is present, a dirty brown colour appears, thus affording a means of differentiating between 1- and 4-chloroanthrones. The most effective way of identifying 4:4'-dichloro-9:9'-dianthrone was by reducing 0.5 g. with tin (1 g.) in boiling glacial acetic acid (40 c.c.) and adding concentrated hydrochloric acid (3 c.c.) until all the solid matter had gone into solution (1½ hours). After filtration from the undissolved tin, water was added to incipient crystallisation, and the 1-chloro-9-anthrone thus obtained identified by direct comparison with an authentic sample.

*Summary.*

1. The reduction of 10-hydroxyanthrone and 10-hydroxy-10-phenylanthrone has been studied. Both compounds undergo the pinacol condensation with the production of dihydrodianthranyl and diphenyldianthranyl respectively.
2. The reduction of dianthranol under various conditions has been found to give anthracene, anthrone, and dihydrodianthranyl.
3. The mechanism of the reduction of a dianthrone to an anthrone has been discussed.
4. 10-Chloroanthrone, a substance of remarkable stability, has been prepared by the action of hydrochloric acid on 10-hydroxyanthrone and of chlorine on anthrone.
5. The action of acids and reducing agents on hydroxyanthrone and 1- and 4-chloro-10-hydroxy-9-anthrone has been examined. With some acids a disproportioning to the corresponding anthraquinone and anthrone takes place; reduction usually leads to the corresponding anthrone.
6. Hydroxyanthrone is easily enolised to anthraquinol by boiling water.

The author desires to express his thanks to the Department of Scientific and Industrial Research for a grant which enabled him to carry out this work.

## XXXVI.—*cycloHexanespirocyclohexane*.

By WOODFORD STANLEY GOWAN PLUCKNETT NORRIS.

THERE is remarkable agreement between the relative ease of production of homologous alicyclic rings, the "formation numbers" calculated from the interatomic angle ( $115^\circ$ ) in saturated carbon chains (Ingold, J., 1921, 119, 305), and the heats of ring formation (Stohmann and Kleber, *J. pr. Chem.*, 1892, 45, 475). The effect of substitution (particularly substitution of a *gem*-grouping) on the ease of closure in any of the simple *cycloparaffins* is very pronounced, even in comparison with the difference, in ease of ring formation, between one member of the series and the next. If, therefore, the above agreement is fundamental and not fortuitous, the introduction of a substituent should cause an alteration in the heat of formation of a *cycloparaffin* ring comparable with the differences, in heat of formation, between successive ring homologues; indeed,

the alteration should be much greater than the accuracy of any individual determination. The application of thermochemical methods to the more complex cyclic substances encountered in the study of *spiro*-compounds and of condensed alicyclic systems should therefore be capable of giving an actual quantitative measure of the influence of substituents on ease of ring formation.

It would, for example, be possible, by determining the heats of combustion of two corresponding series of hydrocarbons (A) and (B), in which R and R' are progressively altered, to obtain a measure

of the effect of substitution on the ease of closure of the ring present in (B). The chief interest of such a line of work would lie in the spirocyclic series. Spiran hydrocarbons have not, however, hitherto been described.\* One such hydrocarbon, *cyclohexanespirocyclohexane*, has now been prepared.

An account of the initial stages of the synthesis has already appeared (Norris and Thorpe, J., 1921, 119, 1199). *cyclohexanespirocyclohexane-3:5-dione* (I) was obtained by hydrolysing the ester (II); the latter was prepared by the condensation of Wallach's ketone, *cyclohexylideneacetone*,  $C_5H_{10} > C:CH \cdot COMe$ , with ethyl sodiomalonate. The reduction of the diketone (I) has now been

accomplished by indirect methods similar in general to those by which Crossley and Renouf (J., 1905, 87, 1494; 1907, 91, 63) prepared 1:1-dimethylcyclohexane.

Crossley and Le Sueur (J., 1903, 83, 110) found that dimethyldihydroresorcinol was converted into 5-chloro-1:1-dimethyl- $\Delta^4$ -cyclohexen-3-one by means of phosphorus trichloride in chloroform

solution. The *spiro*-diketone (I) similarly gives the unsaturated *chloro-ketone* (III). Reduction of this with sodium and moist ether

\* Ingold (J., 1923, 123, 1706) has shown conclusively that the hydrocarbon hitherto represented to be *cyclopropanespirocyclopropane* consists essentially of *methylcyclobutene*, unaccompanied by any of its isomerides in the *cyclopropane* series.

(compare Crossley and Renouf, *loc. cit.*) produced much resinous matter, from which only a trace of the *spiro*-alcohol (IV) could be isolated. However, by the action of zinc dust on the chloro-ketone in boiling glacial acetic acid solution, cyclohexanespirocyclohexan-3-one (V), which is analogous to Kon's cyclohexanespirocyclobutan-3-one (J., 1922, **121**, 515), was obtained in reasonable yield.

The refractive power of the ketone (V) was measured for sodium light and for the red and blue hydrogen lines, but not for the violet line on account of selective absorption. The molecular refraction shows inappreciable exaltation (0.08), in contrast with the increase (0.77) observed by Kon in the molecular refraction of his ketone; moreover, the molecular dispersion between the red and the blue shows no increase over the theoretical value. This result will not be surprising when it is remembered that *cyclopentanes* and *cyclohexanes* normally show scarcely any optical anomaly (compare Eisenlohr, "Spektrochemie organischer Verbindungen"), and that the figure of instability\* (maximum valency curvature) for cyclohexanespirocyclohexane is only 0.22, as against 0.18 for 1:1-dimethylcyclohexane, 0.08 for cyclohexane itself, and 0.13 for cyclopentane.

The ketone (V) gave, on reduction with sodium and moist ether, a good yield of cyclohexanespirocyclohexan-3-ol (IV). The constitution of this alcohol was confirmed by oxidising it with nitric acid to cyclohexane-1-acetic-1-propionic acid (VI).

The conversion of the *spiro*-alcohol (IV) into the *bromo*-derivative (VII) by the action of fuming hydrobromic acid presented unexpected difficulties. Not only did the replacement of the hydroxyl group by bromine proceed with great reluctance, but the boiling points of the two compounds lie very close together, rendering even partial separation a very tedious process. The same difficulty was encountered in attempts to isolate the corresponding *chloro*-derivative.

By reducing the impure bromo-compound (VII) in alcohol with zinc dust, cyclohexanespirocyclohexane (VIII) was obtained together

\* The figure of instability for a 6-carbon ring is expressed by

$$[\delta a / \delta S]_{s=0} = \sin \theta - \sqrt{3} \cdot \cos \theta.$$

with an unsaturated hydrocarbon (IX or X), evidently produced by loss of hydrogen bromide; a result contrasting with the production under similar conditions of 1:1-dimethylcyclohexane only from 3-bromo-1:1-dimethylcyclohexane (Crossley and Renouf, *loc. cit.*).

The final stage in the reduction was effected by shaking the mixture of saturated and unsaturated hydrocarbons with colloidal palladium in an atmosphere of hydrogen.

This investigation cannot be continued for the present, but it will, it is hoped, be concluded at some future date.

#### EXPERIMENTAL.

*cyclohexanespirocyclohexan-3:5-dione* (I).—The diketone of Norris and Thorpe (*loc. cit.*) has been further characterised by the formation, on hydrolytic fission, of *cyclohexane-1-acetone-1-acetic acid*,  $C_5H_{10}>C<\begin{smallmatrix} CH_2\cdot COMe \\ CH_2\cdot CO_2H \end{smallmatrix}$ . The diketone (1 g.) and 6 g. of crystalline barium hydroxide dissolved in 25 c.c. of water were heated at 200° for 24 hours. The ethereal extract of the acidified liquid left, after evaporation of the solvent, a pale yellow oil (yield practically quantitative), which set on cooling to a white solid and gave no colour with ferric chloride. The *keto-acid*, which is volatile in steam, is very soluble in ether, benzene, or alcohol, less so in water, or light petroleum (b. p. 40–60°); it separates from the latter in short, colourless needles, m. p. 67° (Found: C, 66.8; H, 8.8.  $C_{11}H_{18}O_3$  requires C, 66.7; H, 9.1%). The *semicarbazone* separates from methyl alcohol in colourless plates, m. p. 183.5° (decomp.) (Found: C, 56.55; H, 8.4; N, 16.6.  $C_{12}H_{21}ON_3$  requires C, 56.4; H, 8.3; N, 16.5%).

*Action of Phosphorus Trichloride on the Diketone* (I). *cyclohexanespiro-5-chloro-Δ<sup>4</sup>-cyclohexen-3-one* (III).—A mixture of 67 g. of the diketone (which must be dry and free from resinous matter and hydrochloric acid), 250 c.c. of dry chloroform, and 17.5 g. of phosphorus trichloride was heated under reflux for 3 hours, cooled, and the unchanged diketone filtered off. The residue after distillation of the chloroform was dissolved in a little ether and poured into 1300 c.c. of water, which was then extracted with ether four times. The ethereal solution, after being thoroughly washed with 10% sodium hydroxide solution (from which more of the diketone was obtained on acidification), was washed once with 25% sulphuric acid, twice with water, and dried over calcium chloride. The residue, after the ether had been removed through a column, was distilled under reduced pressure. The *chloro-ketone*, b. p. 167°/30 mm., 160°/17 mm., 157°/12 mm., solidified, on cooling, to a white, crystalline mass, which had a pungent camphor-like odour and

separated from light petroleum (b. p. 60—80°) in large, colourless prisms, m. p. 47° (Found : Cl, 17.8.  $C_{11}H_{15}OCl$  requires Cl, 17.8%).

The *semicarbazone* separates from methyl alcohol in glistening plates, m. p. 219° (decomp.) (Found : N, 17.0, 16.2.  $C_{12}H_{18}ON_3Cl$  requires N, 16.4%).

The recovered diketone (24%) was purified with difficulty, owing to the presence of resinous phosphorus compounds, and in many cases could not be used again.

*Reduction of the Chloro-ketone with Zinc Dust in Glacial Acetic Acid.* *cyclohexanespirocyclohexan-3-one* (V).—Zinc dust (33 g.) was added, the first portions in very small quantities because of the violence of the reaction, during 24 hours to a solution of 25 g. of the chloro-ketone in 80 c.c. of glacial acetic acid, boiling under reflux. The liquid was neutralised with caustic soda solution and steam-distilled. From the distillate, ether extracted the ketone (yield 86%).

The *semicarbazone* separated from ethyl alcohol in colourless, flattened needles, m. p. 224.5° (decomp.) (Found : N, 18.9.  $C_{12}H_{21}ON_3$  requires N, 18.8%).

The *ketone*, regenerated from the *semicarbazone* by boiling with oxalic acid and water in a current of steam, and extracted from the distillate with ether, was a colourless, mobile liquid, b. p. 225°/772 mm. or 130°/15 mm., having a pungent odour similar to that of cedarwood oil (Found : C, 79.8; H, 10.7.  $C_{11}H_{18}O$  requires C, 79.5; H, 10.9%). The freshly distilled ketone had  $d_{20}^{25}$  0.98417,  $n_D^{20}$  1.48432,  $n_D^{25}$  1.48685,  $n_F^{25}$  1.49322 (no violet light was transmitted). Hence  $[R_L]_D = 48.55$ ;  $[R_L]_{F-C} = 0.76$ , the calculated values being 48.61 and 0.75, respectively.

The ketone is stable towards neutral permanganate, and slowly attacked by the alkaline reagent in the cold.

The *oxime*, prepared by boiling the ketone for 1 hour with hydroxylamine hydrate (1.5 mols.) in aqueous-alcoholic solution, separated from light petroleum (b. p. 40—80°) in large, colourless prisms, m. p. 128° (Found : C, 73.1; H, 10.6.  $C_{11}H_{19}ON$  requires C, 72.9; H, 10.6%).

*Reduction of the spiroKetone with Sodium in Moist Ether.* *cyclohexanespirocyclohexan-3-ol* (IV).—A solution of 18 g. of the crude ketone (from the reduction of 25 g. of chloro-ketone) in 100 c.c. of ether and 10 c.c. of alcohol was poured on to 200 c.c. of water in a separating funnel, to which was attached a reflux condenser. Sodium (19 g., in thin slices) was gradually added, the water being changed after addition of the first 10 g.; this water was extracted with a little ether, which was then transferred to the funnel. When all the sodium had been added, the ethereal solution was washed

twice with water, the ether removed through a column, and the residue distilled in steam. The ethereal extract of the distillate was washed twice with a saturated solution of sodium bisulphite, and the ether distilled through a column; the residue solidified on cooling in a vacuum (yield 50% of the theoretical, calculated on the chloro-ketone used).

*cycloHexanespirocyclohexan-3-ol* boils at 127—128°/15 mm. and sets to a felted mass of needles, which are too soluble in the ordinary solvents to be recrystallised, but melt quite sharply at 58° after draining well on porous porcelain (Found: C, 78.5; H, 11.75.  $C_{11}H_{20}O$  requires C, 78.5; H, 12.0%). The alcohol has a pleasant camphoraceous odour.

The *p*-nitrobenzoate is produced when the hydroxy-compound and *p*-nitrobenzoyl chloride are boiled with pyridine in ethereal solution. It separates from alcohol in pearly-white plates, m. p. 102° (Found: C, 68.3; H, 7.25.  $C_{18}H_{23}O_4N$  requires C, 68.1; H, 7.3%).

*Oxidation of the spiroAlcohol.* *cycloHexane-1-acetic-1-propionic Acid* (VI).—The hydroxy-compound (19 g.) was gradually added to 45 c.c. of boiling, concentrated nitric acid, and the liquid was then diluted with water and evaporated. This process was repeated until no more nitric acid remained. A gummy acid (19.5 g.) was thus obtained (compare Crossley and Renouf, *loc. cit.*) which did not solidify. This was kept for 36 hours with 60 c.c. of absolute alcohol and 20 c.c. of concentrated sulphuric acid. The fraction, b. p. 179—183°/14 mm., of the neutral ester thus produced (Found: C, 66.4; H, 9.5.  $C_{15}H_{26}O_4$  requires C, 66.6; H, 9.7%) was hydrolysed with boiling alcoholic caustic potash, and the acid extracted from the acidified solution with ether. The residue left after evaporation of the ether gradually solidified when kept in a vacuum, and, after remaining for 3 days in contact with porous porcelain, was recrystallised from a mixture of chloroform and light petroleum (b. p. 40—60°), from which it separated in rosettes of colourless needles, m. p. 142.5° (Found: C, 61.45; H, 8.4.  $C_{11}H_{18}O_4$  requires C, 61.7; H, 8.4%).

The acid may also be purified through the characteristic *calcium* salt, the solubility of which in water apparently increases with increasing temperature almost to the boiling point, and then suddenly decreases.

*Action of Hydrobromic Acid on the Hydroxy-compound.*—The *spiro*-alcohol (20 g.) was heated for 1.5 hours in a sealed soda-water bottle with 110 c.c. of fuming hydrobromic acid, saturated at 0°. The cooled liquid was resaturated with hydrogen bromide, and the

heating repeated. The product was poured into 1500 c.c. of water, and the heavy oil extracted with ether. The ethereal solution was washed well with a solution of sodium carbonate and then with water, and dried over calcium chloride. The residue, after the ether had been removed through a column, was distilled under reduced pressure. The greater portion boiled between  $133^{\circ}$  and  $136^{\circ}/12$  mm., but the liquid could not be separated into definite fractions, even by repeated distillation. A portion taken at  $133^{\circ}$  gave the following figures on analysis : C, 61.2; H, 8.7; Br, 29.2.  $C_{11}H_{19}Br$  requires C, 57.1; H, 8.3; Br, 34.6%. These correspond to 84% of the bromo-derivative, if only bromo-compound and hydroxy-compound were present. A purer sample was not obtained.

*Action of Hydrochloric Acid on the Hydroxy-compound.*—The reaction was conducted as in the preceding case. The fraction of the product most rich in chlorine boiled at  $142$ — $148^{\circ}/33$  mm. and contained 13.7% of chlorine, corresponding with the presence of 72% of  $C_{11}H_{19}Cl$  in the mixture. No fraction containing more than this amount of chlorine could be isolated.

*Reduction of the Bromo-derivative (VII) with Zinc Dust and Alcohol.*—The crude bromo-compound (26.5 g.), containing 84% of the pure material, was dissolved in 90 c.c. of 90% alcohol and mixed with 46 g. of zinc dust and an equal bulk of sand. Enough absolute alcohol (ca. 10 c.c.) was added to form a clear solution, and the whole heated under reflux on the water-bath for 20 hours. The liquid was filtered into 1200 c.c. of water, and the aqueous liquid extracted twice with ether. The ethereal solution was washed with water, and dried over potassium carbonate, the ether removed, and the residue heated for 2 hours over metallic sodium and then distilled. After two further distillations over sodium (the third time the metal remained unattacked), a bright, colourless liquid, b. p.  $204$ — $208^{\circ}/762$  mm., was obtained having a penetrating odour of geranium (Found in a fraction, b. p.  $204$ — $206^{\circ}$ : C, 87.4; H, 13.0. Found in a fraction, b. p.  $206$ — $208^{\circ}$ : C, 87.35; H, 12.9.  $C_{11}H_{20}$  requires C, 86.8; H, 13.2%.  $C_{11}H_{18}$  requires C, 88.0; H, 12.0%. A 50% mixture of  $C_{11}H_{20}$  and  $C_{11}H_{18}$  requires C, 87.4; H, 12.6%).

These figures indicate that the hydrocarbon contained some unsaturated material, a conclusion which was confirmed by the ready absorption of bromine in chloroform solution and by the reduction of permanganate in acetone solution. The analytical figures are so close to those given above for a 50% mixture that at first it was thought that a reaction in the following sense must have occurred :

followed by isomeric change on distillation :

These figures have, however, never been repeated; moreover, 3 g. of the hydrocarbon mixture absorbed, in chloroform solution, 0.345 g. of bromine only, whereas for a 50% mixture 0.530 g. should have been taken up. It is concluded, therefore, that the remarkable agreement of the analytical results with the numbers required for the composition " $\text{C}_{22}\text{H}_{38}$ " is accidental, and that reduction and elimination of hydrogen bromide must have occurred simultaneously.

*Reduction of the Hydrocarbon Mixture with Hydrogen and Colloidal Palladium.* *cyclohexanespirocyclohexane* (VIII).—The mixed hydrocarbons (6 g.) were shaken in an atmosphere of hydrogen for 8 hours with 2.5 c.c. of a 10% solution of palladium chloride, 2.5 c.c. of a 10% solution of gum arabic in water, 5 c.c. of water, and enough alcohol to give a clear solution. The initial pressure of gas was 1070 mm.; this fell gradually to 815 mm. The product was isolated by distillation in steam and extraction of the distillate with ether.

*cyclohexanespirocyclohexane*, b. p.  $208^\circ/777$  mm., is a clear, colourless, mobile liquid having a faint odour of geranium (Found : C, 86.7; H, 13.35.  $\text{C}_{11}\text{H}_{20}$  requires C, 86.6; H, 13.3%). It is quite stable to permanganate and is only slowly dissolved by boiling, fuming nitric acid; bromine, in chloroform solution, is quite without action. The freshly distilled hydrocarbon has  $d_{20}^{25}$  0.87833,  $n_D$  1.47048,  $n_D$  1.47313,  $n_F$  1.47902,  $n_G$  1.48398. Hence  $[\text{R}_L]_D = 48.61$ ,  $[\text{R}_L]_{F-C} = 0.75$ ,  $[\text{R}_L]_{G-C} = 1.19$ . The theoretical figures are 48.60, 0.74, 1.19, respectively. These values show no optical exaltation such as might be expected were the *cyclohexane* rings in the *spiro*-hydrocarbon under a strain comparable with that in derivatives of *cyclobutane*, *cyclopropane* or *cycloheptane*. Crossley and Renouf (*loc. cit.*) quote the following results, determined for 1:1-dimethylcyclohexane by W. H. Perkin, sen.:— $d_{20}^{25}$  0.78543,  $n_D$  1.42958,  $n_D$  1.43728,  $n_G$  1.44203. Hence  $[\text{R}_L]_C = 36.85$ ,  $[\text{R}_L]_G = 37.78$ ,  $[\text{R}_L]_{G-C} = 0.93$ . The calculated figures are 36.78, 37.68, 0.90, respectively. The increase shown by the experimental figures over the theoretical is inappreciable.

*Action of Phosphorus Pentachloride on the spiro-Diketone (I). cycloHexanespiro-3 : 5-dichloro- $\Delta^{2:4}$ -cyclohexadiene.*—After it had been found that the conversion of the *spiro*-alcohol into the corresponding halogen derivatives could not be carried out quantitatively, it was hoped that an increased yield of the final product might be obtained by eliminating both oxygen atoms from the molecule at an early stage of the reduction. Accordingly the action of phosphorus pentachloride on the diketone was investigated, in the hope that the latter might react in the dienol form (XI) to give the dichloro-unsaturated hydrocarbon (XII); an expectation which has been realised.

The diketone (50 g.) was suspended in 130 c.c. of dry chloroform in a flask attached to a reflux apparatus; 125 g. of phosphorus pentachloride were gradually added in small quantities; after each addition the liquid boiled vigorously. The whole was heated for 3 hours on the water-bath, the cooled liquid filtered, and the chloroform distilled off. The residue was shaken well with ice-cold water, and the organic material taken up in ether. The ethereal solution, after being well washed with a dilute solution of caustic soda and then with water, was dried over calcium chloride. The residue after removal of the ether was distilled under reduced pressure. Only a very little impure diketone was recovered from the alkaline washings. *cycloHexanespiro-3 : 5-dichloro- $\Delta^{2:4}$ -cyclohexadiene* was thus obtained (yield 65%) as a pale yellow oil, b. p.  $152^\circ/21$  mm. (Found: Cl, 32.5.  $\text{C}_{11}\text{H}_{14}\text{Cl}_2$  requires Cl, 32.7%).

Unfortunately it has not yet been possible, by the use either of acid or of alkaline reducing agents, to prepare from this material a pure compound free from halogen.

This work was carried out at the Imperial College of Science and Technology under the direction of Professor J. F. Thorpe, C.B.E., F.R.S., to whom the author is grateful for kind help and encouragement. His thanks are also due to the Department of Scientific and Industrial Research and to the Chemical Society for grants which have made this research possible.

## XXXVII. — *The Interaction between Copper and Sulphuric Acid.*

By CECIL WILLIAM ROGERS.

THE reactions which occur between copper and sulphuric acid have been investigated by Berzelius ("Traité de Chimie," IV, p. 324), Barruel (*J. Pharm.*, 1834, **20**, 13), Maumené (*Ann. Chim. Phys.*, 1846, **18**, 311), Calvert and Johnson (*J.*, 1866, **19**, 438), Pickering (*J.*, 1878, **33**, 122), Baskerville (*J. Amer. Chem. Soc.*, 1895, **17**, 904), van Deventer (*Chem. Centr.*, 1905, **1**, 992), and Sluiter (*ibid.*, p. 903).

Berzelius noticed that a black residue formed during the reaction, which could be oxidised by nitric acid, and was of the opinion that it was the sub-sulphate. He made no analyses of the substance. Barruel found that the action could take place at the ordinary temperature if sufficient time was allowed. He held that sulphur dioxide was first formed which attacked the copper with the formation of cuprous sulphide and cupric oxide, the latter then dissolving in the excess of acid to form the sulphate. He also made no analyses of the supposed sub-sulphide. Maumené suggested that more than one reaction proceeds at the same time, and introduced the idea of two primary reactions with a number of secondary reactions. One of these primary reactions led to the formation of sulphur dioxide and cupric sulphate; the other to the production of cuprous sulphide as one resultant, which, in consequence of the secondary reactions, became oxidised through the stages  $\text{Cu}_2\text{S}$ ;  $\text{CuO}, 2\text{Cu}_2\text{S}$ ;  $\text{CuO}, 2\text{CuS}$ ;  $\text{CuO}, \text{CuS}$ ; to  $\text{CuO}$ . Calvert and Johnson carried out a few experiments on the relative effect of concentrated and dilute acid at temperatures between  $130^\circ$  and  $150^\circ$ . They observed the formation of cuprous sulphide, which they considered was due to free sulphur combining with the metal. They made no analyses, but gave the following reasons for their opinions: (1) No hydrogen sulphide is evolved, (2) no sulphur is volatilised, (3) the analogy between this reaction and that of sulphuric acid upon tin.

Pickering carried out a thorough examination of the subject in all its aspects and concluded that there were two primary reactions and two secondary reactions, the latter being dependent on the second primary reaction. He gave the following equations:

### A. *Primary Reactions.*

which was supposed to depend on the formation of nascent hydrogen.

*B. Secondary Reactions.*

He stated that the primary reactions may occur either alone or together; that the metal is attacked at all temperatures from 19° upwards, the extent of the action increasing with rise in temperature; that very little gas was observed below 130°, and none at all insoluble in water; and that a deposit of sulphur was formed in the neck of the vessel either before or after the complete dissolution of the metal. He showed that no hydrogen sulphide was evolved, and he was the first to point out that the black residue in the flask consisted solely of copper and sulphur in the proportions required by the formula  $\text{Cu}_2\text{S}$ . From his observation that the ratio of  $\text{Cu}_2\text{S}/\text{CuSO}_4$ , expressed in terms of the copper content, decreased with diminishing temperature, and that the maximum ratio obtainable in the case of the second primary reaction was 2 : 3, he attempted to ascertain the temperature at which this reaction should go on alone. In this he was not successful, although approximations were obtained with the concentrated acid at 80° and with dilute acid at 130°. In no case was a ratio greater than 2 : 3 observed. He gave a number of reasons to show that the sulphide could not be formed either by the action of nascent hydrogen, hydrogen sulphide, or by the direct action of free sulphur on the metal.

Baskerville also carried out a series of experiments in which most of his work was in accord with that of Pickering. He gave the same equations, but differed in the detail of the operation of the primary reactions. He held that the first primary reaction predominates at all temperatures between 0° and 270° and that the proportion of material conforming to the second primary reaction increases from 0° to 100°, and then decreases from 100° to 270°. Below 100°, the primary reactions alone take place, the secondary reactions becoming evident at the higher temperatures with prolonged action, although even then, with short time, evidence of the operation of only the primary reactions was found.

It is to be noticed that neither Pickering nor Baskerville took any account of the sulphur formed during the reactions beyond recording its formation and tracing its origin to the decomposition of the sulphides. They ignored altogether the possible influence it might have had on the results of their experiments, especially at the higher temperatures. Both are agreed that two primary reactions take place. The present work was undertaken to examine this question of two primary reactions, to discover reasons for the different views expressed upon their influence at various temper-

atures, and to ascertain the effect, if any, of the liberated sulphur upon the final result of the action.

#### EXPERIMENTAL.

The purest electrolytic copper foil obtainable and concentrated sulphuric acid (A.R.) were used. The foil was cut into pieces  $3 \times 1.6$  cm., one piece only being used in each experiment.

The apparatus consisted of a reaction tube, about 6 inches long, furnished with two tapped side tubes for the admission of an inert gas and the removal of the gaseous products, and a ground glass stopper from which the copper was suspended on a fine glass thread. Sufficient acid was employed to cover the metal completely when in the tube, the acid being maintained at the required temperature by means of a suitable bath for at least  $\frac{1}{2}$  hour before the introduction of the metal. A current of purified carbon dioxide was passed through the tube throughout an experiment, this creating an inert atmosphere, effectively removing the gaseous products, and keeping the surface of the metal fairly clean. The sulphur dioxide evolved, which was the only gaseous product of the reactions, was absorbed either by iodine or potassium permanganate. The amount of copper used was found by weighing the strip before and after an experiment, and the copper as sulphate was estimated as cupric oxide.

*The Completed Action.*—It is stated that at  $270^{\circ}$  the reaction represented by the equation

proceeds alone. A series of experiments carried out at  $270^{\circ}$  furnished evidence which, while supporting the above equation in so far as the final result is concerned, showed that this is not the only action which occurs. The complete conversion of the metal into the sulphate takes place within a few seconds of the introduction of the metal, and the gas is evolved with such rapidity that the copper is carried to the upper portion of the acid. Further, before the flood of gas commences, there is an appreciable interval, during which the surface of the metal becomes covered with a black deposit. This deposit is practically entirely acted upon at the conclusion of the experiment except for such very small particles as are carried out of the liquid by the upward rush of gas and deposited on the sides of the reaction vessel. The acid itself quickly assumes a blue colour and white crystals may be observed to fall continuously from the surface of the metal. The crystalline deposit at this temperature is always quite white and free from the grey tints found in that formed at lower temperatures. On examination under the microscope it is found to consist of a large number of imperfectly

formed crystals together with a few tabular crystals, the whole being characteristic of anhydrous copper sulphate when crystallised from the concentrated acid at the same temperature. The examination of the crystalline deposits obtained at different temperatures will be dealt with in a later section. The following results are typical of those obtained at this temperature :

No.	Cu used.	SO <sub>2</sub> found.	Cu as CuSO <sub>4</sub> .	Cu as sulphide.	Sulphur.	Acid.
1	0.2692	0.2618	—	Trace	Trace	Slightly brown
2	0.4649	0.4333	—	"	"	Brown
3	0.4450	0.4208	—	"	"	Slightly brown
4	0.4920	0.4841	0.4820	"	"	"
5	0.4929	0.5016	0.4631	"	"	Red
6	0.5012	0.5126	—	None	None	Colourless

The sulphur dioxide was estimated by absorption in iodine solution and titration of the excess iodine by thiosulphate. The low values for the copper sulphate are due to the fact that the anhydrous salt was filtered off before analysis, the 2—3% of copper which remained in solution thereby being left out of account. That copper still remains dissolved in the acid may be shown by the addition of a saturated solution of potassium bromide, when a dark, amorphous precipitate of the anhydrous bromide is thrown down. The excess of sulphur dioxide in experiments (5) and (6) is probably due to the dissociation of the acid itself; both experiments were prolonged for some time after the action had ceased. The lower values in some of the other cases are due to incomplete collection of the total sulphur dioxide owing to the closure of the experiments within a few seconds of the cessation of the reaction.

An interesting point arises in connexion with experiment (5). After the action had ceased, the reaction tube and its contents were allowed to cool slowly during several hours, and the acid liquid was then bright red. The crystalline deposit was quite normal when viewed under the microscope, and the abnormal colour may be ascribed, perhaps, to the colloidal condition of traces of sulphur remaining in solution. This suggestion is supported by the fact that after several weeks the acid deposited a small quantity of sulphur and became brown; the sulphur redissolved on shaking, producing a reddish-brown solution. All attempts to reproduce this effect met with failure.

Since traces of both sulphur and sulphide were met with at 270°, the reaction temperature was raised, but in the majority of cases both persisted. This circumstance, together with the darkening of the metallic surface before the evolution of gas commences, points to the conclusion that the simple equation is not sufficient to explain the action even at this high temperature, and that the

formation of sulphide and the subsequent liberation of sulphur are probably steps in the series of reactions involved.

*The Black Deposit.*—The black deposit was therefore carefully investigated. Trial experiments showed that it is produced most abundantly between 100° and 130°. The material for examination was prepared by immersing a large piece of the metal in the acid, a current of carbon dioxide being passed continuously. When the metal became coated, it was removed and at once plunged into thoroughly boiled water, beneath which the deposit was removed. The metal, after thorough cleansing and drying, was then returned to the acid, these operations being repeated until sufficient material had accumulated. Although the temperature range is most favourable to the rapid formation of the sulphidic matter, it also happens that the acid reacts with it fairly quickly, so that the actual amount of material collected is comparatively small. At lower temperatures, the rate of reaction is too slow for the rapid collection of the sulphidic matter.

The deposit was transferred from the water to a small platinum funnel, thoroughly washed with boiled water, dried, and weighed. Any sulphur present was extracted with carbon disulphide. The material was then treated with hot, concentrated nitric acid until no further action took place, the residual sulphur being weighed. The sulphur was removed by ignition from the funnel, which was weighed once more as a check. The copper and the oxidised sulphur in the filtrate from the nitric acid treatment were then estimated as cupric oxide and barium sulphate, respectively.

A large number of analyses of this type were carried out, and in every case the total percentage of copper and sulphur was about 100. There can be little doubt that the black residue consists entirely of copper and sulphur. The ratio of copper to sulphur, however, varied considerably, even in specimens collected from the same piece of metal and the same acid for different analyses; but the proportions always exhibited values between those required for cuprous sulphide and cupric sulphide, being nearer to the former than to the latter. It appears, therefore, that the first product is cuprous sulphide, which is then decomposed partly into cupric sulphide. The following table shows results obtained by the method of analysis given above :

Temp.	Cu %.	S %.	Total %.
100°	78.72	21.49	100.21
110	75.44	25.32	100.76
110	77.43	22.11	99.54
120—125	72.54	30.36	103.20
125	73.77	25.67	99.44
132	78.29	21.56	99.85

$\text{Cu}_2\text{S}$  requires Cu, 79.86; S, 20.14% and  $\text{CuS}$  requires Cu, 66.48; S, 33.52%. No oxysulphides were obtained in any of these experiments.

*The Secondary Reactions.*—Experiments were then carried out with the two sulphides prepared by ordinary laboratory methods with the object of ascertaining the mode of decomposition of these substances in contact with the concentrated acid. Cupric sulphide was allowed to react with the acid at the required temperature until all had disappeared. The sulphur dioxide evolved was absorbed by iodine solution. A current of carbon dioxide was passed to assist in the removal of the sulphur dioxide, and to provide an inert atmosphere. The crystalline deposit was examined microscopically and found to be characteristic of cupric sulphate, and to contain inclusions of undecomposed sulphide. For the estimation of the copper, both the crystalline deposit and the acid liquid were taken, since some sulphate remained in solution. The sulphur dioxide evolved was, in general, in excess of that required by the equation given below, the excess increasing up to a definite maximum with rise in temperature and with the duration of the experiment. This can only have been due to the sulphur set free during the reaction, some of which reacted with the acid, while some was volatilised and condensed in pale yellow crystals of the  $\beta$ -form on the cooler parts of the reaction tube. The volatile material, on being heated on a microscope slide covered by a small glass dome, underwent all the changes characteristic of the effect of heat on sulphur. Small portions heated with free access of air gave the unmistakable odour of sulphur dioxide and reduced potassium dichromate. From the data given in the table below, it is evident that the cupric sulphide reacts with the acid according to the equation.

and that the sulphur reacts with more acid :

Temp.	CuS used.	CuO as $\text{CuSO}_4$ .	$\text{SO}_2$ found.
100°	1.486 g.	1.225 g.	1.152 g.
110	2.465	1.975	1.763
120	2.613	2.142	2.435
130	1.753	1.449	1.861
140	3.792	3.097	3.471
160	1.937	1.595	3.912 (prolonged action)
170	1.642	1.348	3.536     "     "

That cuprous sulphide reacts with sulphuric acid to produce cupric sulphide was established by the change of composition of the black sulphide after immersion in the acid for various periods, the acid being diluted considerably to stop the action. Sulphur

invariably made its appearance after a time. The experiments were made in pairs at different temperatures, one of each pair being stopped after a short time, the other carried on for some considerable time, especially at the lower temperatures, the rate of reaction being very slow. The original composition of the black sulphide was 79.81% Cu, 20.58% S in the two experiments at 60° and 79.82% Cu, 20.10% S in the others. The final compositions were :

Temp.	60°.	80°.	100°.	120°.	160°.
% Cu	75.71; 72.23	74.55; 69.64	76.82; 68.92	74.73; 68.51	76.22; 70.61
% S	24.18; 27.72	24.86; 30.02	22.81; 30.82	25.60; 30.72	23.51; 28.64

Sulphur dioxide was evolved continuously, but quantitative measurements were not made. Where a crystalline deposit was obtained, this was examined microscopically and found to be cupric sulphate. It thus appears that the cuprous sulphide decomposes into cupric sulphide with the simultaneous formation of cupric sulphate and sulphur dioxide according to the equation

and that the cupric sulphide so formed then reacts with the acid in the manner already described.

*The Crystalline Deposit.*—This has been stated by previous investigators to be anhydrous cupric sulphate, but as no means of identification were given, and owing to the possibility of the hydrolysis of a more complex substance on the addition of water, and the varying nature of some of the results obtained, it was thought necessary to examine the substance further. For this purpose the microscope was employed.

Except when prepared at the higher temperatures, above 200°, and even then, only when kept at this temperature for some time, under which conditions the substance is fairly soluble, producing a green solution, the deposit is never white; it is generally of a dingy grey appearance. This is due to the fact that it contains a quantity of the two sulphides, the particles of which have served as nuclei round which the crystals have formed, thus protecting them from further attack by the acid. If such a deposit be treated with acid at a temperature higher than that at which it was formed, some of the crystals will dissolve, and the sulphides thus liberated will react with the acid in the usual manner. The employment of sufficient acid to dissolve the whole of the deposit results in the formation of a perfectly white, sulphide-free product on cooling.

At temperatures up to about 200° the crystalline deposit consists almost entirely of crystals belonging to the rhombic system, being combinations of the pinacoids, prism, and macrodome. Typical crystals are shown in the diagram (types a, b, c, d, and e). These

are transparent and colourless, and frequently contain inclusions of sulphide. Twinning is not of common occurrence except in the case of type a. There are, in addition to these rhombic crystals, others which appear to be monoclinic, are green, grouped, few in number, and are formed chiefly at 130° and above, at which

FIG. 1.

temperature the solution also is green. They might possibly be the acid sulphate.

At temperatures above 200° deposits of an entirely different character are obtained. The crystals are, for the most part, imperfectly developed, and of the rhombic crystals, only those of type d reach full development. Types a, b, c, and e are absent. Various

intermediate stages in the growth of type d may be found in abundance, the earlier stages being represented by crystals with one fully developed hexagonal face, partial development of the corresponding parallel face, growth being greatest in the regions opposite to the angles of the hexagon, these faces being united by six inclined planes (types f, g, h). Continued growth of the irregular face leads ultimately to the formation of a hexagonal face corresponding to that originally present, the two being now united by twelve inclined planes and presenting the appearance of k. Subsequent growth fills up the hollows to produce the perfect crystal. The mode of formation appears to resemble that of the crystals of the alkali halides. In addition to these imperfect forms, there are a large number of monoclinic crystals, tabular parallel to the ortho axis (l). These are well developed. On cooling the solution obtained at these temperatures, no further deposition of rhombic crystals takes place; instead, long slender prisms make their appearance below about  $180^{\circ}$  (m). The prisms grow either on the monoclinic crystals just mentioned, or singly, or, occasionally, in groups. They appear to belong to the triclinic system, although their arrangement parallel to the orthopinacoid when growing on the monoclinic plates suggests that they also might be monoclinic (n). Many of them are hollowed out from the position of the basal pinacoid faces inwards, presenting the appearance of p. Copper sulphate pentahydrate, specially prepared for the purpose, was dehydrated either by heat, or by immersion in concentrated sulphuric acid for some days. The anhydrous substance, prepared in either manner, in solution in the concentrated acid below  $180^{\circ}$ , deposits nothing but the prismatic crystals previously mentioned. If, however, the solution is prepared at, say,  $160^{\circ}$ , so that it will become saturated at a considerably lower temperature, and is then set aside out of contact with moisture, nothing deposits from it for some time, but when crystallisation does set in, the rhombic crystals are formed to the exclusion of the long, slender prisms. This process may require two or more days for its completion.

At temperatures above  $200^{\circ}$  the crystals obtained showed all the characteristics of those prepared by the action of the acid on the metal. It was found, further, that neither carbon dioxide nor sulphur dioxide exerted any influence on the type of crystal developed at any temperature, and that no sulphur dioxide was evolved on heating the crystals with the acid. There can be little doubt, therefore, that the crystalline deposit obtained by heating the acid with the metal is anhydrous cupric sulphate; moreover, it appears that the anhydrous salt is at least dimorphous, and possibly tetramorphous.

*The Primary Reaction.*—Both Pickering and Baskerville were agreed that two primary reactions take place. It would seem rather unusual, however, for two substances to react in two totally different ways at the same temperature unless one of them be metameric. Of the reactants concerned, the acid is the only one which could fulfil this condition, and there is no evidence to show that it does actually exist in more than one form. Hence it is to be expected that only one primary reaction could take place. Further, both Pickering and Baskerville state that below  $130^{\circ}$  the evolution of gas is very slow, and that only at this temperature do bubbles of gas make their appearance. If the acid acted on the metal directly with the production of sulphur dioxide, it would be expected that bubbles of gas would be observable with ease at much lower temperatures, as in the case of zinc with dilute sulphuric acid. Even if the zinc and the acid be highly purified, the bubbles may be readily detected, although the action is slow. This again points to the possibility that the gas does not arise from the direct action of the acid on the metal, and that two primary reactions do not, in fact, take place.

If a piece of the purest electrolytic copper foil be totally immersed in the concentrated acid which has been heated to, and maintained at, a given temperature in an atmosphere of carbon dioxide for about  $\frac{1}{2}$  hour before the introduction of the metal, the following observations may be made :

*At  $50^{\circ}$ .* The first visible product of the interaction is a film on the metal, of a brownish hue, the formation of which is indicated by the loss of lustre of the metallic surface. This film gradually leaves the surface of the copper, the whole of which it covers, and it is then seen to be of almost the same shade as the metal itself. It remains suspended in the acid, being slowly moved about by the convection currents, and may be observed to change its colour to yellow and then to disappear—dissolve in the acid—colouring the latter yellow also. After this cycle of changes has proceeded for some time the acid becomes opalescent. No gas bubbles can be observed on the surface of the metal, yet sulphur dioxide is undoubtedly formed after a time.

*At  $50$ — $120^{\circ}$ .* On increasing the initial temperature the formation of the brown material takes place with increasing rapidity, as also the conversion of this into the yellow substance. No gas bubbles can yet be observed.

*At  $130$ — $140^{\circ}$ .* At about  $130^{\circ}$  the same phenomena occur with great rapidity, and at the same time bubbles of gas make their appearance; but no bubbles are formed until a deposition of the film has taken place. The particles constituting the film at this

temperature soon coalesce, the material then appearing black and forming a coating on the metal. The acid darkens owing to the suspended sulphide, but if the metal be removed it rapidly becomes clear again. Sulphur is deposited on the cooler parts of the apparatus.

The initial formation of the brown film could still be detected at temperatures above  $140^{\circ}$ . In every case there was an appreciable interval between the immersion of the metal and the appearance of the gas bubbles, which were never formed until the black sulphide had been produced. Hence the formation of sulphur dioxide is probably not due to the direct action between the acid and the metal. Support for this contention is found in the results of the following experiments.

A single piece of foil was totally immersed in the concentrated acid contained in one of the reaction tubes, the exit tube from which was connected by a series of T-pieces to absorption tubes in such a manner that any one of the latter could be put into communication with the reaction vessel directly, the change from one to another being made with the utmost facility. A current of carbon dioxide was passed throughout each experiment, the acid being heated to, and maintained at the required temperature for at least  $\frac{1}{2}$  hour before the introduction of the metal. The sulphur dioxide evolved was absorbed in potassium permanganate.

*Experiment 1.* At  $50^{\circ}$ . Twenty c.c. of  $N/50$ -potassium permanganate were placed in each of three absorption tubes, each being connected in turn to the reaction vessel. Upon the removal of each tube 25 c.c. of  $0.918 N/50$ -oxalic acid were added to its contents, and the volume of permanganate solution required for the titration of the excess of oxalic acid was measured. In all these experiments the reagents were delivered from over the same range of the burettes employed, this ensuring uniformity in the quantities of liquids taken. By blank tests it was found that 4.8 c.c. of the permanganate solution were required to titrate the excess of oxalic acid. The following results were obtained :

1.	Removed after the expt. had proceeded for	5 mins.	.....	4.8 c.c.
2.	" " " " " "	17 "	.....	4.7 "
3.	" " " " " "	30 "	.....	4.9 "

No film had yet formed.

*Experiment 2.* At  $60^{\circ}$ . The same piece of copper was employed with fresh acid, the remaining details conforming to those of Experiment 1.

1.	Removed after the expt. had proceeded for	5 mins.	.....	4.8 c.c.
2.	" " " " " "	19 "	.....	4.9 "

The film had formed and was about to leave the surface of the copper.

*Experiment 3.* At 50°. The same piece of copper was used with fresh acid.

- |   |          |
|---|----------|
| 1. Removed after the expt. had proceeded for 5 mins. .... | 4.8 c.c. |
| 2. " " " " " " 50 " .....                                 | 4.9 "    |

The film had just made its appearance.

- |  |          |
|--|----------|
| 3. Removed after the expt. had proceeded for 70 mins. .... | 4.9 c.c. |
| 4. " " " " " " 100 " .....                                 | 5.0 "    |

These experiments, and others carried out in a similar manner, clearly indicated that the sulphur dioxide is not produced before the formation of the sulphide, but that after the formation of the latter the liberation of the gas commences. The varying time interval between the immersion of the metal and the appearance of the film is probably due to the nature of the metallic surface.

In order to test the above experiments and to gain additional evidence, another series was carried out with the solutions of permanganate and oxalic acid diluted to  $N/200$ , so that the oxalic acid became  $0.918 N/200$ . The titrations were carried out in Nessler cylinders, the end-points being judged by comparison with similar cylinders containing known amounts of permanganate. By blank tests, it was found that 20 c.c. of permanganate with 25 c.c. of oxalic acid required 5.0 c.c. of permanganate to titrate the excess of oxalic acid.

*Experiment 1.* At 60°.

- |  |          |
|--|----------|
| 1. Removed after the acid had been heated for 45 minutes before the addition of the copper ..... | 5.0 c.c. |
| 2. Removed 10 minutes after the addition of the copper .....                                     | 4.9 "    |
| 3. " 36 " " " " " " " .....  | 5.2 "    |

Film formation first observed at this point.

*Experiment 2.* At 85°. Same piece of copper used with fresh acid.

- |  |          |
|--|----------|
| 1. Removed after the acid had been heated for 30 minutes before the addition of the copper ..... | 5.0 c.c. |
| 2. Removed 12 minutes after the addition of the copper .....                                     | 4.8 "    |
| 3. " 20 " " " " " " " .....  | 4.8 "    |

First indication of film formation.

- |   |       |
|---|-------|
| 4. Copper removed after 45 minutes' immersion, the $KMnO_4$ being allowed to absorb the total $SO_2$ during a period of 2 days (30 c.c. of $KMnO_4$ and 20 c.c. of oxalic acid being used in this case) ..... | 7.2 " |
|---|-------|

These experiments again show that no sulphur dioxide is derived from the action before the film of sulphide has been formed, that no sulphur dioxide is derived from the acid itself at this temperature, and that the production of sulphur dioxide commences after the sulphide has formed.

There is, therefore, no justification for asserting that two primary reactions occur. For, if the first primary reaction of Pickering and Baskerville predominated at all temperatures, sulphur dioxide would be expected before the formation of the film, and if the second primary reaction took precedence, as asserted by Baskerville at the particular temperature of these experiments, no change should be observable in the sulphide film, and the gas evolved should first appear on the surface of the metal.

There is only one primary reaction, that one producing cuprous sulphide and cupric sulphate irrespective of the temperature at which the experiment is carried out, the sulphide then decomposing in the usual manner. The formation of the sulphur dioxide is thus dependent on the secondary reactions between the acid, the sulphides and the sulphur, the quantity actually formed being governed by the extent of occlusion of the sulphides by the sulphate, and the volatility of the sulphur in addition to the time and concentration factors.

The following experiments were made with the object of ascertaining the total production of sulphur dioxide at different temperatures, its amount being also expressed as a percentage of that theoretically obtainable from the simple equation

The experiments were prolonged until all the sulphides had disappeared, and the sulphur had either reacted, volatilised, or remained practically inactive, and all the sulphur dioxide had been collected :

Temp.	Cu used.	SO <sub>2</sub> found.	Per cent.	Temp.	Cu used.	SO <sub>2</sub> found.	Per cent.
50°	0.0013	0.0009	69	140°	0.2146	0.1853	86
50	0.0011	0.0006	55	180	0.3621	0.3317	91
85	0.0052	0.0025	50	200	0.3165	0.2849	90
100	0.0131	0.0075	57	270	0.4920	0.4841	98
110	0.0163	0.0124	76	270	0.4450	0.4208	95
120	0.0251	0.0213	85				

It is clear that the percentage of sulphur dioxide increases with increase of temperature. So also does the rate of reaction between the sulphides, the sulphur, and the acid, so that these substances have less chance of being occluded or volatilised. As the temperature increases, they are acted upon more and more rapidly until,

in the region of  $270^{\circ}$ , they are removed practically as fast as they are formed. It is also evident that below  $100^{\circ}$  the sulphur must react with the acid very slowly, in fact it is sometimes possible to find quite large particles present in the liquid after several days. If the quantity of acid employed be sufficiently large to dissolve the whole of the sulphate produced, thus preventing occlusion, and the time of the experiment be prolonged, there seems no reason, other than the volatility of the sulphur, why results closely agreeing with the simple equation should not be obtained at any temperature at which appreciable action between the substances concerned takes place. In particular, over the range  $130$ — $200^{\circ}$ , the sulphur is volatilised to an extent sufficient to allow its weight to be determined. The continuous removal of the sulphide makes impossible the direct determination of the quantitative relationships of the first reaction, but if an experiment be stopped at any point, and the cuprous sulphide and the sulphur dioxide be estimated, it is possible to obtain approximate values. From the consideration of the secondary reactions, it is known that 40% of the sulphur dioxide evolved in the completed reactions is due to the decomposition of the sulphides. If the corresponding amount of cuprous sulphide be calculated and this result be added to the sulphide actually found, the total must represent that portion of the copper which has either passed, or is passing through, the sulphide stage. The difference between this figure and the total copper used gives the amount of metal which would have been found as sulphate had no sulphide been decomposed. The ratio of copper as cuprous sulphide to copper as cupric sulphate then determines the action.

The following table shows the results of a number of experiments calculated in this manner :

Temp.	Cu used.	Cu as $\text{Cu}_2\text{S}$ .	$\text{SO}_2$ .	Cu as $\text{Cu}_2\text{S}$ = 40% of $\text{SO}_2$ .	Total Cu as $\text{Cu}_2\text{S}$ = A.	Residual Cu as $\text{CuSO}_4$ = B.	Ratio A/B.
$16^{\circ}$	0.1176	0.0113	0.0513	0.0205	0.0318	0.0858	2/5.4
80	0.0280	0.0013	0.0215	0.0086	0.0099	0.0181	2/3.7
80—90	0.0235	0.0005	0.0216	0.0086	0.0091	0.0144	2/3.2
100	0.0135	0.0016	0.0092	0.0037	0.0053	0.0082	2/3.1
100	0.0417	0.0120	0.0084	0.0034	0.0154	0.0263	2/3.4
120	0.0431	0.0085	0.0200	0.0080	0.0165	0.0266	2/3.2
140	0.0526	0.0079	0.0288	0.0115	0.0194	0.0332	2/3.4
160	0.2167	0.0217	0.1473	0.0589	0.0806	0.1361	2/3.4
170	0.2483	0.0198	0.1926	0.0771	0.0969	0.1514	2/3.1
190	0.2936	0.0176	0.2387	0.0995	0.1131	0.1805	2/3.2
200	0.3137	0.0157	0.2585	0.1034	0.1191	0.1946	2/3.3
240	0.4361	0.0087	0.3972	0.1589	0.1676	0.2685	2/3.2

Making allowance for the comparative inactivity of the sulphur at  $16^{\circ}$  and for the volatilisation of the sulphur at the higher temperatures, both of which tend to lower the ratio, it is clear that the value

of Cu as Cuprous Sulphide/Cu as Cupric Sulphate approximates to 2/3. This is satisfied by the following equation :

which is the second primary reaction of Pickering and Baskerville. If this equation be added to those given for the secondary reactions, the simple equation—the first primary of Pickering and Baskerville—is obtained.

It will now be evident why it was considered that one of the primary reactions proceeded alone at 270°. The various actions succeed one another so rapidly that there is little chance of any sulphide or sulphur escaping. Hence the quantity of sulphur dioxide evolved agrees closely with that required theoretically. Pickering's failure to determine the temperature at which his second primary reaction took place exclusively is also explained. It proceeds alone momentarily only, for as soon as a film of cuprous sulphide is formed it begins to react with the acid. The obstructive properties attributed to the compact deposit of sulphide on the surface of the metal are due not so much to the sulphide itself as to the layer of inert sulphate with which it soon becomes covered when the acid is saturated; for, if a further quantity of acid be added so as to reduce the concentration of the sulphate, and thereby allow some of that on the metal to dissolve, the action at once becomes vigorous again.

#### *Summary.*

It is shown by these experiments that :

1. There is only one primary reaction.
2. The sulphur produced exercises a considerable influence on the final results of the reaction, very much more than has been ascribed to it hitherto.
3. The white crystalline deposit is undoubtedly anhydrous cupric sulphate, and this substance is at least dimorphous.
4. At any temperature the completed reaction may be represented by the simple equation

which is the sum of the equations

these representing the actual sequence of events, and which, in suitable combination, will yield an equation expressing the stage attained by the reactants at any particular moment during an interaction.

In conclusion, the author desires to acknowledge his indebtedness to the Research Fund Committee of the Chemical Society for a grant and the loan of apparatus that enabled this research to be carried out.

### XXXVIII.—*Hydrogen Electrode Studies of the Reactions between Solutions of Salts of Weak Metallic Bases and the Acetate, Oxalate, and Tartrate of Sodium, with a Note on the Effect of Dextrose on Zirconium Chloride Solution.*

By HUBERT THOMAS STANLEY BRITTON.

It has been shown (this vol., p. 125) that in the reactions between certain metallic salts and the alkali-metal salts of very weak acids (chromic [second stage], boric, and carbonic), basic substances separate when the solutions attain the  $p_H$  at which the respective hydroxides are precipitated.

The present paper deals with the reactions of the sodium salts of moderately weak acids, weak at least in respect of one stage of ionisation, with solutions of salts of weak bases and of bases which form "soluble basic salts." Sodium tartrate was one of the salts selected, first because of the comparative weakness of the acid and secondly because it was thought that the titrations might give some insight into the nature of complex tartrate solutions. Titrations with the hydrogen electrode have also been made of zirconium chloride solutions containing dextrose and alkali, in order to study the function of the hydroxy-group in these complex solutions.

All the electrometric titrations now recorded were performed with the hydrogen and normal calomel electrodes described in J., 1924, 125, 1576; 1925, 127, 2111.

#### I. *Sodium Acetate Titrations.*

As acetic acid has a small dissociation constant,  $1.8 \times 10^{-5}$ , it was thought that the hydron concentrations produced during some reactions would be so low that the  $p_H$  would not be attained at which the hydroxides are precipitated, and it was expected, therefore, that basic acetates would be obtained from solutions of salts of the weakest bases.

*Zirconium.*—A solution of zirconium oxychloride,  $ZrOCl_2$ , slowly yields a precipitate on treatment with sodium acetate, but no pre-

cipitate is produced if there has been added to the solution the quantity of hydrochloric acid corresponding with the formula  $\text{ZrCl}_4$ .

The solubility of freshly precipitated zirconium hydroxide in acetic acid is inconsiderable; and this is in accord with hydrogen-ion requirements, for zirconia is precipitated from chloride or sulphate solution (J., 1925, 127, 2135, 2138) before the hydron concentration has been reduced to  $10^{-2}$ , which acetic acid can barely acquire even in concentrated solution. Also it is not surprising that the zirconium tetra-acetate prepared (Rosenheim and Hertzmann, *Ber.*, 1907, 40, 810) by dissolving anhydrous zirconium chloride in boiling anhydrous acetic acid hydrolyses completely and rapidly in water.

FIG. 1.

Fig. 1 shows the titration curve of 100 c.c. of  $M/100$ -zirconium chloride and  $N/10$ -sodium acetate at  $18^\circ$ . The solution remained clear throughout the titration. The extent to which the sodium acetate reacted with the zirconium chloride may be deduced from the hydrogen-ion concentrations of the solution when more than 40 c.c. (i.e., 4 mols. of  $\text{NaAc} : 1$  mol. of  $\text{ZrCl}_4$ ) of sodium acetate had been added. These are in Table I,  $E$  being the *E.M.F.* of the hydrogen electrode measured against a  $N$ -calomel electrode.

TABLE I.

C.c. of $N/10$ -NaAc.	$E$ .	$p_H$ .	$p_H$ calc.
40	0.392	3.62	3.15
60	0.536	4.38	4.34
80	0.553	4.69	4.64
100	0.560	4.80	4.81

The values given in the last column were calculated on the assumption that no acetic acid had combined with the zirconium hydroxide, the reaction supposed to have taken place being  $\text{ZrCl}_4 + 4\text{NaAc} + 4\text{H}_2\text{O} \rightarrow \text{Zr}(\text{OH})_4 + 4\text{HAc} + 4\text{NaCl}$ , and that the hydrogen-ion concentrations of the solution were due to the equilibria between these ions, the acetate ions from the sodium acetate (taken as 79% dissociated), and the acetic acid.

The agreement between the calculated and the observed values of  $p_{\text{H}}$  for additions of 60, 80, and 100 c.c. of sodium acetate seems to confirm the view that the solution, although quite clear, must have contained uncombined zirconium hydroxide. There is, however, no agreement between the values of  $p_{\text{H}}$  for the addition of 40 c.c. of sodium acetate; the higher, observed  $p_{\text{H}}$  is probably to be attributed to the presence of undecomposed sodium acetate, and not merely to the dissociation of all the acetic acid shown in the equation. It has been found from an acetic acid titration curve (see Prideaux, "Theory of Indicators," 1917, p. 226) that the observed value of  $p_{\text{H}}$  is 3.62 for an acetic acid solution which has been neutralised to the extent of 9% by sodium hydroxide. (In titrations of dilute solutions of weak acids the concentration of the solution has very little effect on the  $p_{\text{H}}$  ruling during the major part of the titration, the variations in  $p_{\text{H}}$  occurring at the beginning and the end.) In the zirconium titration, this proportion of acetic acid neutralised corresponds to 3.6 c.c. (*i.e.*, 9% of 40) of *N*/10-sodium acetate having remained unattacked, and therefore the reaction at this stage may be represented by the following scheme, 4 mols. of sodium acetate having been added to 1 mol. of zirconium chloride:  $4\text{NaAc} + \text{ZrCl}_4 + 3.64\text{H}_2\text{O} \rightarrow \text{ZrCl}_{0.36}(\text{OH})_{3.64} + 3.64\text{HAc} + 0.36\text{NaAc}$ . A highly basic zirconium chloride was therefore present in the solution. Its composition happens to be similar to that of the basic zirconium chloride,  $\text{ZrCl}_{0.5}(\text{OH})_{3.5}$ , present during the greater part of the alkali titration of zirconium chloride solution (J., 1925, 127, 2135).

The agreement of the observed with the calculated value of  $p_{\text{H}}$  obtained when an excess of sodium acetate had been added shows that the chloride which had earlier been attached to the zirconium hydroxide reacted with sodium acetate. It seems evident that the zirconium hydroxide was present in the solution in a colloidal state, although the solution was clear, probably owing to some slight solvent action of the acetic acid. Boiling brought about its slow decomposition.

The titrated solution was precipitable with alkalis, a precipitate first appearing when 1.2 equivalents of *N*/10-sodium hydroxide had been added.

*Thorium.*—Under certain conditions, sodium acetate produces a precipitate from thorium sulphate solutions, but not from those of thorium chloride. Two hydrogen electrode titrations were carried out, one of 100 c.c. of 0.01*M*-thorium chloride and the other of 100 c.c. of 0.01*M*-thorium sulphate, with *N*/10-sodium acetate. The curves are given in Fig. 1. Precipitation from the sulphate solution began when 10 c.c. of sodium acetate had been added and  $p_H$  3.4 attained (the precipitation value of  $p_H$  is 3.5 for thorium hydroxide) and appeared to be at a maximum when 25 c.c. had been added, but after the addition of 30 c.c. the precipitate, which was chiefly basic sulphate, dissolved and a clear solution was obtained. No trace of a precipitate formed in the thorium chloride solution under these conditions. The two titration curves converged at 60 c.c. and then became coincident, at least during the addition of the next 40 c.c. of sodium acetate.

The changes in hydrogen-ion concentration which occurred after 60 c.c. of sodium acetate had been added are indicated by the data : 80 c.c.,  $p_H$  4.97 ; 100 c.c.,  $p_H$  5.15, and were such as would be caused by the presence of acetic acid in amounts varying from 1.5 to 1.9 equivalents per one atom of thorium. It appears, therefore, that the thorium hydroxide present in these solutions was associated with at least 2 equivalents of acetate radical. The fact that the solutions were quite clear, although the precipitation value of  $p_H$ , 3.5, for the hydroxide had been exceeded, seems to indicate that the thorium-ion concentration had become considerably reduced by the change which had taken place in the solution, a change which might have been due to the formation of complex ions, or, perhaps more probably, to the formation of basic thorium acetate micelles which were capable of undergoing a different kind of ionisation.

The precipitate Haber obtained by boiling a thorium chloride solution with sodium acetate (*Monatsh.*, 1897, **18**, 687) is interesting, in that it contained 2 equivalents of acetate to one atom of thorium.

The precipitation of basic thorium sulphate from thorium sulphate solutions by sodium acetate seems to be accounted for by the tendency of sulphates of weak bases to form fairly stable basic sulphates in solution (compare zirconium sulphate, *J.*, 1925, **127**, 2140). The sodium acetate added to the 0.01*M*-thorium chloride solution had a continuous hydrolysing action, shown in the curve by the greater hydrogen-ion concentrations ruling during the early part of the reaction, whereas when it was added to the thorium sulphate solution hydrolysis was somewhat impeded, with the result that basic thorium sulphate was precipitated.

Acetic acid may have some solvent action on thorium hydroxide, for the hydrogen-ion concentrations of dilute solutions of the acid

are a little greater than that at which thorium hydroxide is normally precipitated ( $p_H$  3.5). This solvent action may be responsible for the holding of thorium hydroxide in solution at a  $p_H$  greater than 3.5, by causing, through the formation of comparatively inert basic thorium acetate micelles, the concentration of thorium ions to be so reduced that the solubility product of thorium hydroxide is not exceeded.

*Chromium.*—Substances containing chromium and the acetate radical have been the subject of many investigations, chiefly by Weinland and his collaborators (see Weinland, "Einführung in der Chemie der Komplex-Verbindungen," Stuttgart, 1919). Their chief interest lies in the remarkable colour changes which they exhibit on becoming more and more basic; *e.g.*, the green solution of chromium acetate itself, on addition of alkali, may remain green or become red or reddish-violet according to conditions such as time of keeping or of boiling (compare Recoura, *Compt. rend.*, 1899, **129**, 158, 208). Weinland and Büttner (*Z. anorg. Chem.*, 1912, **75**, 293) claim that these colours are due to salts of one or more complex "acetato-chromium" bases, whose constitutions are supposed to be accounted for by the co-ordination theory. The fact that these so-called bases, although essentially basic substances, contain varying amounts of acetate, *viz.*, 2.67, 2.33, 2.17, 2, or 1.5 equivalents of acetate for each atom of chromium, suggests that the colours may be due to the basic acetates themselves, and this view is supported by the experiments now to be described.

The curve in Fig. 1 represents the titration of 100 c.c. of 0.01*M*-chrome alum with *N*/10-sodium acetate. The  $p_H$ , which was 4.80 when 60 c.c. of sodium acetate had been added, became, on addition of 100 c.c., 5.02, and only just fell short of the precipitation value (5.34) for the hydroxide. The failure of the sodium acetate to produce a higher  $p_H$  after the theoretical quantity (60 c.c.) had been added was due to the "buffering" effect of the liberated acetic acid. It was pointed out in previous papers that in salts of chromium with strong acids one equivalent of the acid radical is loosely bound and reacts with alkali-metal salts of weak acids as if it were free acid, liberating an equivalent quantity of weak acid. In the present titration, this would correspond to the setting free of 20 c.c. of *N*/10-acetic acid. An idea of the amount of acetic acid actually liberated may be obtained from the fact that the  $p_H$  produced on addition of 60 c.c. of sodium acetate was the same as that produced by neutralising 60% of the acid in *N*/10- or *N*/100-acetic acid with sodium hydroxide. It seems certain, therefore, that the solution, besides containing an appreciable amount of free acetic acid, contained also basic chromium acetate aggregates capable of supplying

acetate ions to the solution. The solution remained green throughout the titration and was precipitated by alkalis, but the precipitate redissolved on addition of less alkali than would have been necessary had the precipitate been obtained from a solution of a chromium salt of a strong acid.

Chromium combined with acetic acid sometimes resists precipitation by alkalis. This property depends on the treatment to which the solution has been subjected, as may be seen from the data in Table II: under *a* is the number of c.c. of *N*/10-sodium acetate that were added to 10 c.c. of *M*/10-chrome alum, and in the last two columns are the equivs. of *N*/10-sodium hydroxide (per 1 atom of chromium) that were required to produce (*b*) a precipitate and (*c*) neutrality to phenolphthalein.

TABLE II.

<i>a.</i>	Remarks.	Colour.	<i>b.</i>	<i>c.</i>
60	Violet chrome alum solution used, and mixed at room temperature.	Green.	0.64	2.81
"	Green chrome alum solution, mixed at room temperature.	"	1.18	2.67
"	Reactants mixed, boiled, and cooled to room temperature.	Purplish-green.	No ppte.	1.89
"	Alkali added to boiling reactants.	Green.	2.21	2.21 to 2.80
"	Reaction mixture on protracted boiling became completely precipitated as basic acetate.	Solution colourless.	—	2.51
"	Violet chrome alum; mixture kept for 24 hours.	Bluish-red.	1.76	2.38
120	"	Purple.	No ppte.; solution green.	2.11
"	Mixture boiled for 20 minutes and kept for 24 hours.	Green.	No ppte.	2.22

It will be noticed that in one case prolonged boiling caused basic chromium acetate to be precipitated completely; 2.51 equivs. of acetic acid remained in the solution, and therefore the composition of the precipitate was  $\text{CrAc}_{0.49}(\text{OH})_{2.51} \cdot x\text{H}_2\text{O}$ . In three instances, solutions were obtained which were non-precipitable with sodium hydroxide; one of these, which contained a larger proportion of sodium acetate, was purple and had been rendered non-precipitable merely by keeping, the other two had been rendered so by initial boiling. The amounts of alkali required to make the three solutions alkaline to phenolphthalein, being approximately 2 equivalents to one atom of chromium, suggest that about 1 equivalent of acetate radical was linked to the chromium hydroxide in an inert manner,

probably in a colloidal complex. The reaction which took place while the chromium solution was thus changed by boiling may perhaps be represented by the following equation:  $\text{Cr}_2(\text{SO}_4)_3 + 6\text{NaAc} + 2x\text{H}_2\text{O} = 2\text{CrAc}_{3-x}(\text{OH})_x + 2x\text{HAc} + 3\text{Na}_2\text{SO}_4$ . The data in the table show that the value of  $x$  in the basic complex, after any acid this may have set free by hydrolysis had been neutralised, varied from 1.89 to 2.22.

A further electrometric titration was carried out to ascertain whether the acid liberated in the formation of the basic complex was a complex acid or merely acetic acid. A mixture of 120 c.c. of  $N/10$ -sodium acetate with 10 c.c. of  $M/10$ -chrome alum was rendered non-precipitable by boiling for 5 minutes, and the reddish-violet solution cooled to  $18^\circ$ . The *E.M.F.* of the hydrogen electrode, compared with the *N*-calomel electrode, was 0.551 volt, and therefore  $p_{\text{H}}$  was 4.64. The first section of the curve representing the titration with  $N/10$ -sodium hydroxide was similar to that of acetic acid, and the free acid became neutralised when 46.8 c.c. of alkali had been added. The solution remained violet throughout the titration, but the violet solution to which 60 c.c. of  $N/10$ -sodium hydroxide had been added appeared colloidal after 24 hours, and was precipitated on continued boiling. If the basic acetate complex did not undergo any hydrolysis during the titration, the free acid was equivalent to 46.8 c.c. of  $N/10$ -acid and the excess of sodium acetate to 60 c.c. of  $N/10$ , 13.2 c.c. of  $N/10$ -sodium acetate having been decomposed. The sodium acetate being assumed to be 79% ionised, and the free acid to be acetic ( $K = 1.8 \times 10^{-5}$ ), the hydrogen-ion concentration of the solution should have been  $10^{-4.74}$ , which is in fair agreement with the observed value. The experiment seems, therefore, to confirm the view expressed by the equation.

When the solution is rendered inert to alkalis merely by keeping, the hydrolysis is not so marked, and probably much of the acetic acid is in a state of loose combination. The change that renders the basic chromium acetate complex inert is probably similar to that which chromium hydroxide undergoes slowly on keeping, and rapidly on boiling, in contact with its mother-liquor. The hydroxide becomes considerably less reactive and requires an appreciable time for dissolution in acids. If the basic chromium acetate complexes are colloidal, they may undergo some ageing or stabilising process and their size may have some effect on the absorptive power for light which modifies the colour of the solution.

## II. Sodium Oxalate Titrations.

Oxalic acid is a strong acid in regard to its first stage of ionisation, but fairly weak in respect to its second stage,  $K_2$  being  $1.3 \times 10^{-4}$

(J., 1925, 127, 1905). The titrations described in this section were therefore carried out to see if the latter had any influence on the reactions between sodium oxalate and salts of weak bases. It is significant that the hydroxides which are generally supposed to enter into complex formation with oxalates are weak bases, all of which are precipitated by alkalis from solutions whose hydron concentrations are greater than  $10^{-7}$  (compare Schäfer and Abegg, *Z. anorg. Chem.*, 1906, 14, 293).

*Zirconium.*—As zirconium hydroxide is ordinarily precipitated from solutions whose hydrogen-ion concentrations are greater than

FIG. 2.

$10^{-2}$ , it was considered that the hydrogen-ions arising from the second dissociation of oxalic acid would be too few to affect the dissolution of the hydroxide.

The reaction between 100 c.c. of  $M/100$ -zirconium chloride and  $N/10$ -sodium oxalate was studied by means of the hydrogen electrode. The variation in hydrogen-ion concentration is given in Fig. 2. A gelatinous precipitate appeared when 10 c.c. of sodium oxalate had been added, and precipitation was at a maximum with 40 c.c., after which the precipitate began to dissolve; the solution became quite clear again on addition of 50 c.c. The precipitate obtained when 20 c.c. of sodium oxalate had been added had the composition  $\text{Zr}(\text{OH})_{2.69}(\text{C}_2\text{O}_4)_{0.69} \cdot x\text{H}_2\text{O}$ . The precipitates obtained by Venable

and Baskerville (*J. Amer. Chem. Soc.*, 1897, **19**, 11) on treating zirconium chloride solutions with a saturated solution of oxalic acid had the compositions  $\text{Zr}(\text{OH})_{2.67}(\text{C}_2\text{O}_4)_{0.67}$  and  $\text{Zr}(\text{OH})_{2.4}(\text{C}_2\text{O}_4)_{0.8}$ .

The complex formed on re-solution of the basic zirconium oxalate was not readily precipitated with alkalis: *e.g.*, the acid liberated by the interaction of 100 c.c. of *M*/100-zirconium tetrachloride and 100 c.c. of *N*/10-sodium oxalate was neutralised (phenolphthalein) by 35.3 c.c. of *N*/10-sodium hydroxide without a precipitate forming, and indeed only a slight opalescence was produced when sufficient alkali had been added to convert all the zirconium salt into the hydroxide and the solution boiled (40 c.c.).

The titration curve shows that a large concentration of hydrogen ions persisted throughout the whole reaction,  $p_{\text{H}}$  being 2.32 at 60 c.c., 3.10 at 80 c.c., and 3.64 at 100 c.c. There occurred a small inflexion just after 50 c.c. of sodium oxalate had been added, which indicated the stage at which oxalate ions had been added in an amount just sufficient to combine with the hydrogen ions from the first stage of dissociation to form  $\text{HC}_2\text{O}_4'$  ions (compare oxalic acid titration curve, *loc. cit.*). Thereafter the hydrogen-ion concentration arose from the ionic equilibrium  $\text{HC}_2\text{O}_4' \rightleftharpoons \text{H}^+ + \text{C}_2\text{O}_4''$ .

The zirconium hydroxide is present in the oxalate solution probably in the colloidal state, having been rendered so by combination with or adsorption of oxalate ions through the interplay of slight chemical forces. As the first stage of the ionisation of oxalic acid is that of a strong acid, there is reason to believe that this acid would, like hydrochloric or nitric acid, be capable of maintaining zirconium hydroxide in solution. Two molecules of oxalic acid, which on valency grounds should react with zirconium hydroxide to form the unknown zirconium oxalate,  $\text{Zr}(\text{C}_2\text{O}_4)_2$ , are only capable of reacting as if they were two molecules of a monobasic acid, thus:

The basic zirconium hydro-oxalate, by analogy with the chloride (*q.v.*), would be strongly hydrolysed in solution, giving highly basic hydro-oxalate aggregates which would tend to remain in colloidal solution by virtue of the tendency which they may have to react with the hydrogen ions from the  $\text{HC}_2\text{O}_4'$  ions. The fact that sodium hydroxide does not readily precipitate zirconium hydroxide from oxalate solutions seems to show that zirconium ions are absent, or nearly so, from the solutions.

Sodium oxalate when added to a zirconium sulphate solution did not give a precipitate. An attempt was made to follow the changes in hydron concentration during the addition of sodium oxalate by means of the hydrogen electrode, but the entry of a little potassium chloride, used in the junction liquid, into the zirconium sulphate

solution immediately rendered it precipitable. *M*/100-Zirconium sulphate (100 c.c.) was titrated and precipitation due to the potassium chloride began, but the precipitate did not redissolve until 85 c.c. of the oxalate solution had been added.

The clear solution obtained by adding sodium oxalate in not too great an excess to a zirconium sulphate solution gave a precipitate on addition of a little electrolyte, *e.g.*, the chloride or nitrate of sodium or potassium.

*Chromium.*—The curve in Fig. 2 is that of the titration of 100 c.c. of *M*/100-chrome alum with *M*/10-sodium oxalate. The solution was green initially, but became red towards the end of the titration. The diagram shows a very slight inflexion just after 30 c.c. of sodium oxalate had been added, *i.e.*, 3 mols.  $\text{Na}_2\text{C}_2\text{O}_4$  to 1 mol.  $\text{Cr}_2(\text{SO}_4)_3$ , but the curve does not thereafter assume the upward course which it would take had simple double decomposition taken place. The very gradual diminution in hydron concentration caused by the addition of sodium oxalate was due to the "buffering" action of the hydro-oxalate ions which had failed to react. The hydrogen-ion concentration at the end of the titration was  $10^{-4.4}$ , which was greater than the precipitation value,  $10^{-5.3}$ , for the hydroxide, but gradually approached it when larger quantities of sodium oxalate were employed. The solution to which 60 c.c. of *M*/10-sodium oxalate had been added was afterwards titrated with *N*/10-sodium hydroxide by means of the hydrogen electrode. Precipitation began when 1.85 equivalents had been added ( $p_{\text{H}}$  5.4); thereafter the alkali caused only a partial precipitation and the graph of the change in  $p_{\text{H}}$  plotted against the amount of alkali added was rectilinear instead of curved, as is usually the case for precipitation by alkali. The slow change in hydron concentration appears to have been caused by slight decomposition of the basic complex.

Some experiments were made to ascertain the conditions which rendered the solutions non-precipitable by alkalis. A mixture of *M*/10-chrome alum (1 mol.) and *M*/10-sodium oxalate (3 or 6 mols.) at room temperature gave a precipitate on treatment with *N*/10-sodium hydroxide; but if it had been first boiled and then cooled, no precipitate was obtained. Non-precipitable solutions were also produced by keeping. For example, two solutions, each 250 c.c., containing 30 and 60 c.c., respectively, of *M*/10-sodium oxalate and 10 c.c. of *M*/10-chrome alum, were kept over-night; the one containing the larger quantity of oxalate failed to give a precipitate with alkali.

An interesting gradation in colour was observed in a series of solutions, of the same concentration with respect to chrome alum but containing different quantities of sodium oxalate, the smallest

being 3 mols. (to 1 mol. of the sulphate), which had been boiled for the same length of time (a few minutes) and then kept over-night. They were all red in transmitted light, but had a green tinge in reflected light; the redness increased in intensity with increasing molar proportion of sodium oxalate. This may have been due to the effect of the diminishing hydrogen-ion concentration on the basic chromium oxalate complexes, produced by the increasing amounts of sodium oxalate. The solutions gave no precipitate in the cold on treatment with alkali, but a precipitate slowly formed on boiling. If the alkali was added in amounts just sufficient to convert the chromium salt into chromium hydroxide, precipitation took place after about a day. These alkaline solutions were also coagulated by the addition of 2 or 3 c.c. of saturated potassium chloride solution. Solutions which had been rendered non-precipitable by keeping only were very slightly more hydrolysed than the others.

An oxalic acid solution of chromium hydroxide was prepared by boiling a chromic acid solution with oxalic acid until reduction was complete. The solution so obtained was claret-red and was not immediately precipitable by alkalis; on evaporation, it gave a green mass and oxalic acid crystals. From such a solution another was prepared which contained oxalic acid and chromium hydroxide in the proportions required by Werner's hypothetical tribasic chromi-oxalic acid,  $H_3[Cr(C_2O_4)_3]$  (*Ber.*, 1912, 45, 3061). The molar ratio may therefore be represented as  $3H_2C_2O_4 : Cr_2(C_2O_4)_3$ . The quantity of free and combined oxalic acid in 100 c.c. of the solution was equivalent to 51 c.c. of *N*/10-alkali, and on the latter method of representing the formula one-half of this, 25.5 c.c., may be regarded as combined with the chromium. This solution was titrated with 0.1082*N*-sodium hydroxide at 18° by means of the hydrogen electrode. The titration curve is given in Fig. 3. (The lower curve represents the titration, with the same alkali, of 51 c.c. of *N*/10-oxalic acid diluted to 100 c.c.) In reply to the objection that such a solution cannot possibly supply any information concerning Werner's hypothetical acid, it may be mentioned that the acid solution has the peculiar properties of Gregory's double salt,

which Werner regarded as a salt,  $K_3[Cr(C_2O_4)_3]$ , of his complex hypothetical acid and named potassium trioxalochromiate. The titration curve gives no evidence of the existence of a tribasic acid, but is composed of two distinct sections. Although no precipitate formed, it is significant that the claret-red solution began to turn green just when the hydron concentration had become that at which chromium hydroxide is normally precipitated. This suggests that the colour is in some way related to the hydroxide itself.

The fact that the first half of the reaction terminated with an inflexion in the curve and a change in colour seems to be connected with the great difference between the two stages of ionisation of oxalic acid. The simplest explanation is to regard the chromium in the original solution as combined almost entirely with  $\text{HC}_2\text{O}_4$  radicals, thus:  $\text{Cr}(\text{OH})_2 + 3\text{H}\cdot\text{HC}_2\text{O}_4 \rightarrow \text{Cr}(\text{HC}_2\text{O}_4)_3 + 3\text{H}_2\text{O}$ . The relatively large hydrion concentration could then be accounted for by slight hydrolysis having taken place owing to some little reaction with the hydrions from the hydro-oxalate ions. The first half of the titration would therefore be mainly that of the hydrogen ions from the large amount of  $\text{HC}_2\text{O}_4$  ions with the added hydroxyl ions, and

FIG. 3.

therefore the range of hydrion concentration covered would be approximately that covered in the second half of the oxalic acid titration. The high initial concentrations in the chromium titration being excluded, it will be seen that the two ranges are comparable. When exactly half the theoretical amount of sodium hydroxide had been added, the reaction  $3\text{NaOH} + \text{Cr}(\text{HC}_2\text{O}_4)_3 \rightleftharpoons 3\text{H}_2\text{O} + \text{Cr}(\text{NaC}_2\text{O}_4)_3$  may be considered to have taken place, and the second half of the sodium hydroxide would therefore have to react with the double sodium chromium oxalate to form a basic oxalate, probably associated with some sodium. The second portion of the chromium curve shows that only a part of the theoretical amount of the alkali had reacted, for the solution became alkaline on addition of considerably less sodium hydroxide than in the case of the oxalic acid

titration. Therefore, if  $x$  be the fraction of sodium hydroxide which had reacted, the reaction may be represented by the equation:  $\text{Cr}(\text{NaC}_2\text{O}_4)_3 + 3x\text{NaOH} \rightleftharpoons \text{Cr}(\text{OH})_{3x}(\text{NaC}_2\text{O}_4)_{3-3x} + 3x\text{Na}_2\text{C}_2\text{O}_4$ .

The basic chromium oxalate complex is probably capable of ionising, but not so much so that it would produce in the solution the concentration of chromium ions requisite for precipitation. From the titrated solution to which 60 c.c. of 0.1082*N*-sodium hydroxide had been added, *i.e.*, 12.9 c.c. in excess of that required for the complete decomposition of the chromium oxalate, the chromium was completely precipitated after 24 hours, and, like the previous solutions, those which had been rendered just alkaline were also immediately coagulable on addition of a few c.c. of saturated potassium chloride solution and shaking. These observations seem to point to the colloidal nature of the basic oxalate complexes.

The absorption spectra of solutions representing different stages of the titration were examined. The solutions corresponding to the first half of the reaction absorbed light in the red, yellowish-green, and extreme blue regions. The absorption in the blue region was fairly uniform throughout the titration, whereas the absorption band in the green became considerably reduced in the second half. The chief change in absorption appeared suddenly in the red region almost immediately after the middle point of the titration had been passed; for the solution corresponding to the end of the titration, the band extended over the whole red field and partly into the orange. These absorptions were probably due to the size of the semi-colloidal particles. Lapraik's researches on the absorption spectra of chromium solutions (*J. pr. Chem.*, 1892, 47, 305) included that of a colloidal solution of chromium hydroxide prepared by dialysing chromium chloride for some months, and also of chromium hydroxide suspended in water. He stated that the close resemblance between the absorption spectra of solutions of chromium hydroxide in several organic acids, including oxalic and some hydroxy-acids, despite the great difference in the molecular complexity of the acids used as solvents, suggested the probability of the absorption spectra being due mainly to the chromium hydroxide or oxide, and not to its compounds with the solvents. This constitutes strong support for the view that solutions of chromium salts of weak acids are essentially colloidal.

E. A. Werner (*J.*, 1904, 85, 1438) made the interesting observation that chromium hydroxide dissolves in hot oxalic acid solution to the extent required by the formula  $\text{Cr}_2(\text{C}_2\text{O}_4)_3$ . This, however, is no evidence for the existence of chromium oxalate in the solution, for solutions of the chromium salts of strong acids may be rendered basic beyond the point corresponding with the formula  $\text{Cr}(\text{OH})\text{R}_2$ ,

before any precipitation takes place. Hence in Werner's solution probably little more than the ions from the first stage of the dissociation of the oxalic acid combined with the chromium hydroxide, and this was present largely as a basic chromium hydro-oxalate; a small proportion of the second-stage hydrogen ions may have entered into reaction. Such an explanation would account for the anomalous conductivity data obtained by Rosenheim (*Z. anorg. Chem.*, 1896, **11**, 225) for a solution containing chromium oxide and oxalic acid in the proportion 1 : 3; he could obtain from the data no conclusive evidence that the substance in solution was either a free complex acid or a chromium salt of a complex chromioxalic acid.

The formula of the hypothetical tribasic chromioxalic acid is based on Rosenheim's measurements (*Z. anorg. Chem.*, 1896, **11**, 196, 225; 1899, **21**, 8) of the conductivity of solutions of double oxalates having the formula  $3R_2C_2O_4 \cdot Cr_2(C_2O_4)_3 \cdot xH_2O$ , where R is K, Na, or  $NH_4$ . Regarding these as complex salts,  $R_3[Cr(C_2O_4)_3]$ , he found that the difference between  $\Lambda_{1024}$  and  $\Lambda_{32}$  (where  $\Lambda$  is the conductivity of  $1/3R_3[Cr(C_2O_4)_3]$ )

varied from 32.4 to 35.8 for the three salts, and thence deduced the tribasicity of the complex acid,  $H_3[Cr(C_2O_4)_3]$ . It may be pointed out that there is no accord between Rosenheim's data for the potassium salt solutions and the earlier values of Kistiakovsky (*Z. physikal. Chem.*, 1890, **6**, 98). Rosenheim's figures also show that the ammonium salt is much more ionised than the potassium salt. The conductivities of the sodium and ammonium salts measured by Burrows and Walker (J., 1923, **123**, 2738) are somewhat lower than those of Rosenheim, but the differences  $\Lambda_{1024} - \Lambda_{32}$  are 29.3 and 32.9, respectively. By means of their cryoscopic and conductivity measurements these authors were able to show that in those solutions which were more dilute than 1/16-molar the number of ions into which each molecule of the salt dissociated was greater than 4. They concluded that it is only in comparatively concentrated solutions, greater than  $M/10$ , that the salt  $R_3[Cr_2(C_2O_4)_3]$  dissociates into  $3R^+$  and  $[Cr(C_2O_4)_3]^{3-}$ , and that at higher dilutions either the salt hydrolyses, giving ROH and  $H_3[Cr(C_2O_4)_3]$ , or the complex anion dissociates still further. The evidence for the existence of the complex tribasic chromioxalic acid is therefore inconclusive.

Some experiments have been carried out on Gregory's salt,  $3K_2C_2O_4 \cdot Cr_2(C_2O_4)_3 \cdot 6H_2O$  (*vide* Graham, "Chemical and Physical Researches," Edinburgh, 1876, p. 369). It was obtained in deep blue needles by allowing to crystallise a solution, containing chromic anhydride, potassium oxalate, and an excess of oxalic acid, which had been boiled until the anhydride was completely reduced

[Found : Cr, 10.7 ;  $C_2O_4$ , estimated by Burrows and Walker's method (*loc. cit.*), 54.1. Calc. : Cr, 10.7 ;  $C_2O_4$ , 54.2%].

On addition of  $N/10$ -sodium hydroxide to an  $M/120$ -solution of the salt there was no immediate reaction, as shown by hydrogen electrode measurements, but the red solution on becoming alkaline turned green, and when sufficient alkali had been added to convert the chromium oxalate into chromium hydroxide and the solution kept for 12 hours, it became opalescent and addition of a little potassium chloride caused precipitation. Addition of potassium chloride to a solution rendered just alkaline produced opalescence within a few minutes and the chromium was completely precipitated as the hydroxide in the course of 2 hours.

Werner made use of Gregory's salt in the development of his theory of "mirror-image isomerism." He suggested that the substance, regarded as the salt of a complex acid, should show a type of molecular asymmetry and be resolvable into optically active isomerides. The six molecules of water were regarded as water of crystallisation, and not of constitution as in the case of the hexahydrated chromium chloride. He achieved a fugitive resolution, by means of strychnine, in which water must have played an important part, for the optical activity disappeared much more quickly in aqueous than in acetone solutions. Jaeger (*Rec. trav. chim.*, 1919, **38**, 245) obtained much larger rotations. Rideal and Thomas (*J.*, 1922, **121**, 196) found that the resolved salt on dissolution left a small, insoluble residue. This is surprising in view of the great ease with which the double oxalate dissolves. Their suggestion that the speedy loss in optical activity is due to decomposition of the complex anion into a less complex one seems to be confirmed by the *E.M.F.* measurements of Thomas and Fraser (*J.*, 1923, **123**, 2973).

As water appeared to be the important factor in those optical rotation experiments, measurements have been made with the hydrogen electrode to ascertain if any parallel hydrolytic change occurs. The *P.D.* between a hydrogen electrode immersed in 100 c.c. of water at 18° and the normal calomel electrode, with saturated potassium chloride solution as junction liquid, was measured ; 0.8123 g. of Gregory's salt was then rapidly dissolved in the water, and the *E.M.F.* observed every few minutes over a period of several hours. The results, which are in Table III, showed that

TABLE III.

Mins. ....	0	5	15	29	41	52
$p_H$ .....	6.67	7.03	7.05	6.22	5.69	5.64
	(water)					
Mins. ....	70	93	105	138	180	20 hrs.
$p_H$ .....	5.56	5.49	5.39	5.36	5.32	5.33

immediately following dissolution the hydron concentration gradually increased until the  $p_H$  had become 5.49 (93 minutes); thereafter the change was much slower and the  $p_H$  became constant (5.33) after 12 hours and remained so during the next 20 hours. This  $p_H$  happens to be that at which chromium hydroxide is ordinarily precipitated. If the chromium oxalate in the salt were in a condition similar to that of the chromium salts of strong acids, a considerably higher hydrogen-ion concentration would have been produced. On referring to Fig. 3, it will be seen that the  $p_H$  (6.0) attained when the quantity of sodium hydroxide added was that required to form  $3Na_2C_2O_4 \cdot Cr_2(C_2O_4)_3$  (indicated by the vertical line through the mid-point) was a little higher than the precipitation  $p_H$  of chromium hydroxide, probably owing to some decomposition of the oxalate complex having taken place. It therefore seems likely that the existence of the double salt may be due to the two different degrees of reactivity of oxalic acid, and that the change in hydron concentration that occurs on its passing into solution may be due to the formation of basic complexes as suggested by the solution reaching the precipitation  $p_H$  of the hydroxide.

The concentration of oxalate ions in these complex salt solutions is small, for calcium chloride fails to give an immediate precipitate. Instead of being due to a complex anion, this may be equally well accounted for by the view now put forward, that the greater part of the oxalate ions is, in effect, removed from the solution in the form of colloidal complexes.

The fact that double oxalates of the general formula

exist, where M may be trivalent iron, chromium, or aluminium, seems to be attributable to the nature of oxalic acid. The bases of these elements are so weak that it is exceedingly doubtful whether they are capable of entering into reaction to form normal oxalates, and yet in conjunction with the alkali metals they form well-defined compounds. There seems to be little doubt that the weak bases enter into combination with the  $HC_2O_4$ -ions, leaving the  $C_2O_4$  ions to the alkali metals.

*Aluminium.*—The curve in Fig. 2 represents the hydrogen electrode titration of 100 c.c. of 0.005*M*-aluminium sulphate with 0.05*M*-sodium oxalate. No precipitate appeared, although the precipitation  $p_H$  of aluminium hydroxide was soon exceeded. The curve was only slightly inclined during the addition of the first 30 c.c. of sodium oxalate [i.e., 3 mols.  $Na_2C_2O_4$  to 1 mol.  $Al_2(SO_4)_3$ ] and the corresponding  $p_H$ 's differed but slightly from the precipitation  $p_H$  (4.14) of aluminium hydroxide, which was attained when 10 c.c. of sodium oxalate had been added. This suggests that aluminium

hydroxide, although it was not precipitated, existed in the solution in a more or less nascent state. Also the fact that the sodium oxalate in excess of 30 c.c. produced a gradual change in hydron concentration, instead of an almost instantaneous fall to a concentration of the order produced by free sodium oxalate, shows that equilibria were being set up between the hydro-oxalate ions, which had failed to react with the aluminium hydroxide, and the oxalate ions from the added sodium oxalate. After the addition of 100 c.c. of *N*/10-sodium oxalate, the solution was titrated with *N*/10-sodium hydroxide; it became alkaline to phenolphthalein when 2.13 equivalents of sodium hydroxide (to one atom of aluminium) had been added, but no precipitate formed. Three equivalents of alkali, which were sufficient to convert all the aluminium salt into hydroxide, were then added; a precipitate appeared only after some time.

### III. Sodium Tartrate Titrations.

Tartaric acid is comparatively weak in its first stage of ionisation,  $K_1 = 1.27 \times 10^{-3}$ , and much weaker in its second stage,  $K_2 = 9.65 \times 10^{-5}$  at 18° (J., 1925, 127, 1905). Of the metallic bases studied in these investigations, the only two that give basic tartrates on treatment with sodium tartrate are the very weak bases thorium and zirconia; these also dissolve in excess of the precipitant to give complex solutions which are not precipitable by alkalis. The reactions between zirconium, thorium, aluminium, beryllium, chromium, zinc, and lanthanum salts and *N*/10-sodium tartrate have been followed with the hydrogen and the normal calomel electrode. The titration curves of 100 c.c. of each of the solutions at 18° are in Fig. 4.

*Zirconium*.—The curve (Fig. 4) shows the changes in hydron concentration that occurred during the addition of *N*/10-sodium tartrate to 100 c.c. of *M*/100-zirconium chloride. A gelatinous basic tartrate began to be precipitated when 10 c.c. of sodium tartrate had been added ( $p_H$  1.66), but it began to redissolve on addition of 30 c.c. With 40 c.c., the solution was translucent, but became clear with 42.5 c.c.

The precipitate corresponding with the addition of 20 c.c. of *N*/10-sodium tartrate was produced by mixing large volumes of the reactants, the supernatant liquor being poured off, and the precipitate washed by decantation. It passed entirely into a translucent colloidal solution. The precipitate had therefore to be freed from the adhering liquor as completely as possible by pressing between filter-paper; some sodium tartrate, however, remained [Found in the air-dried precipitate:  $ZrO_2$ , 39.7; C (by "wet" combustion with chromic acid), 7.1%]. If the water content is neglected,

the composition of the precipitate may be expressed by the formula  $\text{ZrT}_{0.45}(\text{OH})_{3.1}$ .\*

In order to get some idea of the amount of titratable acid in these zirconium tartrate solutions, various quantities of  $N/10$ -sodium tartrate were added to 100 c.c. of  $M/100$ -zirconium chloride, and the resulting solutions titrated with  $N/10$ -sodium hydroxide. The results are in Table IV:  $a$  = c.c. of tartrate added, and  $b$  and  $c$

FIG. 4.

= c.c. of  $N/10$ -alkali required to produce neutrality to phenolphthalein at  $18^\circ$  and  $100^\circ$ , respectively.

TABLE IV.

$a$ .....	10	20	30	40	60	80
$b$ .....	33.2	33.1	33.0	33.1	33.2	33.2
$c$ .....	34.9	34.6	35.0	34.3	34.1	34.2

The alkali produced a precipitate, which did not redissolve, from the solution to which 10 c.c. of sodium tartrate had been added, but the precipitates that formed initially in the 20 c.c.- and 30 c.c.- solutions redissolved when 25 c.c. and 14 c.c., respectively, of the alkali had been added. If no hydrolysis of the complex tartrate occurred, the table shows that, no matter how much sodium tartrate

\* Throughout this paper T denotes  $\text{C}_4\text{H}_4\text{O}_6$ .

had been added, the quantity of free acid in the solution at 18° was equivalent to about 33.1 c.c. of *N*/10-sodium hydroxide, or 3.31 eqivs. to 1 atom of zirconium. Under these conditions, the simplest formula for the basic complex in these solutions is  $\text{ZrT}_{0.35}(\text{OH})_{3.3}$ , which is in fair agreement with that obtained for the imperfectly washed, basic precipitate, viz.,  $\text{ZrT}_{0.45}(\text{OH})_{3.1}$ .

To confirm the existence of this complex in solution, and to show that the free acid was tartaric, the following titration was made. The change in hydron concentration which occurred after 40 c.c. of *N*/10-sodium tartrate had been added was what would be expected to occur on addition of sodium tartrate to a solution containing free tartaric acid only. A solution (140 c.c.) was therefore prepared containing 33.1 c.c. of *N*/10-tartaric acid, which appears to be the amount of acid liberated on addition of the first 40 c.c. of sodium tartrate in the zirconium titration. The *E.M.F.* of the solution, measured with the hydrogen electrode against the normal calomel electrode, was 0.422 volt (the *E.M.F.* for the corresponding stage of the zirconium titration was 0.421 volt). Increasing quantities of *N*/10-sodium tartrate were now added; the voltages obtained are shown in the diagram by the broken line just above the zirconium curve. During the addition of the first 20 c.c. of *N*/10-sodium tartrate, i.e., corresponding to 60 c.c. in the zirconium titration, the broken curve lay at a distance representing 3 millivolts at most from the zirconium curve, but during the addition of the next 40 c.c. (i.e., corresponding with 60 to 100 c.c. in the zirconium titration) the two curves became coincident.

Tartaric acid also precipitates a basic tartrate from zirconium chloride solutions, but a considerably larger excess is required to effect its re-solution than in the case of sodium tartrate. For example, the precipitate formed when *N*/10-sodium tartrate was added to 100 c.c. of *M*/100-zirconium chloride solution required just over 40 c.c. for both precipitation and dissolution, whereas, when *N*/10-tartaric acid was used, re-solution did not occur until about 150 c.c. had been added. The precipitate so formed dissolved readily in alkali, and the composition of the soluble complex thereby produced appeared to be the same as that in the sodium tartrate solutions. It may be that re-solution was actually due to the sodium tartrate which was formed, as may be seen from the following experiment. The heavy, gelatinous precipitate produced by adding *N*/10-sodium hydroxide to a mixture of 100 c.c. of *M*/100-zirconium chloride and 40 c.c. of *N*/10-tartaric acid dissolved when about 45 c.c. had been added, and the solution became alkaline to phenolphthalein with 73.2 c.c., which shows that the composition of the complex must have been  $\text{ZrT}_{0.34}(\text{OH})_{3.32}$ .

The last column of Table IV shows that the complexes underwent very little decomposition in boiling alkaline solution.

The solubility of the basic zirconium tartrate precipitates in sodium hydrogen tartrate is less than that in the neutral tartrate, but greater than that in the free acid. The limiting amount of sodium tartrate to be added to a zirconium chloride solution to render it non-precipitable by alkali appears to be about 1 molecular proportion. With this proportion, a precipitate is obtained, but it dissolves on the addition of alkali; at a stage, however, before the solution becomes alkaline.

*Thorium.*—The curve (Fig. 4) represents the titration of 100 c.c. of  $M/100$ -thorium chloride with  $N/10$ -sodium tartrate. It is remarkable in that it shows that the addition of a normal tartrate rendered the solution more acid and then produced a precipitate. The  $p_H$  of the original solution was 2.68, but had fallen to 2.15 on addition of 25 c.c. of sodium tartrate, when precipitation began. By analogy with the formation of other basic precipitates—chromates, borates, and carbonates (Britton, this vol., p. 125)—it would have been expected that the precipitation of a basic tartrate would not have taken place until the precipitation  $p_H$  of the hydroxide had been attained, *viz.*, 3.5. A basic tartrate of thorium may also be precipitated by free tartaric acid; precipitation began at  $p_H$  1.75 when 27.5 c.c. of 0.112*N*-tartaric acid were added to 100 c.c. of  $M/100$ -thorium tartrate, the large hydrion concentration being no doubt due to hydrochloric acid produced by hydrolysis.

The precipitates were flocculent and were not of definite composition. Haber's analyses (*Monatsh.*, 1897, **18**, 687) of precipitates obtained with tartaric acid, the water contents being disregarded, lay between those required for  $\text{ThT}(\text{OH})_2$  and  $\text{ThT}_{1.33}(\text{OH})_{1.33}$ . The basic tartrate produced above from sodium tartrate and thorium chloride contained still less tartrate. The precipitate obtained on addition of 30 c.c. of sodium tartrate was, when air-dried, amorphous and contained 45.51%  $\text{ThO}_2$  and 5.69% C (found by "wet" combustion), corresponding to the formula  $\text{ThO}_2 \cdot 0.69\text{T} \cdot 11.91\text{H}_2\text{O}$ , or, the water content being disregarded,  $\text{ThT}_{0.69}(\text{OH})_{2.62}$ .

Like basic zirconium tartrate, basic thorium tartrate redissolved when a little more than 40 c.c. of  $N/10$ -sodium tartrate had been added, *i.e.*, when the proportion was  $2\text{Na}_2\text{T} : \text{ThCl}_4$ . The acid liberated in the solution was equivalent to 26.2 c.c. of  $N/10$ -sodium hydroxide. Therefore, of the acid initially present as thorium chloride (= 40 c.c., expressed in terms of  $N/10$ -acid), 26.2 c.c. had been replaced by hydroxide and 13.8 c.c. by tartrate, and consequently the simplest formula of the basic thorium complex in the solution is

which happens to be also that of the precipitated basic tartrate. If it be assumed that 26.2 c.c. of  $N/10$ -tartaric acid were liberated during the interaction of 40 c.c. of  $N/10$ -sodium tartrate and 100 c.c. of  $M/100$ -thorium chloride, the concentration of the tartaric acid in the 140 c.c. of solution was  $9.33 \times 10^{-3}$ , and  $K_1$  of tartaric acid being taken as  $1 \times 10^{-3}$  (the effect of  $K_2$  is negligible—see J., 1925, 127, 1899), the  $p_H$  was 2.51. A solution (140 c.c.) of tartaric acid of this concentration was found, by means of the hydrogen electrode, to have exactly this  $p_H$ . The solution was titrated electrometrically with  $N/10$ -sodium tartrate; the titration curve, beginning at 40 c.c., is represented by the broken line lying a little below the thorium curve (Fig. 4). The differences in hydrogen-ion concentration shown in the two curves may be due to some interaction between the basic tartrate and the tartaric acid while the former is dissolving.

These solutions did not yield precipitates when treated with alkalis. Non-precipitable solutions could also be prepared by using less sodium tartrate. From the solutions employed in the titrations alkalis produced complete precipitation if 1 mol. or less of either tartaric acid or sodium tartrate had been added for each mol. of thorium chloride. Although  $1\frac{1}{2}$  mols. of sodium tartrate produced a precipitate, this dissolved on addition of alkali and the solution became non-precipitable. Basic thorium tartrate, as was the case with the zirconium precipitate, required a considerable excess of tartaric acid to redissolve it, and the basic complex in the acid solution appeared to be the same as that in the sodium tartrate solution.

Rosenheim, Sammtner, and Davidsohn (*Z. anorg. Chem.*, 1903, 35, 424), in their investigation on complex thorium tartrates, isolated what they regarded as two series of salts containing the thorium in the anion, viz.,  $R_2[ThOT_2]$  and  $R_2[ThO_2T]$ , where  $R = K, Na, \text{ or } NH_4$ . Some of the products are described as "crusts." They attempted to ascertain which of these two salts existed in solution by determining the proportions of thorium nitrate, tartaric acid, and alkali which produced the maximum optical activity. These were stated to be  $Th(NO_3)_4 : 2H_2T : 6ROH$ , and therefore the authors concluded that the salt  $R_2[ThOT_2]$  was indicated. On recalculation, however, these proportions are found to be in error, approximately 1 mol. of tartaric acid having been required instead of the 2 mols. stated, and the amount of alkali ranging from 5 to 7 mols. These are roughly the proportions required in the formation of 1 mol. of thorium hydroxide and 1 mol. of alkali-metal tartrate (compare the series  $R_2[ThO_2T]$ , i.e.,  $R_2T$  and  $ThO_2$ ). The data of those authors show that such a solution was on the point of precipitation, for when the amount of thorium nitrate was increased in the ratio 8 : 7,

a precipitate appeared. As stated above, solutions of thorium chloride and sodium tartrate in equimolecular proportions fail to give a complex solution.

The amounts of  $N/10$ -sodium hydroxide required to neutralise the acid in these complex thorium tartrate solutions, when boiling, were a little greater than those required when the solutions were cold. Whatever the amount of  $N/10$ -sodium tartrate that had been added to 100 c.c. of  $M/100$ -thorium chloride, approximately 35 c.c. of  $N/10$ -sodium hydroxide were required to neutralise the boiling solution, which shows that the basic tartrate complex had slightly hydrolysed to  $\text{ThT}_{0.25}(\text{OH})_{3.5}$ .

The fact that basic thorium tartrate cannot be redissolved by alkali except in the presence of sodium tartrate suggests that sodium tartrate or partly neutralised tartaric acid is responsible for its dissolution. It can scarcely be attributed to the formation of salts of a complex acid, and yet it seems to be due to some reaction taking place between the basic complex and the tartrate ions when present in sufficiently high concentration. A tartaric acid solution, on being gradually neutralised with alkali, therefore acquires a correspondingly increasing solvent capacity for both basic zirconium and basic thorium tartrates.

*Aluminium.*—The curve (Fig. 4) represents the titration of 100 c.c. of  $M/200$ -aluminium sulphate with  $N/10$ -sodium tartrate by means of the hydrogen electrode. Again, an unexpected increase in hydron concentration was shown during the addition of the first 30 c.c. of tartrate solution ( $= 3$  mols.). No precipitate separated and the solution remained clear. Hence, as the sodium tartrate was added, and sodium sulphate thereby formed, a considerable quantity of tartrate ions, instead of combining with the aluminium, was set free to form hydrotartrate ions, some free acid, and a basic aluminium tartrate complex in the solution. The maximum hydron concentration,  $10^{-3.02}$ , was attained when 15 c.c. of sodium tartrate solution had been added. This concentration was probably due mainly to hydrogen ions from the first-stage dissociation of the tartaric acid, the hydrotartrate ions having reacted with the aluminium hydroxide.

Titration were made of the acid liberated in the solutions obtained by adding various quantities of  $N/10$ -sodium tartrate to 100 c.c. of  $M/200$ -aluminium sulphate. Ten c.c. of sodium tartrate were insufficient to produce a solution non-precipitable by alkali, but when 20 c.c. [i.e., 2 mols.  $\text{Na}_2\text{T}$  for 1 mol.  $\text{Al}_2(\text{SO}_4)_3$ ] or more were used, the solutions became non-precipitable and the amounts of alkali required to produce neutrality to phenolphthalein varied from 2.4 to 2.7 equivalents (for 1Al). In the boiling solutions, 2.8 equivalents

produced neutrality in each case. Therefore both in cold and in hot solutions a little tartrate remained firmly bound to the aluminium hydroxide. These experiments again seem to show that the non-precipitability is due to the existence of stable basic tartrates, the compositions of which, in the solutions studied, varied from  $\text{AlT}_{0.3}(\text{OH})_{2.4}$  to  $\text{AlT}_{0.1}(\text{OH})_{2.8}$ .

*Beryllium*.—A small diminution in the hydrogen-ion concentration occurred in the titration of 100 c.c. of  $M/40$ -beryllium sulphate with  $N/10$ -sodium tartrate. This was not due to the formation of a less hydrolysed beryllium tartrate, for, as is shown by the curve (Fig. 4), no distinct change in hydrogen-ion concentration occurred when the requisite amount of sodium tartrate (50 c.c.) had been added. The small variation in the hydron concentration was caused by equilibria set up between the added tartrate ions and the hydrotartrate ions, which, by failing to react with the beryllium, left it in the solution in the form of a basic tartrate. The high concentration of hydrotartrate ions was evidently due to their incapacity to react with that part of the beryllium hydroxide which gives rise to "soluble basic salts."

Solutions which contained one or more mols. of beryllium sulphate to one of sodium tartrate were completely precipitated by alkali, although solutions containing the reactants in the molar ratio 1 : 2 did not yield precipitates. The amounts of titratable acid in the complex tartrate solutions were approximately 1.53 equivalents for each molecule of beryllium sulphate taken, and consequently the composition of the final basic complex may be expressed by the formula  $\text{BeT}_{0.24}(\text{OH})_{1.53}$ .

Rosenheim and Woge (*Z. anorg. Chem.*, 1897, **15**, 283) and Rosenheim and Itzig (*Ber.*, 1899, **32**, 3424) isolated two series of complex beryllium tartrates having the general formulæ  $\text{R}_2[\text{Be}_4\text{O}_3\text{T}_2]$  and  $\text{R}_2[\text{Be}_2\text{OT}_2]$ , where  $\text{R} = \text{K}, \text{Na}, \text{or } \text{NH}_4$ . The individuality of these salts is questionable. Salts of the former series were obtained by evaporating hydrogen tartrate salt solutions, saturated with beryllium hydroxide, to syrups and allowing these to solidify, whereas salts of the latter series were prepared in the same way with the one exception that the calculated quantities of beryllium hydroxide were used. The salts were either glassy masses or microcrystalline crusts. Complex salts of the first type cannot give rise to non-precipitability, for, as Rosenheim and Woge state, ammonia produces a precipitate. As already mentioned, solutions containing beryllium sulphate and sodium tartrate in the molar ratio 2 : 1, which is that in  $\text{R}_2[\text{Be}_4\text{O}_3\text{T}_2]$ , are precipitable by alkalis. The latter workers have established, by means of the polarimetric method also used in the case of complex thorium tartrate solutions, that the important complex salt in the

solution was this particular compound,  $\text{Na}_2[\text{Be}_4\text{O}_3\text{T}_2]$ , from a study of solutions containing mixtures of beryllium sulphate, tartaric acid, and sodium hydroxide. The fact that the products which Rosenheim and Woge obtained by saturating solutions of acid salts with beryllium hydroxide should have corresponded to the formula  $\text{R}_2[\text{Be}_4\text{O}_3\text{T}_2]$  is of interest in that the products may be considered as being made up of the neutral tartrate,  $\text{R}_2\text{T}$ , and the basic tartrate,  $\text{Be}_4\text{O}_3\text{T}_2$ , or  $\text{BeT}_{0.25}(\text{OH})_{1.5}$ , which happens to be almost that suggested by these experiments to be present in the complex solutions.

*Chromium.*—The curve (Fig. 4) represents the hydron concentration changes which occurred during the titration of 100 c.c. of  $M/100$ -chrome alum with  $N/10$ -sodium tartrate. The hydron concentrations indicate that the amount of hydrotartrate ions liberated was less than that in the case of the corresponding beryllium titration. The difference appears to be accounted for by the fact that, although the precipitation  $p_{\text{H}}$ , 5.69, of beryllium hydroxide is a little higher than that of chromium hydroxide, 5.34, one-half of the beryllium hydroxide molecule is associated with the formation of soluble basic salts as compared with one-third in the case of chromium, and consequently a larger equivalent amount of acid is rendered available for reaction. The sodium tartrate caused the violet chromium salt solution to turn green.

The formation of complex chromium tartrate solutions which are not precipitable by alkali depends not so much on the amount of sodium tartrate added as on the treatment to which the solutions have been subjected, and in this respect appears to be similar to that of complex oxalate solutions. There is, however, the one difference that whereas oxalate solutions, on prolonged boiling with alkali, yield a precipitate, those of chromium tartrate in general do not. Chromium tartrate solutions, on boiling, become purplish-red, but if they are now treated with alkali at room temperature they turn green as soon as the precipitation  $p_{\text{H}}$  of the hydroxide is reached. As in the case of oxalate solutions, boiling caused the liberation of acid and the simultaneous formation of inert basic salt.

*Zinc.*—The curve (Fig. 4) is that of the titration of 100 c.c. of  $M/50$ -zinc sulphate with  $N/10$ -sodium tartrate. Although the sodium tartrate did not precipitate zinc hydroxide, the hydron concentration on addition of the first 40 c.c. (when the molecular ratio was  $\text{Na}_2\text{T} : \text{ZnSO}_4$ ) was reduced to nearly the precipitation  $p_{\text{H}}$ , 5.2, of zinc hydroxide. Titrations were made with sodium hydroxide and phenolphthalein of the acid liberated when varying quantities of  $N/10$ -sodium tartrate were added to 100 c.c. of  $M/50$ -zinc sulphate; the results are in Table V, where  $a$  = mols. of sodium tartrate per

mol. of zinc sulphate, and  $b$  and  $c$  = equivs. of sodium hydroxide required to produce a precipitate and neutrality, respectively.

TABLE V.

$a$ .....	2	2.5	3	4	5
$b$ .....	0.41	1.00	—	—	—
$c$ .....	1.14	1.13	1.19	1.14	1.03

The table shows that the minimum quantity of sodium tartrate required to prevent precipitation by alkali was 3 mols. for 1 mol. of zinc sulphate (= 120 c.c.). This quantity is much greater than those required in the case of the weaker bases. Moreover, all the solutions referred to in the table gave a precipitate when boiled with alkali. The change in hydrion concentration after 40 c.c. of sodium tartrate solution had been added shows that not all the hydrions of the tartaric acid had reacted, and the amounts of alkali required to neutralise the acid which had failed to react indicate that the compositions of the basic tartrates in the complex solutions varied from  $\text{ZnT}_{0.49}(\text{OH})_{1.03}$  to  $\text{ZnT}_{0.41}(\text{OH})_{1.19}$ .

*Lanthanum.*—When sodium tartrate was added to a lanthanum nitrate solution, a white, flocculent precipitate formed at  $p_{\text{H}}$  between 6 and 7 [Found in the air-dried precipitate:  $\text{La}_2\text{O}_3$ , 34.6; C (by "wet" combustion), 15.5.  $\text{La}_2(\text{C}_4\text{H}_4\text{O}_6)_3 \cdot 12\text{H}_2\text{O}$  requires  $\text{La}_2\text{O}_3$ , 34.75; C, 15.4%]. Czudnowicz (*J. pr. Chem.*, 1860, 79, 39) and Holmberg (*Z. anorg. Chem.*, 1907, 53, 87) prepared this salt, but based their formulæ on the lanthana content only, and reported that the water corresponded to  $9\text{H}_2\text{O}$ . Clève (*Bull. Soc. chim.*, 1874, 21, 202) stated that the water content of the salt dried in a desiccator was  $3\text{H}_2\text{O}$ .

Lanthanum tartrate, although insoluble in water (Rimbach and Schubert, *Z. physikal. Chem.*, 1909, 67, 192), is so readily soluble in mineral acids that when tartaric acid is added to a solution of a lanthanum salt of a strong acid no precipitate is formed; but one is obtained from a solution of lanthanum acetate. It is also readily soluble in alkalis and dissolves in an excess of sodium tartrate or tartaric acid solution. The following experiments were made to ascertain something of its nature in solution. Lanthanum tartrate was precipitated on addition of 30 c.c. of  $N/10$ -sodium tartrate to 30 c.c. of  $N/10$ -lanthanum nitrate. The solution became alkaline to thymol-blue on addition of 11.2 c.c. of  $N/10$ -sodium hydroxide, and the precipitate completely dissolved on addition of 13 c.c. The amount of alkali required for re-solution shows, if it be assumed that the alkali had been converted into sodium tartrate, that the lanthanum had passed back into solution as a basic tartrate,

In another experiment, 50 c.c. of  $N/10$ -sodium tartrate were added to 30 c.c. of  $N/10$ -lanthanum nitrate, and the solution containing the suspended precipitate was titrated, by means of the hydrogen electrode, with  $N/10$ -sodium hydroxide. The precipitate dissolved at  $p_H$  7.9, when 12 c.c. of alkali had been added, the soluble basic tartrate then being  $LaT_{0.90}(OH)_{1.20}$ , but the inflexion indicating the attainment of marked alkalinity did not occur until 14.4 c.c. had been added, and therefore the soluble basic lanthanum tartrate had become slightly decomposed to  $LaT_{0.78}(OH)_{1.44}$ . The curve obtained on adding more alkali showed that the basic tartrate was undergoing further decomposition. The following experiment gives some idea of the extent of the decomposition which takes place in alkaline solutions. Lanthanum tartrate (0.1960 g.) was shaken mechanically with 100 c.c. of 0.014*N*-sodium hydroxide for 24 hours; all the tartrate had then dissolved. The solution was titrated by means of the hydrogen electrode with  $N/10$ -hydrochloric acid, and the excess of free alkali was equivalent to 6.35 c.c. of the acid. The lanthanum tartrate therefore existed in the alkaline solution as  $LaT_{0.59}(OH)_{1.82}$ , and was much more basic than those mentioned above. In this titration, the basic lanthanum tartrate began to be precipitated when the free alkali had just been neutralised, and the  $p_H$  then attained was that required for the precipitation of lanthanum hydroxide.

#### *Discussion.*

The foregoing investigations show that complex tartrate solutions are essentially basic in nature. This is especially evident in the cases of the complex zirconium and thorium tartrate solutions produced by the re-solution, probably without change in composition, of the basic tartrates first precipitated. Unlike the complex solutions which were sometimes formed with acetates and oxalates, those of the tartrates are extremely stable. The basic tartrates, like the basic aggregates in solution, are strongly resistant to alkalis, which probably explains their non-precipitability by such means.

The existence of these basic tartrate complexes would also account for the properties of Fehling's solution. The fact that the ease of reduction to cuprous oxide is comparable with that of freshly precipitated cupric hydroxide suggests that the condition of the cupric salt in alkaline tartrate solutions is in some way related to that of cupric hydroxide itself, as would obtain in basic tartrate complexes.

The condition of copper tartrate on passing into these complex alkaline tartrate solutions is, at any rate, basic. For example, Kahlenberg (*Z. physikal. Chem.*, 1895, **17**, 586), Masson and Steele (*J.*, 1899, **75**, 725), and Pickering (*J.*, 1911, **99**, 169) found that the quantity of sodium or potassium hydroxide necessary to produce

alkalinity in a solution of copper tartrate varied from 1.25 to 1.36 mols., and therefore the basic complexes in the solutions must have varied from  $\text{CuT}_{0.38}(\text{OH})_{1.25}$  to  $\text{CuT}_{0.32}(\text{OH})_{1.36}$ .

Previous workers attempted to account for the anomalies of complex tartrate solutions by regarding the heavy metal as being present in a complex anion. Masson and Steele obtained a substance,  $\text{K}_3\text{Cu}_4\text{C}_{12}\text{H}_7\text{O}_{18}\cdot 5\text{H}_2\text{O}$ , by precipitation with alcohol from a copper tartrate solution which had been neutralised with 1.25 equivalents of potassium hydroxide. The substance, which was isolated as a dark blue, gummy mass (and therefore was of questionable character), was in effect composed of  $3\text{K}_2\text{T}$  and  $8\text{CuT}_{0.375}(\text{OH})_{1.25}$  and was probably a mixture of potassium tartrate with a preponderance of basic copper tartrate. Their migration experiments on solutions of this substance are important in that they show that some copper had passed into the portion carrying the negative charge, but this may have been due equally well to the colloidal nature of the basic copper tartrate as to the presence of a complex copper anion. Pickering also obtained flocculent precipitates from copper tartrate solutions by adding alcohol. The unwashed precipitates (whose constitutions he tried to establish by regarding some of the copper as quadrivalent) contained variable quantities of potassium salt, all of which, together with some copper, could be removed by washing. Wark (J., 1923, 123, 1815, 1826; 1924, 125, 2004) has suggested that the complexity of solutions containing copper and malic acid is due to the formation of cuprimalic acid,  $\text{HCuC}_4\text{H}_3\text{O}_5$ , isomeric with the normal cupric malate.

The formation of the complex tartrate solutions of zirconium and thorium by the re-solution of the basic precipitates seems to have been due to the sodium tartrate which was present, although it has not been possible to associate any precise quantity of the latter with that of the respective basic tartrates. Many attempts have been made to account for the complexity of tartrate solutions by assuming that their formation involves reactions with the hydrogen atoms of the hydroxy-groups. It is difficult, however, to imagine that zirconium hydroxide, for example, one of the weakest bases, should be capable of so reacting, when strong bases show so very little aptitude. If the hydroxy-groups of tartaric acid are weakly acidic (their acidity is so small that it is not measurable by any physical method), they might be able to react with metallic bases, provided that the products formed were insoluble and therefore were removed from the sphere of action. Such a condition would probably be satisfied if the bases which had combined passed into the dispersed particles of a colloidal solution.

Many hydroxy-compounds, such as the sugars and glycerol, have

a definite, though very slight, acid character (compare Michaelis and Rona, *Biochem. Z.*, 1913, **49**, 248) and their dissociation constants can be measured. The dissociation constant of glycerol as a monobasic acid at  $17.5^\circ$  is  $7 \times 10^{-15}$ , and, in fact, the presence of glycerol in an alkali solution has a barely measurable effect on the  $p_H$ . Yet its effect on a zirconium chloride or ferric chloride solution may be such that alkalis fail to precipitate the hydroxide.

The reaction which must take place between the glycerol and the metallic base provides an explanation of the well-known protective action on ferric oxide hydrosols prepared by dialysis of ferric

Fig. 5.

chloride-glycerol solutions. It is significant, too, that the hydrosols so prepared are clear in transmitted light. The glycerol may retard the growth of the colloidal particles.

If the behaviour of the hydroxy-groups of tartaric and other hydroxy-acids is due to their feebly acid character, then it seems that complex tartrate solutions are essentially protected colloidal solutions. The following electrometric titrations were carried out to test this view. Michaelis and Rona (*loc. cit.*) having shown that dextrose is a stronger acid ( $K = 6.6 \times 10^{-13}$ ; compare Britton, J., 1925, **127**, 1902) than glycerol, it was decided to use the former in the titrations. A solution (100 c.c.),  $M/100$  with respect to zirconium chloride and  $M/2$  with respect to dextrose (9 g. in 100 c.c.), was titrated with  $N/10$ -sodium hydroxide at  $18^\circ$  by means of the

hydrogen and the normal calomel electrode. The curve is shown in Fig. 5, the points obtained being marked by crosses. A very slight opalescence was produced by 38.5 c.c. of the alkali ( $p_H = 5.22$ ), and a precipitate by 39.5 c.c. ( $p_H = 5.89$ ). This began to dissolve when 40 c.c. (*i.e.*, 4NaOH : ZrCl<sub>4</sub>) had been added, and the solution was cleared by 50 c.c. In the titration of zirconium chloride solution alone (J., 1925, 127, 2125), the solution first became visibly colloidal with 1.5 equivalents of alkali ( $p_H = 1.86$ ), but in the present titration the effect of the dextrose was manifested in the delay of precipitation until nearly the whole of the alkali required to convert the zirconium chloride into the hydroxide had been added and the hydrogen-ion concentration had become extremely small, *viz.*,  $10^{-6}$ . The fact that the solution remained clear until 3.85 equivalents of alkali had been added suggests that, although the dextrose was incapable of influencing the hydrogen-ion concentration of the solution, it had the effect of repressing the growth of the basic particles below the limit necessary to produce visible colloidalty. Table VI, compiled from the observed voltages, shows that during the addition of the first 40 c.c. of alkali the zirconium chloride was more basic than ZrCl(OH)<sub>3</sub>. The ionisation of dextrose is much too small to affect the hydrogen-ion concentrations of solutions whose  $p_H$  is less than 6, and consequently the hydron concentrations of the basic zirconium chloride solutions have been regarded as coming entirely from the hydrolysed acid.

TABLE VI.

C.c. of N/10- NaOH.	E.M.F.	% Hydrolysis of un- neutralised part.	Atoms of Cl in ZrCl <sub>4</sub> neutralised.	Composition of basic zirconium chloride. Atoms per 1Zr.		Mols. of free HCl referred to 1Zr.
				Cl.	OH.	
0.0	0.370	77.8	0	0.89	3.11	3.11
5.0	0.374	79.5	0.5	0.78	3.22	2.72
10.0	0.379	79.8	1.0	0.61	3.39	2.39
15.0	0.386	75.7	1.5	0.61	3.39	1.89
20.0	0.395	68.7	2.0	0.63	3.37	1.37
25.0	0.413	46.5	2.5	0.80	3.20	0.70
30.0	0.438	26.8	3.0	0.73	3.27	0.27
35.0	0.491	6.7	3.5	0.47	3.53	0.03
37.5	0.552	1.2	3.75	0.25	3.75	0.003
38.0	0.566	1.1	3.8	0.20	3.80	0.002
39.0	0.598	0.5	3.9	0.10	3.90	0.0005
39.5	0.623	0.4	3.95	0.05	3.95	0.0002
40.0	0.634	0	4	0	4	0

The last column shows that when the solution began to opalesce, with 38.5 c.c. of alkali, the amount of free acid had become negligible. It is remarkable that the dextrose was able to maintain the highly basic zirconium chloride (columns 5 and 6) in a solution which was quite clear. Borax and sodium carbonate also delay precipitation

by alkali until somewhat more than 3 equivalents have been added (this vol., p. 125).

In order to ascertain whether the dextrose had entered into any reaction which might have influenced the  $p_H$  of the solution during the re-solution of the zirconium hydroxide in the sodium hydroxide, a solution of 140 c.c. (i.e., the volume of the titrated solution when the stoichiometrical amount of alkali had been added) containing 9 g. of dextrose was titrated with  $N/10$ -sodium hydroxide. The data and dissociation constant figures of dextrose as a monobasic acid are given in a previous paper (J., 1925, **127**, 1902). In Fig. 5 the titration curve is the one beginning at 40 c.c. of  $N/10$ -sodium hydroxide given at the top of the diagram. By comparing the two curves, it will be seen that the presence of the zirconium hydroxide in the one solution caused a perceptible diminution in  $p_H$ , and consequently the hydroxide on dissolution must have combined in some way with the dextrose. It is difficult to understand how the zirconium hydroxide effected this increase in hydrogen-ion concentration. Had it reacted simply with the dextrose to form inert colloidal aggregates, this, in effect, would have been equivalent to the removal of some dextrose from the solution and therefore would have given rise to a diminished hydron concentration. An increased hydrogen-ion concentration seems to be possible only by assuming that the zirconium hydroxide had, in combining with the dextrose, given rise to a complex acid slightly stronger than dextrose itself. All that the titration can be said to show is that dextrose does enter into some kind of reaction with the zirconium hydroxide in effecting its dissolution in alkali solutions.

A second titration was that of 100 c.c. of  $M/100$ -zirconium chloride and  $M/1$ -dextrose solution (18 g. in 100 c.c.). The increased amount of dextrose was without further effect during the addition of the first 40 c.c. of alkali, but tended to cause a more rapid re-solution of the zirconium hydroxide as the excess of alkali was added. The data for this curve are indicated by circles in Fig. 5.

### *Summary.*

(1) Sodium acetate at the ordinary temperature fails to precipitate weak bases, although the precipitation  $p_H$ 's of the respective hydroxides may be exceeded. An exception is the reaction with thorium sulphate solution. There is good evidence that weak metallic bases exist in complex acetate solutions as basic acetates.

(2) Sodium oxalate produces a basic precipitate from zirconium chloride solution through the incapacity of the hydrions from the second stage of dissociation of oxalic acid to react with zirconium hydroxide, but the precipitate dissolves in excess of the reagent.

The oxalate does not produce precipitates from solutions of salts of slightly stronger bases, *e.g.*, aluminium and chromium hydroxides, even although it is probable that very little reaction can take place between them and the hydro-oxalate ions. Observations on solutions of chromium hydroxide in oxalic acid and of potassium chromium oxalate suggest that both their properties and the existence of the series  $3R_2C_2O_4, Cr_2(C_2O_4)_3$  arise from the nature of the reactants.

(3) The reaction of sodium tartrate with salts of thorium and aluminium in solution is remarkable in that increased hydron concentrations are at first produced; in the case of thorium, a basic tartrate precipitate is formed, even although the hydron concentration is considerably higher than that necessary for the precipitation of the hydroxide.

(4) Hydrogen electrode titrations of zirconium chloride solutions containing dextrose with sodium hydroxide show that some reaction must take place between the zirconia and the hydroxy-groups of dextrose.

The author desires to express his thanks to the Department of Scientific and Industrial Research for a personal grant, to the Chemical Society for a grant from its Research Fund for the purchase of salts of the rarer metals, and to Professor J. C. Philip, F.R.S., for kindly placing facilities at his disposal.

### XXXIX.—*The Absorption of Gases by Colloidal Solutions.*

By ALOIS GATTERER.

ONE of the most important studies of colloid chemistry is that dealing with adsorption and absorption in colloidal solutions, for not only is it of considerable practical value, but also it may throw light on the structure of the colloids themselves. The study of gaseous absorption in particular may be expected to yield definite and valuable results because of the chemical and electrical neutrality of solvent and solute. Of the few investigations of this kind that have hitherto been made, those of Geffcken (*Z. physikal. Chem.*, 1904, **49**, 297) and Findlay and his co-workers (*J.*, 1910, **97**, 536; 1912, **101**, 1459; 1913, **103**, 636; 1914, **105**, 291) are limited in their scope, being confined to comparatively few gases and solutions, to low concentrations and, above all, to one temperature, *viz.*, 25°.

Consequently, our knowledge of the absorptive power of colloidal

solutions is meagre and does not furnish a sufficiently broad experimental foundation for a trustworthy theory. A wide investigation of absorption has therefore been undertaken, with various colloidal solutions and at temperatures ranging from 5° to 25°. The colloidal solutions have been characterised by determinations not only of density and concentration but also of electrical conductivity, viscosity, the Tyndall effect, and absorption of light, for only in this way is it possible to define these complex systems so precisely that they can be exactly reproduced.

The observations here recorded refer only to two gases, carbon dioxide and acetylene, and to two colloidal solutions, ferri ferrocyanoide and ferric hydroxide; the former were chosen because of their acidic and neutral character respectively, and the latter because they are, respectively, positive and negative colloids.

#### EXPERIMENTAL.

*Preparation of Solutions.—Ferri ferrocyanoide.* The solution was prepared according to Zsigmondy ("Kolloid Chemie," 1920, 3rd ed., p. 500) by mixing 2*N*-solutions of sodium ferrocyanoide and ferric chloride. The precipitate was carefully washed, redissolved in a small quantity of the ferrocyanoide, and the solution was concentrated by heating in a vacuum. The maximum concentration obtained was about 8%.

*Ferric hydroxide.* A solution of pure ferric hydroxide in acetic acid was diluted and, after the method of Péan de St. Gilles, boiled until the ratio of acetic acid to ferric hydroxide became 1 : 30—1 : 60. The solution was then evaporated, not under atmospheric pressure, but under reduced pressure, whereby a much higher degree of dispersion, as shown by the Tyndall effect (compare Figs. 1 and 2), was obtained. This more highly dispersed solution appears to be intermediate between the solution of Graham and that of P. de St. Gilles.

*Preparation of Gases.—*The carbon dioxide was carefully washed and its purity was confirmed by the value obtained for its solubility in distilled water. Acetylene was generated from calcium carbide and freed from impurities by treatment with chromic acid and potassium hydroxide and by absorption in acetone. Analyses of the purified product by means of ammoniacal cuprous chloride showed residues of 0, 2, and 3 c.c. in 100 c.c.

*Apparatus and Outline of Method.—*The method of Ostwald was employed to measure absorption (Ostwald-Luther, "Handbuch der Physicochemischen Messungen," 1910, 3rd ed., p. 246). The solutions were freed from air by boiling in a vacuum and, without contact with air, transferred to the vacuum mixing vessel at 25°.

The gases were saturated with water vapour at the same temperature. Five measurements were made with a given solution at five different temperatures, the process being repeated after an interval of several hours to check the former results. The calculation of the solubility is based on the formula (see Ostwald-Luther, *op. cit.*)

$$l = \left[ V_{b_1} \frac{T_a(b_1 - h_{b_1})}{T_{b_1}(b_1 - h_a)} - V_{b_2} \frac{T_a(b_2 - h_{b_2})}{T_{b_2}(b_2 - h_a)} - V_a \right] \frac{1}{V_f},$$

where  $l$  = Ostwald's solubility;  $V_{b_1}$  = initial volume of gas in the burette at temperature  $T$  (abs.) and pressure  $b_1$ ;  $V_{b_2}$  = final volume of gas in the burette;  $T_a$  = absolute temperature of the thermostat;  $T_{b_1}$  and  $T_{b_2}$  = initial and final temperature, respectively, of gas in burette;  $b_1$  and  $b_2$  = pressure of the atmosphere at commencement and end of experiment;  $h_a$ ,  $h_{b_1}$ , and  $h_{b_2}$  = tension of water vapour at  $T_a$ ,  $T_{b_1}$ , and  $T_{b_2}$ , respectively;  $V_a$  = volume of liquid withdrawn, measured at  $T_a$ ;  $V_f = V - V_a$  = volume of liquid contained in the absorption vessel; and  $V$  = volume of the absorption vessel at temperature  $T_a$ .

The changes in volume of the solutions and of the mixing vessel at various temperatures were taken into consideration. The probable error was  $\pm 0.4\%$ . In certain cases, owing to an exceedingly slow rate of absorption, the completion of this was not reached, and this may be the explanation of the lack of smoothness in some of the curves. The values of  $l$  are given either in percentages, *i.e.*, number of grams in 100 c.c. of solution, or in gram-equivalents. All values of volume are calculated for  $20^\circ$ . Although it is uncertain whether the colloids in question have definite chemical formulæ, yet for the sake of clearness the gram-equivalent of Prussian blue was taken as  $1/12 \text{ Fe}_4[\text{Fe}(\text{CN})_6]_3 = 71.603$ , and that of ferric hydroxide as  $1/3 \text{ Fe}(\text{OH})_3 = 35.621$ .\*

#### *Solubility of Carbon Dioxide in Solutions of Prussian Blue.*

The values in Table I have been obtained by different workers for the solubility of carbon dioxide in water.

Findlay (*loc. cit.*) gives a somewhat lower value, *viz.*, 0.817 at  $25^\circ$ .

The solubility values ( $l$ ) of carbon dioxide in solutions of Prussian blue are in Table II and Fig. 3 (unbroken lines).

\* According to Hofmann ("Lehrbuch der Anorganischen Experimental-chemie," 1918, p. 641) soluble Prussian blue has the formula  $\text{Fe}(\text{CN})_6\text{NaFe}$ . This, of course, would change the above equivalent weight. Hofmann's formula, however, is not generally accepted, and, moreover, does not agree with the author's results. Further, if Hofmann's formula is assumed, the results obtained by the gravimetric and the volumetric methods do not agree.

*Solubility of Acetylene in Solutions of Prussian Blue.*

The following solubility values of purified acetylene in distilled water were obtained (Table VI).

TABLE VI.

T.	l.			Mean.
30°	0.951	0.950	0.954	0.952
25	1.030	1.028	1.031	1.030
20	1.126	1.125	1.127	1.126
15	1.239	1.239	1.241	1.239
10	1.381	1.383	1.383	1.382

FIG. 4.

*Solubility of acetylene in solutions of Prussian blue.*

The values of Winkler, according to unpublished communications (Landolt-Börnstein-Roth, "Physikalisch-Chemie Tabellen," 1912, p. 600), are calculated only to the second decimal place and, on the average, are smaller by 1.5—2% than those of the author, as the following figures show :—

	30°.	25°.	20°.	15°.	10°.
Abs. coeff. (Winkler) .....	0.84	0.93	1.03	1.15	1.31
Abs. coeff. from Table VI, mean values .....	0.858	0.944	1.049	1.175	1.330
Diff. % .....	2.1	1.5	1.8	2.1	1.5

Only a more accurate study of Winkler's experiments could determine whether or not this difference is due to impurities in the gas.

Table VII and Fig. 4 show the solubility of acetylene in solutions of Prussian blue, and Table VIII the temperature-coefficients per degree.

*Examination of the Colloidal Solutions.*

In order to define the colloid systems employed and to facilitate re-examination, detailed investigations have been made into the chemical and physical properties of the colloidal solutions used, in the hope that from a consideration of the solubility phenomena and other properties, the intrinsic structures may perhaps be determined. The systems were investigated, therefore, from the point of view of (1) concentration, (2) density, (3) electrical conductivity, (4) depression of the freezing point, and (5) viscosity.

1. *Concentration.*—(a) *Prussian blue.* Gravimetric and volumetric analyses were made. The evaluation of the effective concentration met with some difficulty, owing to a certain quantity of peptising agent which was present in solution. This was avoided in the following way. A certain quantity of solution (5—10 g.) was heated and sodium hydroxide added until all the Prussian blue was converted into ferric hydroxide, which was filtered off. The filtrate was acidified with dilute sulphuric acid, and the sodium ferrocyanide titrated with  $N/10$ -potassium permanganate until the pink colour was permanent. From the quantity of permanganate used, the amount of  $\text{Fe}(\text{CN})_6'''$  ions which remained after the reaction with sodium hydroxide was easily calculated. There were also  $\text{Fe}(\text{CN})_6'''$  ions present from the beginning in the peptised solution, and for this reason the total  $\text{Fe}(\text{CN})_6'''$  found would give too large a

value for the Prussian blue content. To establish the exact quantity of the latter volumetrically, the ratio ( $\phi$ ) of  $\text{Fe}(\text{CN})_6'''$  formed from the Prussian blue to the total  $\text{Fe}(\text{CN})_6'''$  present was determined by gravimetric analysis of the precipitated ferric hydroxide. This was dissolved in dilute hydrochloric acid, re-precipitated with ammonia, and estimated as ferric oxide. The sodium ferrocyanide equivalent to the ferric oxide found was the amount of ferrocyanide obtained from the Prussian blue, which was thus directly determined. The value of  $\phi$  could now be found—using the results with permanganate—and was calculated to be 0.9430. Since  $\phi$  was constant (all solutions being of one preparation), all measurements of the concentration of Prussian blue could then be made by the permanganate method, which was therefore used. Both methods show a satisfactory agreement to within 0.1%, *e.g.*, solution I gave 3.91% volumetrically and 4.02% by the gravimetric method, and solution III, 7.368 and 7.362%, respectively.

(b) *Ferric hydroxide.* The concentration of this solution was determined from the amount of ferric oxide obtained on evaporating a definite quantity of the solution and heating the residue to redness. Considerable difficulty was experienced in determining the quantity of the peptising agent (acetic acid). In the first place, the ratio  $\text{Fe}(\text{OH})_3$ : peptising agent was not constant, because the latter changed whenever the solution was boiled; and secondly, the quantity of acetic acid present was so small that direct titration could afford no exact results. Finally, about 30–40 g. of the solution were acidified with dilute sulphuric acid and about one litre of the resulting solution was distilled. The acetic acid in the distillate was neutralised with baryta, and the excess of this precipitated with carbon dioxide. The whole was concentrated to a small volume, the barium carbonate filtered off, and the barium acetate in the filtrate precipitated with sulphuric acid. The amount of acetic acid was calculated from the weight of barium sulphate found. The greater solubility of barium carbonate over barium sulphate was taken into consideration in the results, which are in Table XII.

2. *Density.*—Densities were determined with a large pycnometer, and the results compared with the density of water at 4° and reduced to vacuum values. Only the results actually obtained are in Tables XI and XII. The results show that, over the whole temperature range studied, density is a linear function of concentration.

3. *Electrical Conductivity.*—The object of these measurements was to determine to what degree the colloid was free from contamination by electrolytes; for an increase in conductivity might have been due to such contamination and eventually to colloidal

ions. Moreover, the questions arise (1) to what extent is peptisation changed by the action of the colloidal solution, and (2) are ionisation and ionic mobility much the same, at similar concentrations, as in a pure solvent?

The Kohlrausch method, with inductor and telephone, was employed and the results are in the following tables and diagrams.

(a) *Prussian Blue* (see Table XIII and Fig. 6). All measurements were made at 18°. For purposes of comparison the conductivity of pure sodium ferrocyanide is given in Table XIV and shown graphically in Fig. 7.

FIG. 6.

9.3	1000	110.0

A remarkable feature of Fig. 7 is that the curve for the peptising agent in the solution lies below that of the ferrocyanide in water. Hence it was assumed that the conductivity of the colloid was wholly due to the amount of peptising agent present, and therefore the

abscissæ of the lowest curve in the figure are those of the peptising agent in Prussian blue solution: the ordinates are corresponding values of equivalent conductivity of Prussian blue. The values are taken from Table XIII. The continuations of these ordinates cut the curve for sodium ferrocyanide in water, and the data at these points of intersection show the conductivities of a pure solution of sodium ferrocyanide of the same concentration as in the colloid. The conductivity curve for sodium ferrocyanide with peptisation

FIG. 8.

*Ferric hydroxide.*

is a straight line, and the gradient of this line with respect to the curve for sodium ferrocyanide in water is about 0.368. Hence the ordinates,  $y_1$ , of the one curve are constant multiples of the ordinates,  $y_2$ , of the other, i.e.,  $y_1 = \text{constant} \times y_2$ . It would be of interest to investigate the behaviour of other colloids in a similar way.

(b) *Ferric hydroxide* (see Table XV and Fig. 8). All the measurements were made at  $25^\circ$ . The curve for equivalent conductivity seems to pass through a minimum at a normality of about 0.5. The equation,  $y_1 = y_2 \times \text{constant}$ , found for Prussian blue, unfortunately, cannot be examined in this case, for the conductivity of

this colloid is far superior to that of the peptising agent—if this alone is considered—as the following data show :

Acetic acid.		Coll. $\text{Fe}(\text{OH})_3$ .		
$N \times 10^3$ .	$\kappa_{25^\circ} \times 10^6$ .	No.	Peptisation ( $N \times 10^3$ ).	$\kappa_{25^\circ} \times 10^6$ .
2	67	2	2	105
5	110	4	3	314
10	158	3	9.6	509
20	229	5	11.0	903

The figures in this table show that ions of acetic acid—and it may be others as well—transport electric charges. These others, especially chlorine ions, may arise from impurities adsorbed by the ferric hydroxide when it was first precipitated and irremovable by washing. The discussion which follows later shows that the

greater conductivity of these solutions of ferric hydroxide may possibly be due to "colloidal ions."

4. *Depression of Freezing-point.*—These determinations, which were carried out in a Beckmann apparatus, were made in order to estimate, as far as possible, the relative numbers of particles in the solutions and also to determine whether these numbers vary proportionally to the concentration. The results are in Table XVI (see also Fig. 9).

TABLE XVI.  
*Freezing-point Depression,  $\Delta t$ .*

Prussian blue.			Ferric hydroxide.		
Soln.	Conc. ( $N$ ).	$\Delta t$ .	Soln.	Conc. ( $N$ ).	$\Delta t$ .
1	0.896	0.040°	5	0.967	0.029°
2	0.51	0.020	3	0.513	0.018
3	0.37	{ 0.030** 0.019**	1	0.144	0.008
4	0.126	0.012			

A small freezing-point depression is an indication of the comparative purity of a colloidal system. The values marked \*\* in the table were obtained at different times and the value 0.030 was constant. The curve may possibly rise to a maximum for a concentration of 0.3*N*, or there may here be a point of inflexion if the lower and more probable value, 0.019, be plotted.

III	1.0171	150.6	2.448	III	1.0442	446.7	7.452

FIG. 10.  
*Viscosity.*

The molecular weights of ferric hydroxide calculated from the results are 2240, 2000, and 1090 for solutions 5, 3, and 1, respectively. These values, of course, carry little weight, but they seem to indicate that with increasing concentration the particles in the solution coalesce to form larger aggregates.

5. *Viscosity.*—These measurements were made because there may be an intimate relation between the viscosity of a colloidal solution and its absorptive power. The apparatus, an Ostwald viscosimeter, was in a large thermostat at 25° and, as usual, two series of experiments were made. The viscosities were calculated by means of the equation  $\eta = \eta_w \cdot st / s_w t_w$ , where  $\eta$  and  $\eta_w$  are the relative viscosities of the solution and water, respectively, *s* is the density of the solution and *t* is the time of flow. The results are in Table XVII and are shown graphically in Fig. 10.

*Discussion of Results.*

An examination of the solubility tables reveals the very different behaviour of the two colloidal solutions towards carbon dioxide and acetylene.

The solubility of carbon dioxide in the more concentrated solutions of ferric hydroxide exceeds its solubility in water by as much as 20%. Moreover, it is almost directly proportional to the concentration—a relation found by Findlay also (*loc. cit.*), although his absolute values of  $l$  were considerably smaller than those now recorded.

Carbon dioxide is also more soluble in solutions of Prussian blue than in water, but only moderately so (at the most, 3–4%). A well-defined maximum occurs in the values of  $l$  at all the temperatures used, in every case at a concentration of 0.3-normal.

Towards acetylene, however, both colloidal solutions display an essentially different behaviour, the solubility of the gas being always less than its solubility in water. The diminution is 1% for ferric hydroxide and 7–8% for Prussian blue (compare Findlay's curves, reproduced in Fig. 5, for nitrous oxide in ferric hydroxide at 25°).

For these colloidal systems the relation between the solubility of gases and the temperature is in accord with the ordinary laws governing the solution of gases, *viz.*, the temperature coefficient is negative and its numerical value increases rapidly with diminishing temperature (see Table VIII). This magnitude appears to be a function of concentration (at constant temperature). The following rule, therefore, may be deduced. At a given temperature, the numerical value of the temperature coefficient varies, with increasing concentration, as the absorptive power of the colloidal solution for the dissolving gas. For instance, in the system carbon dioxide–ferric hydroxide,  $l$  increases rapidly with  $c$  and consequently the quotient  $\Delta l/\Delta t$  increases as  $c$  increases: or, in the system acetylene–ferri ferrocyanide,  $l$  diminishes greatly as  $c$  increases, and consequently  $\Delta l/\Delta t$  decreases as  $c$  increases. Such behaviour, however, is not so well defined in the systems carbon dioxide–ferri ferrocyanide and acetylene–ferric hydroxide, since  $l$  varies but little. In the latter case, a diminution even of the temperature coefficient might be assumed owing to the small diminution of  $l$ .

The factors which may account for the observed phenomena are (1) the chemical nature of the colloid and of the gas absorbed (chemical combination), (2) the influence of the specific surface (adsorption), (3) the nature of the electric change, and (4) temperature.

1. *Chemical nature.* This is, presumably, the most important factor in all absorption phenomena, but, unfortunately, it is still

very obscure. Clearly, the more inert the gas and the colloidal solution are chemically, the smaller will be the effect of this factor. An obvious conclusion from this is that  $l$  for the systems carbon dioxide-Prussian blue and acetylene-ferric hydroxide will differ but little from the value of  $l$  for water, since fairly inert substances meet each other. On the other hand, a chemical reaction may be expected to take place between the basic ferric hydroxide and the acidic carbon dioxide. It is true that there is as yet no evidence of the existence of a compound  $\text{Fe}_2(\text{CO}_3)_3$ . Since, however, electro-positive ferric hydroxide, according to Pauli and Mattula (*Kolloid-Z.*, 1917, 21, 49), has the constitution  $[\alpha\text{Fe}(\text{OH})_3]_2\gamma\text{Fe}'''$ , and there is formed by the dissociation of the dissolved carbon dioxide a small amount of  $\text{CO}_3''$ , a combination of this with the trivalent iron to give complex colloidal  $\{[\alpha\text{Fe}(\text{OH})_3]_2\gamma\text{Fe}\}_2(\gamma\text{CO}_3)_3$  may reasonably be assumed. This assumption seems to be justified by the strikingly high conductivity of the colloidal solution, which far exceeds that due to the peptising agent present.

2. *Specific surface.* The present results, as well as those of Geffcken and Findlay, clearly show that some factor is operating in addition to adsorption. The extent of the latter is determined by the degree of dispersion, and to account for the different behaviour of the two colloids by adsorption alone the specific surface of the ferric hydroxide would have to be 8—10 times larger than that of the Prussian blue—an assumption that cannot be justified.

Dispersion, however, has an effect, and to determine it the absorption of carbon dioxide for different dispersions of ferric hydroxide at the same concentration (0.066*N*) was measured.

*Values of  $l$ .*

	25°.	20°.	15°.	10°.
High dispersion .....	0.854	0.961	1.095	1.268
Low dispersion .....	0.817	0.930	1.068	1.239
Water .....	0.826	0.936	1.070	1.240

At the higher temperatures the absorptive power of the less highly dispersed system is markedly depressed, even below that of water. This diminution, however, depends not only on the specific surface of the colloid, but also on the quantity of peptising agent present. In the less highly dispersed system this was 0.3% and the basic character of the ferric hydroxide was greatly diminished and its electrical nature correspondingly changed.

3. *Electric change.* The changes that take place when carbon dioxide is in contact with a colloidal solution of ferric hydroxide may be represented by the following scheme; for a given temperature and pressure a definite equilibrium will be set up :

(3) The colloidal particles become associated with  $\text{Fe}^{+++}$ :  
 $[\text{xFe(OH)}_3] + \text{yFe}^{+++} \rightarrow [\text{xFe(OH)}_3]\text{yFe}^{+++}.$

(5)  $2[\text{xFe(OH)}_3]\text{yFe}^{+++} + 3\text{yCO}_3'' \rightleftharpoons \{[\text{xFe(OH)}_3]\text{yFe}\}_2 (\text{yCO}_3)_3.$   
 (compare Pauli and Mattula, *loc. cit.*).

The remarkably high solubility of carbon dioxide in ferric hydroxide and the readiness with which the gas is expelled by heating may thus be explained.

The preceding explanation involves the basic character of ferric hydroxide, the positive charge on the colloidal particles, and the acid nature of the gas. The last factor may for all practical purposes be neglected in the case of acetylene and nitrous oxide. Geffcken (*loc. cit.*, p. 301) has shown the indifferent nature of nitrous oxide by conductivity determinations with saturated aqueous solutions. The following measurements, made by the author, reveal the slight increase in conductivity that occurs when water is saturated with acetylene: water 2.18, 2.81,  $2.94 \times 10^{-6}$ ; mean  $2.63 \times 10^{-6}$ . Water saturated with acetylene 5.64, 4.98,  $4.03 \times 10^{-6}$ ; mean  $4.88 \times 10^{-6}$ . This result is in agreement with the investigations of Billitzer (*Z. physikal. Chem.*, 1902, 40, 535), who pointed out a very slight dissociation of acetylene, represented by the following scheme,

and found that the gas in saturated aqueous solution at atmospheric pressure corresponds to an acid about 400 times weaker than carbonic acid. Acetylene, therefore, and nitrous oxide may be regarded as inert gases, and their similar behaviour towards ferric hydroxide is thus satisfactorily explained. It is chiefly absorption that takes place, and this accounts, to some extent at least, for the diminution of solubility which occurs with increasing concentration. The large decrease of  $l$  for the system acetylene-Prussian blue is attributable to the high concentration of the colloid (above 7%), in comparison with that of the ferric hydroxide (3%), and to its negative charge.

4. *Temperature.* The rule stated on p. 313 may be explained on the basis of the kinetic theory. If the solubility increases with the concentration, the content both of colloid and of gas particles in the solution also increases and the conditions for the presence of gas particles become less favourable; so the rate of diminution of solubility per  $1^\circ$  rise in temperature becomes greater. A decrease in solubility with increasing concentration favours the retention of the gas particles in the solution: hence the diminished quantity

of gas corresponding with  $1^\circ$  may be expected to remain constant or even to fall.

*Summary.*

1. Two typical, highly concentrated colloidal solutions have been prepared, and a very highly dispersed system of ferric hydroxide has been obtained by a modification of P. de St. Gilles's method.

2. Measurements of the solubility of carbon dioxide and acetylene in these systems have been made at five temperatures and different concentrations, and the temperature coefficients determined.

3. The colloids have been characterised by determinations of density, concentration, conductivity, viscosity, and depression of freezing-point.

4. Certain regularities in solubility have been found and an attempt has been made to analyse the factors that produce them.

The author wishes to express his thanks to Dr. Charles Brunner, and to acknowledge his indebtedness to the late Dr. Chas. Hopfgartner, at whose suggestion the work was undertaken.

INNSBRUCK,  
SILLGASSE, 2.

[Received, July 18th, 1925.]

## *XL.—The Reciprocal Salt Pair (Na, Ba)–(Cl, NO<sub>3</sub>) in Aqueous Solution at 20°.*

By ALEXANDER FINDLAY and JAMES CRUICKSHANK.

THE investigation of this system was undertaken with a view to ascertain the best conditions for the preparation of barium nitrate from the chloride by interaction with sodium nitrate. The most important equilibria were investigated by one of us in 1917, and the further investigation of the system was taken up later with the intention of completing the equilibrium data at  $20^\circ$  and of extending the study also to higher temperatures. This extension of the investigation, however, has been rendered unnecessary by the work of Coppadoro (*Gazzetta*, 1912, 42, 1; 1913, 43, 138). We have restricted ourselves, therefore, to an examination of the equilibria at  $20^\circ$ .

The following values have been determined for the composition of aqueous solutions in equilibrium with one, two, and three salts, respectively, included in the above reciprocal salt pair.

1. Single salts.

Solid phase.	G. of anhydrous salt in 100 g. of soln.	Solid phase.	G. of anhydrous salt in 100 g. of soln.
NaCl	26.40	BaCl <sub>2</sub> .2H <sub>2</sub> O	26.32
NaNO <sub>3</sub>	46.77	Ba(NO <sub>3</sub> ) <sub>2</sub>	8.41

2. System NaCl-BaCl<sub>2</sub>-H<sub>2</sub>O.

Solid phase.	Percentage composition of solutions.		
	NaCl.	BaCl <sub>2</sub> .	H <sub>2</sub> O.
NaCl	25.28	1.65	73.07
NaCl; BaCl <sub>2</sub> ·2H <sub>2</sub> O	24.59	3.07	72.34
BaCl <sub>2</sub> ·2H <sub>2</sub> O	21.23	4.17	74.60
"	18.52	6.51	74.97
"	14.50	10.04	75.46
"	9.54	14.99	75.47
"	7.80	16.89	75.31

3. System NaCl-NaNO<sub>3</sub>-H<sub>2</sub>O.

Solid phase.	Percentage composition of solutions.		
	NaCl.	NaNO <sub>3</sub> .	H <sub>2</sub> O.
NaCl	18.49	18.62	62.89
"	17.34	21.30	61.36
NaCl; NaNO <sub>3</sub>	13.80	30.34	55.86
NaNO <sub>3</sub>	9.56	34.85	55.58
"	7.67	37.18	55.15

4. System BaCl<sub>2</sub>-Ba(NO<sub>3</sub>)<sub>2</sub>-H<sub>2</sub>O.

Solid phase.	Percentage composition of solutions.		
	BaCl <sub>2</sub> .	Ba(NO <sub>3</sub> ) <sub>2</sub> .	H <sub>2</sub> O.
BaCl <sub>2</sub> ·2H <sub>2</sub> O	26.07	1.31	72.62
BaCl <sub>2</sub> ·2H <sub>2</sub> O; Ba(NO <sub>3</sub> ) <sub>2</sub>	25.09	6.93	67.98
Ba(NO <sub>3</sub> ) <sub>2</sub>	20.81	6.54	72.65
"	12.31	6.72	80.97
"	7.51	7.17	85.32

5. System NaNO<sub>3</sub>-Ba(NO<sub>3</sub>)<sub>2</sub>-H<sub>2</sub>O.

Solid phase.	Percentage composition of solutions.		
	NaNO <sub>3</sub> .	Ba(NO <sub>3</sub> ) <sub>2</sub> .	H <sub>2</sub> O.
NaNO <sub>3</sub> ; Ba(NO <sub>3</sub> ) <sub>2</sub>	45.74	1.86	52.40
Ba(NO <sub>3</sub> ) <sub>2</sub>	37.07	2.07	60.86
"	14.59	2.49	82.92
"	5.61	3.89	90.50

## 6. Quaternary Solutions.

Solid phase.	Percentage composition of solutions.				
	NaCl.	NaNO <sub>3</sub> .	Ba(NO <sub>3</sub> ) <sub>2</sub> .	BaCl <sub>2</sub> .	H <sub>2</sub> O.
NaNO <sub>3</sub> ; Ba(NO <sub>3</sub> ) <sub>2</sub>	6.57	37.82	1.62	—	53.99
NaCl; Ba(NO <sub>3</sub> ) <sub>2</sub>	15.79	24.08	0.14	—	59.99
BaCl <sub>2</sub> ·2H <sub>2</sub> O; Ba(NO <sub>3</sub> ) <sub>2</sub>	2.02	—	6.49	22.66	68.83
NaCl; Ba(NO <sub>3</sub> ) <sub>2</sub> ; NaNO <sub>3</sub>	14.23	29.75	0.13	—	55.89
NaCl; Ba(NO <sub>3</sub> ) <sub>2</sub> ; BaCl <sub>2</sub> ·2H <sub>2</sub> O	24.16	0.50	7.14	—	68.20

The last noted solution is incongruently saturated.

For the practical application of the above determinations, the following numbers are of interest :

Initial composition of mixture (g. of anhydrous salt per 1000 g. of water).		Percentage of salt precipitated as Ba(NO <sub>3</sub> ) <sub>2</sub> .	
NaNO <sub>3</sub> .	BaCl <sub>2</sub> .	BaCl <sub>2</sub> .	NaNO <sub>3</sub> .
283	337.8	76.45	74.45
471.8	337.8	92.55	54.06

It will, in general, be advantageous to use a relatively large proportion of sodium nitrate in the initial mixture so as to obtain as complete a utilisation as possible of barium chloride. The mother-liquor containing sodium nitrate can be used, after evaporation and separation of the sodium chloride, for the conversion of a further quantity of barium chloride.

## XLI.—*The Equilibrium between Ethyl Alcohol and the Alkali and Alkaline-earth Salts. Part I.*

By DAVID GLYNWYN ROBERT BONNELL and WILLIAM JACOB JONES.

THE first investigator in this field was Graham (*Phil. Mag.*, 1828, 4, 265, 331), who prepared the ethyl alcoholate of calcium chloride. His work was repeated by Einbrodt (*Annalen*, 1848, 65, 115), by Chodnew (*Bull. Acad. St. Petersburg*, 1865, 8, 150), by Heindl (*Monatsh.*, 1881, 2, 200), and by Menshutkin (*J. Russ. Phys. Chem. Soc.*, 1906, 38, 1010). The calcium bromide tri-alcoholate (Roques, *J. Pharm.*, 1895, 1, 301), the hexa-alcoholates of magnesium chloride (Simon, *J. pr. Chem.*, 1879, 20, 371), bromide and iodide (Menschutkin, *Bull. St. Petersburg Polytec. Inst.*, 1906, 3, 12), the tetra-alcoholates of lithium chloride (Simon, *loc. cit.*) and bromide (Turner and Bissett, *J.*, 1914, 105, 1783) have all been described. Solubility determinations over ranges of temperatures have been carried out as follows: lithium chloride (Turner and Bissett, *J.*, 1913, 103, 1904), sodium and potassium iodides (Tyrer, *J.*, 1910, 97, 621) and calcium chloride (Menschutkin, *loc. cit.*).

The purpose of the present series of investigations was to determine the following: (1) The solubility over a wide range of temperature. (2) The composition of the various solid phases. (3) The transition temperatures. In the present paper are described the conditions of equilibrium between ethyl alcohol and the following salts: lithium bromide, sodium bromide, calcium bromide, barium bromide, and barium iodide.

### EXPERIMENTAL.

For obvious reasons great attention was directed to the purity of the substances used, and especially to their freedom from traces of water, since, owing to the far greater affinity of salts for this than for alcohol, the composition of the solid phase is particularly influenced by its presence.

The alcohol was purified by Lapworth's method (*J.*, 1910, 97, 24).

The densities, without correction of the weighings to vacuum, of the two specimens that were used in the present work were  $d_4^{25}$  0.78494 and 0.78496. Great care was exercised both during the purification and preservation and in subsequent work to exclude atmospheric moisture.

The salts were purified by recrystallisation from water and then dehydrated by Turner and Bissett's method (P., 1913, 29, 233) (Found by the gravimetric silver halide method: LiBr 99.81, NaBr 99.93, CaBr<sub>2</sub> 99.90, BaBr<sub>2</sub> 99.89, BaI<sub>2</sub> 99.87%).

The graduated vessels, weights and thermometers had been carefully standardised. In the solubility determinations above 20° ordinary thermostats, which kept constant within 0.02°, were used. At 15° and at 10°, the temperature was maintained constant within 0.04° by a regulated inflow of cold water and by continuous and vigorous stirring. For 0°, a bath of washed, finely powdered ice was used. In each determination the anhydrous salt and alcohol were put together in a clean, dry, glass-stoppered flask, which thereafter was kept in the thermostat, and as far as possible in the dark. A tightly fitting, thick paper cap was tied over the stopper. The mixtures were shaken by hand at intervals over a long period, and a portion of the solution was then withdrawn for analysis after the solid had settled completely. Thereafter the mixtures were again shaken and the procedure described was repeated until two consecutive analyses agreed within the experimental error. By operating in this manner saturation was ensured and incursion of atmospheric moisture was better precluded than if an internal stirring arrangement had been used. In some of the experiments, the equilibrium point was approached by first preparing a saturated solution at a temperature at which the solubility was greater than at the temperature under investigation, then placing it in the thermostat at the latter temperature, and, after keeping it therein for some time with frequent shaking, analysing the liquid phase. In all cases, the solubility so found was identical with that found by the procedure previously described. There can therefore be no doubt that in our experiments the systems were truly in equilibrium when the solubility determinations were made.

For the determination of the composition of the solid phase a small quantity was scooped out, quickly dried between filter-paper, and analysed. For such solid phases as were stable only at temperatures much above the ordinary, the procedure was modified as follows. Some of the salt was suspended by means of a basket of metal gauze in a saturated solution in a stoppered flask, which was immersed in the thermostat. When equilibrium had been attained, the basket was drawn up into the vapour space above the solution

and was there allowed to drain. When draining was complete, the solid in the basket was withdrawn and analysed.

The transition temperatures obtained by the solubility determinations were confirmed by the dilatometric method.

### Results.

Solubility in gram of salt per gram of alcohol, of					
Temp.	sodium bromide.	barium bromide.	barium iodide.	calcium bromide.	lithium bromide.
0°	0.02445	0.05880	0.7775	0.4670	0.3261
10	0.02379	0.05067	0.7735	0.4801	0.3602
15	0.02343	0.04590	—	0.5051	—*
20	0.02322	0.04130	0.7700	0.5350	—*
25	0.02314	—	—	0.5395	0.7210
30	0.02292	0.03322	0.7660	0.5552	0.7251
40	0.02276	0.02433	0.7620	0.6011	0.7303
50	0.02259	0.01837	0.7585	0.6564	0.7752
60	0.02312	0.01479	0.7550	0.7602	0.8284
70	0.02345	0.01253	0.7510	0.9381	0.8913
75	—	—	—	1.0220	0.9412
80	—	—	—	1.0310	0.9910
85	—	—	—	1.0610	—

\* Retroflex region (see later table).

All the above values were determined directly.

Throughout in the cases of sodium bromide, barium bromide, and barium iodide the solid phases were respectively NaBr, BaBr<sub>2</sub>, and BaI<sub>2</sub>.

In the case of calcium bromide, below 17.0° the solid phase is CaBr<sub>2</sub>·4C<sub>2</sub>H<sub>5</sub>·OH, between 17.0° and 73.9° CaBr<sub>2</sub>·3C<sub>2</sub>H<sub>5</sub>·OH, and above 73.9° CaBr<sub>2</sub>·C<sub>2</sub>H<sub>5</sub>·OH (CaBr<sub>2</sub>·4C<sub>2</sub>H<sub>5</sub>·OH: ethyl alcohol found, 48.6; calc., 48.0%. CaBr<sub>2</sub>·3C<sub>2</sub>H<sub>5</sub>·OH: ethyl alcohol found, 42.4; calc., 40.9%. CaBr<sub>2</sub>·C<sub>2</sub>H<sub>5</sub>·OH: ethyl alcohol found, 20.5; calc., 18.7%). The form of the solubility curves exhibits a close parallelism to those of calcium chloride in water and in methyl alcohol.

When lithium bromide and alcohol were brought together, great heat was developed and a solution of a slightly brown tint was obtained. At 25° and 30° the solution was very viscous, and consequently took a long time to settle sufficiently to allow of measurements being taken. In the temperature range 13.2° to 23.8° there is a retroflex region, the solid phase being LiBr·4C<sub>2</sub>H<sub>5</sub>·OH (ethyl alcohol found, 69.2; calc., 67.9%). The congruent melting point of the tetra-alcoholate was 23.8°, and the solid phase in contact with the saturated solution at the higher temperatures has the composition LiBr. The eutectic point for the anhydrous salt and the alcoholate is 13.2°. The alcoholate crystallises in flat plates which are highly deliquescent in the atmosphere, and, owing to the

hygroscopicity of the salt, it was impracticable to determine its affinity for alcohol. Greater detail regarding the eutectic region is given in the following table :

Retroflex Region of the Solubility of Lithium Bromide in Ethyl Alcohol.

Solubility in gram of lithium bromide per gram of ethyl alcohol with solid phases.

Temp.	LiBr.	LiBr, 4C <sub>2</sub> H <sub>5</sub> .OH.	LiBr, 4C <sub>2</sub> H <sub>5</sub> .OH.
13.2°	0.700	0.700	0.700
15.0	0.702	0.687*	0.381
16.0	0.704	0.675*	0.390
20.0	0.708	0.606*	0.420
23.0	0.712	0.530*	0.460
23.8	0.713	0.472	0.472

The asterisked values were obtained by thermal analysis, the remaining values being obtained either by direct determinations of solubility or from a graph.

When the barium iodide was brought into contact with the alcohol great heat was developed, and in a short time the solution acquired an orange tint due to the presence of traces of free iodine. A fresh solution was made in a black flask, but even in this the colour again developed and it was found impossible to obtain colourless solutions.

## XLII.—The Dissociation Pressures of Alcoholates. Part I.

By DAVID GLYNWYN ROBERT BONNELL and WILLIAM JACOB JONES.

No account of work on this subject has yet been published, and because of its importance in relation to the affinity of salts for the alcohols and to residual affinity in general, we have undertaken the present investigation.

The methods, which are applicable in the case of hydrates, may be divided into the following classes : (a) indirect, (b) tensimetric, and (c) dynamical, or gas current saturation. In the following, the applicability of each method is discussed.

Among indirect methods are those of Müller-Erbach (*Ber.*, 1881, 14, 1093; *Z. physikal. Chem.*, 1888, 2, 113), Wilson (*J. Amer. Chem. Soc.*, 1921, 43, 704), Lescœur (*Ann. Chim. Phys.*, 1889, 16, 378; 1890, 19, 533), Cumming (J., 1909, 95, 1772), Linebarger (*Z. physikal. Chem.*, 1894, 13, 500), Foote and Scholes (*J. Amer. Chem. Soc.*, 1911, 33, 1309), and Noyes and Westbrook (*ibid.*, 1921, 43, 726). Müller-Erbach employed two methods. In the first,

he compared the rates of diffusion of aqueous vapour from water and from the hydrate. His second method was to find the dilution of aqueous sulphuric acid solution over which the hydrate neither gained nor lost weight, and, when this was the case, the dissociation pressure was equal to the known aqueous pressure of the acid solution at the temperature of the experiment. Wilson's method is identical in principle with the latter method of Müller-Erbach. This method might be made applicable to alcoholates if, first, the aqueous sulphuric acid were replaced by an alcoholic solution of a difficultly volatile substance and, secondly, the alcoholic vapour pressures of solutions of various concentrations of this substance in alcohol had been previously determined at various temperatures. The time required for such an investigation might, however, be prohibitive. Both Lescoeur and Cumming determined the dew point of the vapour phase in equilibrium with the pair of hydrates. Their method is directly applicable to the alcoholates, but, where the dissociation pressure is low, suffers from the disadvantage that the steep gradient of temperature in the apparatus introduces a serious source of error. Linebarger found the aqueous vapour pressure of a pair of salt hydrates, at the boiling point of ether, by determining the boiling point of the moist ether in contact and equilibrium with them, and then referring to a table giving the boiling points of various aqueous ether mixtures and their partial aqueous vapour pressures at those temperatures. Foote and Scholes shook a mixture of two hydrates with alcohol, and, after the attainment of equilibrium, determined the water content of the alcoholic layer. The dissociation pressure of the hydrate at the temperature of the experiment is equal to the known partial pressure of a water-alcohol mixture of the same composition as this layer. Noyes and Westbrook have employed a method which in principle is identical with that of Foote and Scholes, the reference liquid used being *iso*-amyl alcohol. In the latter three methods, the properties of the reference liquids are so strictly circumscribed that it would be difficult to find a suitable liquid for use in the investigation of the alcoholates. Thus the salt must be insoluble in the reference liquid, the reference liquid must not form stable solid solvates with the salts in the presence of the alcohols, its affinity for the alcohols must be negligible compared with that of the salts for alcohol, and it must be only partly miscible with alcohol.

In order to apply the tensimetric method of Frowein (*Z. physikal. Chem.*, 1887, 1, 1, 362), a liquid in which the alcohols are insoluble has to be employed in the manometer, and mercury, which is the only practicable liquid, is so dense that accuracy cannot be conveniently obtained by its use. Moreover Menzies (*J. Amer. Chem. Soc.*, 1920,

42, 1952) has found that it is extremely difficult to evacuate the tensimeter satisfactorily.

The dynamical method, which is originally due to Tammann (*Ann. Physik*, 1888, **33**, 329), has been elaborated and perfected for the hydrates by Partington (J., 1911, **99**, 466), Baxter and Lansing (*J. Amer. Chem. Soc.*, 1920, **42**, 419), Partington and Huntingford (J., 1923, **123**, 160), Schumb (*J. Amer. Chem. Soc.*, 1923, **45**, 342), and Baxter and Cooper (*ibid.*, 1924, **46**, 923). We have found that this method is eminently suited to the investigation of the dissociation pressures of the alcoholates.

Two objections have been urged against this method, namely, first, that equilibrium is approached only from the side of undersaturation of the air current, and, secondly, that attainment of equilibrium between vapour phase and crystals is so slow that the time allowed in the passage of the air over the solid is insufficient. The first objection is disposed of by the data in Table I, where some experiments are detailed in which the equilibrium was approached both from undersaturation and from supersaturation, with results which within experimental error are identical. The second objection can be met only by ensuring that the rate of passage of air employed in the experiments is sufficiently slow, and by demonstrating that the same value is obtained for the dissociation pressures when a considerably slower rate is employed. The necessary slowness of the current depends, among other things, on the nature of the solvent, the salt, the temperature, and the dimensions of the saturator used. In our experiments the passage of 100 c.c. per hour gave the same result as that obtained with 500 c.c. per hour, and these were the extreme rates used. Furthermore, the fact that in our experiments air which was initially supersaturated with alcohol vapour gave the same result as air which was initially dry proves that the air leaving the saturator was adequately saturated with alcohol vapour and that a true state of equilibrium was attained.

#### EXPERIMENTAL.

The method adopted in the present work consisted in drawing a measured volume of dry air, free from carbon dioxide, through an intimate mixture of the pair of alcoholates, and finding the weight of alcohol vapour taken up by the air, either by collecting the alcohol in weighed U-tubes containing phosphorus pentoxide, or by determining the loss of weight of the mixture. The air, which was drawn through the mixture of alcoholates by means of an aspirator, was purified by passage in succession through concentrated sulphuric acid, a large calcium chloride tower, a U-tube filled with broken sticks of potassium hydroxide, and finally a 210 cm. train of freshly

prepared phosphorus pentoxide powder mixed with glass wool. The purified air passed into the saturator, which was similar in form to that used by Partington (J., 1911, 99, 468, Fig. 1A), except that our U-tubes were sealed off instead of being closed with paraffined corks. The saturator was filled to the level of the side tube with a mixture of the pair of alcoholates under investigation. The diameter of the column of mixture was 2 cm. and its mean length 42 cm. The saturator was immersed in a thermostat with only the side tubes emergent. A differential mercury manometer attached to the exit side tube served to give the difference in pressure between the external atmosphere and the mixture of air and alcohol vapour as it left the saturator, and consequently the sum of the partial pressures of the alcohol and air could be found. The saturated air afterwards passed into a U-tube filled with phosphorus pentoxide mixed with glass wool, whereby it was deprived of its alcohol. All connexions in this part of the apparatus were made with tightly fitting rubber tubing, inside which the ends of the glass tubes were brought into contact with each other. The air next passed into a U-tube filled with calcium chloride, which served as a trap to prevent back-diffusion of moisture from the aspirator in which the air was finally collected. At the beginning of the experiment the aspirator was filled to the top with water, which had been allowed to come to room temperature before the air current was started. The air inlet tube reached practically to the bottom of the water in the aspirator, and the air acquired the temperature of the aspirator during its passage downwards through the inlet tube and upwards through the water to the top of the aspirator, where it collected. The volume of air passed over the alcoholates was found by weighing the water expelled from the aspirator. The temperature of the room was maintained constant. An open-limb differential mercury manometer served to give the difference in pressure between the air collected inside the aspirator and the external atmosphere.

Care was taken that the dry air always entered the saturator at the same end in order that the air leaving the saturator should always come into contact with a mixture of both solid phases. Similar care was taken with the phosphorus pentoxide tube in order to retain all traces of alcohol. Atmospheric moisture was rigorously excluded in the preparation of the alcoholates, and in their transfer to the saturator, which had been previously thoroughly dried by a current of hot air.

The alcoholic dissociation pressure,  $p$ , of the pair of alcoholates under investigation at the temperature of the thermostat is given in mm. of mercury by the equation  $p/p' = v/(V + v)$ , where  $v$  and  $V$  are the respective volumes of alcohol vapour and dry air in the

mixture leaving the saturator at the temperature of the experiment and under the pressure  $p'$ , which is the sum of the partial pressures of the alcohol vapour and air as they leave the saturator, expressed in mm. of mercury. Since we are dealing with a ratio of volumes, the ratio of the pressures is unaltered if we substitute the values of the volumes at  $N.T.P.$ , which can be determined as follows :

$$v = \frac{22410m}{M}; \quad V = \frac{273.1(P-f)W}{(273.1+t)760d},$$

wherein  $m$  is the mass of alcohol in grams lost from the saturator and  $M$  is the molecular weight of the alcohol,  $P$  is the final pressure of the air inside the aspirator,  $f$  is the aqueous vapour pressure at the temperature,  $t^\circ$ , of the aspirator, both pressures being expressed in mm. of mercury,  $W$  is the mass in grams in a vacuum of the water expelled from the latter, and  $d$  its density.

$$\text{Thus } p = \frac{22410 \times 760(273.1+t)p'md}{273.1 \times WM(P-f) + 22410 \times 760(273.1+t)md}.$$

$P$  is determined by taking the barometer reading at the end of the experiment and subtracting therefrom the reading of the aspirator manometer.

The sum of the partial pressures,  $p'$ , is equal to the average barometric pressure during the run minus the average value of the readings of the mercury manometer attached to the exit tube of the saturator.

The mass,  $m$ , of the alcohol lost by the saturator was found either by the increase in weight of the phosphorus pentoxide tube or by the decrease in weight of the saturator, or by both means. In these weighings suitable counterpoises were employed. Both methods agreed, as is shown in the tables.

In a typical experiment the results obtained were as follows :  $\text{CaBr}_2, 3n\text{-C}_3\text{H}_7\cdot\text{OH} - \text{CaBr}_2$  at  $60^\circ$ .  $P$  766.7;  $p'$  764.7;  $t$   $17.7^\circ$ ;  $f$  15.0;  $d$  0.99868;  $W$  4281;  $M$  60.06;  $m$  by loss in weight of saturator 0.2200;  $m$  by gain in weight of phosphorus pentoxide tube 0.2193; giving  $p$  by loss in weight of saturator 15.447, and by gain in weight of phosphorus pentoxide tube 15.398, in both cases in mm. of mercury.

The losses in weight of the saturators recorded in the present experiments were between 0.0148 and 0.6271 g., whilst the volumes of air employed fell between 356.4 and 14155 c.c.

In order to eliminate initial disturbances due to liquid alcohol adhering to the crystalline alcoholates each new charge in the saturator was aged by drawing through it a small volume of dry air before the readings were begun.

The present method is applicable only where the dissociation

pressure is lower than the vapour pressure of the pure alcohol at room temperature, since, if the former is greater than the latter, condensation will occur in the side tubes which emerge from the thermostat.

### Results.

In Table I,  $p_i^s$  denotes the values of  $p$  at  $t^s$  determined from super-saturation, and  $p_u^s$  those determined from undersaturation, by the gain in weight of the  $P_2O_5$  tube, and  $p_i^v$  and  $p_g^v$  denote the values of  $p$  determined from the loss in weight of the saturator and the gain in weight of the  $P_2O_5$  tube, respectively.

TABLE I.

$p_i^{30^s}$	19.99, 19.57, 19.78, 19.82, 19.88.

Determinations of the dissociation pressures of other alcoholates are now in progress, and it is hoped to make the results obtained and the comparison of the affinities of the alcohols for salts the subjects of a further communication.

We desire to thank the Chemical Society for a grant which partly defrayed the expenses incurred in this investigation.

UNIVERSITY COLLEGE, CARDIFF.

[Received, November 28th, 1925.]

### XLIII.—The 4- and 4'-Methoxybenzoylbenzoins.

By HERBERT GREENE.

ALKALINE reagents and notably sodium ethoxide convert benzoyl-mandelonitrile (Francis and Davis, J., 1909, 95, 1404) into benzoylbenzoin (Robinson and Robinson, P., 1913, 29, 266; J., 1914, 105, 1456). By adding benzaldehyde to the reaction mixture, Greene and Robinson (J., 1922, 121, 2182) increased the yield of this product and found similarly that benzoylpiperoin was advantageously prepared from a mixture of benzoyl-3:4-methylenedioxy-mandelonitrile and piperonal. These observations were in harmony with Lapworth's view of the course of the benzoin reaction (J., 1903, 83, 1004) and further evidence of a condensation of the aldol type was obtained when the interaction of benzoyl-mandelonitrile and anisaldehyde resulted in the isolation of a methoxybenzoylbenzoin melting at 119·5—120·5°. The structure of this product is discussed below.

It was also shown that 3:4-methylenedioxybenzoylbenzoin,  $\text{CH}_2\text{O}_2\text{:C}_6\text{H}_3\text{CO·CH(OBz)Ph}$  (I), is the main product of condensation between benzoyl-3:4-methylenedioxy-mandelonitrile and benzaldehyde, whereas 3':4'-methylenedioxybenzoylbenzoin,

(II), is obtained from benzoyl-mandelonitrile and piperonal. A migration of the benzoyl group was therefore definitely established. By reducing the time of reaction, these products may be obtained almost pure, and the same is true of the piperonyl-furyl isomerides,

to which, by analogy, structures (III) and (IV) are assigned. The similarity existing between benzaldehyde and furfuraldehyde extends in this case to the yields of "mixed" benzoin. Thus substances (I) and (III) are obtained in small yield only (5 to 10%), whereas piperonal reacts with the benzoylcyanohydrins of these two aldehydes to give substances (II) and (IV) in much larger amount (25 to 30%).

In the same way, anisaldehyde and benzoylmandelonitrile react to give 4'-methoxybenzoylbenzoin (V; m. p. 127—128°), whilst benzoyl-*p*-methoxymandelonitrile and benzaldehyde yield the isomeric 4-methoxybenzoylbenzoin (VI; m. p. 119.5—120.5°). Here, however, the allocation of formulæ is not so simple, for the lower-melting isomeride is also obtainable from the other reaction mixture (Greene and Robinson,\* *loc. cit.*, p. 2189). In fact, either of the isomerides may be obtained from benzoylmandelonitrile and anisaldehyde. The reaction system is very sensitive to changes in the experimental conditions, which have therefore been studied in detail.

On standing in contact with cold sodium ethoxide solution, both isomerides are hydrolysed to *p*-methoxybenzoin (Ekecrantz and Ahlqvist, *Arkiv Kem. Min. Geol.*, 1908, 3, No. 13, 26). It is desirable, therefore, to interrupt the reactions some 15 minutes after addition of the condensing agent, and when this is done the yields are roughly as follows:

	Benzoylmandelonitrile and anisaldehyde.	Benzoyl- <i>p</i> -methoxymandelonitrile and benzaldehyde.
$\frac{1}{2}$ Mol. of NaOEt. Rapid interruption.	Higher-melting isomeride, 30%.	No crystalline product.
1 Mol. of NaOEt. Rapid interruption.	Lower-melting isomeride, 8%.	Lower-melting isomeride, 15%.
$\frac{1}{2}$ Mol. of NaOEt. Gradual addition.	Both isomerides.	Benzoylbenzoin.

In the cases mentioned above, the diminution of the quantity of sodium ethoxide to a half-molecular proportion leads to the spontaneous separation of substances I, II, III, and IV. It seems reasonable, therefore, to regard the isomeride melting at 127—128° as the normal product of condensation between benzoylmandelonitrile and anisaldehyde, and this substance is therefore 4'-methoxybenzoylbenzoin. The isomeride of m. p. 119.5—120.5° is accord-

\* Compare this communication for the scheme of numbering.

ingly 4-methoxybenzoylbenzoin and its occurrence as a product of condensation of benzoylmandelonitrile and anisaldehyde appears to be due to a double decomposition which results in the formation of benzaldehyde and benzoyl-*p*-methoxymandelonitrile. The following results demonstrate that such a reaction can occur. Attempted condensations of benzoylmandelonitrile and furfuraldehyde on the one hand and of benzoylfurfuraldehydecyanohydrin (VII) and benzaldehyde on the other have uniformly furnished mixtures of benzoylbenzoin (m. p. 125°) and benzoylfuroin (m. p. 92—93°) in slightly varying proportions.

It is clear that the formation of benzoylfuroin from benzoylmandelonitrile and furfuraldehyde involves preliminary transference of the benzoyl cyanide addenda from benzaldehyde to furfuraldehyde. The benzoylfurfuraldehydecyanohydrin so formed then reacts with unchanged furfuraldehyde in the normal manner, and benzoylfuroin is, in fact, readily accessible through this derivative. In the second series of experiments, we have the inverse change. Some benzoylmandelonitrile is formed at the expense of the benzoylfurfuraldehydecyanohydrin, and it then reacts with unchanged benzaldehyde, yielding benzoylbenzoin. All these reaction mixtures originally contained excess of free aldehyde, and accordingly, where the gradual addition of sodium ethoxide during a period of three or four hours has favoured equilibrium, the products of this type of change are present in relatively greater amount.

Under similar conditions, benzoylbenzoin was actually the only crystalline product obtained from benzoyl-*p*-methoxymandelonitrile and benzaldehyde (table above). Here again we must infer degradation of the original nitrile and formation of benzoylmandelonitrile, which subsequently undergoes its normal condensation with unchanged benzaldehyde. With benzoylmandelonitrile and anisaldehyde, the concomitant processes are represented by the scheme below, in which it has not been considered necessary to illustrate the contemporaneous formation of benzoylbenzoin and benzoylanisoin.

In the studies now recorded, the formation of isomeric derivatives of mixed benzoins was observed in three out of four cases. It is apparently favoured by disparity of the constituent aldehydes.

#### EXPERIMENTAL.

*Benzoylfurfuraldehydecyanohydrin.*—Always a good and, on one occasion, a practically theoretical yield of this substance was

obtained by application of the general method of Francis and Davis (*loc. cit.*). Furfuraldehyde (24 g.), benzoyl chloride (35 g.), and a solution of potassium cyanide (17 g.) in water (200 c.c.) were shaken together for 1 hour with cooling. The product separated from 90% alcohol in colourless, hexagonal plates (Found: C, 68.9; H, 4.3.  $C_{13}H_9O_3N$  requires C, 68.7; H, 4.0%). This material, m. p. 48°, was used for the preparation of the derivatives described below. Distillation under reduced pressure and recrystallisation from alcohol raise the melting point to 49°.

*Benzoylfuroin*,  $C_4H_3O \cdot CO \cdot CH(OBz) \cdot C_4H_3O$ .—A cold solution of sodium ethoxide (0.6 g. of sodium) in ethyl alcohol (30 c.c.) was rapidly added to one of benzoylfurfuraldehydecyanohydrin (11 g.) and furfuraldehyde (12 g.) in ethyl alcohol (25 c.c.). The reaction mixture was shaken for 4 minutes in running water, which checked a slight rise of temperature, and then cooled in ice-water. The product that separated was collected after 15 minutes and extracted with boiling ethyl alcohol (20 c.c.). The filtered solution yielded 6.15 g., m. p. 92–93° (Found for twice recrystallised material: C, 68.7; H, 4.1.  $C_{17}H_{12}O_5$  requires C, 68.9; H, 4.0%); a further 1.2 g., m. p. 91–93°, could be isolated. The substance separates from alcohol in colourless octahedra, the predominant prismatic modification being derived by prolongation along one axis. With cold concentrated sulphuric acid, an intense green colour is developed and this gradually changes to brown on warming. By the action of alcoholic sodium ethoxide, a small amount of furil, m. p. 164°, was produced, which was identified by the melting point of its mixture with an authentic sample (E. Fischer, *Annalen*, 1882, 211, 221).

*Benzfuroin*.—It seemed possible to clear up the question as to whether benzfuroin (E. Fischer, *loc. cit.*) is a single substance by benzoylating it and comparing the product with the isomeric benzoylbenzfuroins.

Benzfuroin was recovered unchanged after being shaken with aqueous potassium hydroxide and benzoyl chloride, even in presence of ether, or with pyridine and benzoyl chloride, and heating with the acid chloride alone resulted in profound decomposition. Difficulties of quite another kind were met in attempts, described in detail below, to prepare the isomeric derivatives; for the most part, mixtures of benzoylbenzoin and benzoylfuroin were obtained. Neither of the required isomerides being present in isolable amount, this method of attack was abandoned. There are, however, grounds for believing that benzfuroin is a mixture of two isomerides.

The melting points of four preparations of benzfuroin showed variations (recorded: 135–141°, 134–135°, 134–137°, 138–140°).

These may, of course, be due in part to the presence of benzoin or furoin. Benzofuroin was the sole product isolated in an attempt to prepare a benzoylbenzfuroin by the very slow addition, during 5 or 6 hours with water cooling, of sodium ethoxide (1.15 g. of sodium) in ethyl alcohol (40 c.c.) to a cold solution of benzoylmandelonitrile (11 g.) and furfuraldehyde (12 g.) in ethyl alcohol (40 c.c.). The product (1.9 g.) was isolated by means of ether and crystallised from boiling water, giving 0.5 g. of long, feathery crystals, m. p. 139—141°. The granular, amorphous residue was recrystallised from a little absolute alcohol and then from aqueous alcohol. This material (0.2 g.) melted at 141.5—143.5°, and at 138—140° when mixed with the other fraction or with benzofuroin (m. p. 137—139°) prepared by Fischer's method. The possibility that benzofuroin was here the product of hydrolysis again suggests its composite character. Finally, apart from decomposition, the material was practically unchanged by the action of boiling alcoholic sodium ethoxide, a reagent which doubtless induces enolisation. The recovered material softened at 136° and melted at 140—142°, alone or mixed with the original material.

*Attempts to prepare Isomeric Benzoylbenzfuroins.*—In each experiment the reaction mixture was treated with ether and water. The ethereal layer was washed successively with aqueous sodium bisulphite, sodium carbonate solution, and water, and dried with anhydrous sodium sulphate. The following table summarises the results of the experiments.

		Products from	
		Benzoylmandelonitrile and furfuraldehyde.	Benzoylfurfuralde- hydecyanohydrin and benzaldehyde.
½ Mol. of NaOEt.	Rapid interruption.	Benzoylbenzoin and benzoylfuroin.	Benzoylbenzoin and benzoylfuroin.
1 Mol. of NaOEt.	Rapid interruption.	Ditto (together with benzofuroin).	Benzoylbenzoin and benzoylfuroin (A).
½ Mol. of NaOEt.	Gradual addition.	Ditto (richer in benzoylfuroin).	Ditto (richer in benzoylbenzoin).

The following is a typical experiment resulting in the formation of the product (A). A solution of sodium ethoxide (1.15 g. of sodium) in ethyl alcohol (30 c.c.) was added in one portion to one of benzoylfurfuraldehydecyanohydrin (11.4 g.) and benzaldehyde (10 g.) in ethyl alcohol (30 c.c.). The mixture was shaken in running water for 15 minutes and then extracted as above. After removal of solvent and addition of a little methyl alcohol, crystals readily separated, which were filtered off after 3 hours (4.3 g.). Recrystallised from 90% alcohol (15 c.c.), they melted at 87—88° and showed under the microscope a variety of shapes strongly resembling those observed in the case of 4-methoxybenzoylbenzoin. This crop was

recrystallised from 90% alcohol (15 c.c.), giving two crops, and a third by addition of water: Crop I, 2.45 g., m. p. 86—87°; crop II, 0.75 g., m. p. 87°; crop III, 0.26 g., m. p. 85—87°. Crop I, recrystallised from absolute alcohol, gave two crops, of which the larger weighed 2.19 g. and melted at 86—87°. It still showed a variety of shapes under the microscope (Found: C, 74.0; H, 4.7.  $C_{21}H_{16}O_3 + C_{17}H_{12}O_5$  requires C, 74.5; H, 4.6%). For comparative purposes, an equimolecular mixture of benzoylfuroin and benzoylbenzoin was prepared. After preliminary softening, this began to melt at 85.5° and still contained some solid at 90°, whilst when mixed with product (A) it melted at 84.5—88°. This leads us to conclude that both mixtures are in the neighbourhood of the eutectic. Product (A) is therefore a mixture containing benzoylfuroin, benzoylbenzoin, and probably some benzoylbenzfuroin, although this has on no occasion been isolated.

4-Methoxybenzoylbenzoin (VI; m. p. 119.5—120.5°).—This substance, obtained with fortuitous ease from a reaction mixture of benzoylmandelonitrile and anisaldehyde, was described (Greene and Robinson, *loc. cit.*) as 4'-methoxybenzoylbenzoin. Reasons for adopting the alternative configuration have now been given.

4-Methoxybenzoylbenzoin is best prepared by condensing benzoyl-*p*-methoxymandelonitrile and benzaldehyde. The reaction requires rather more than 1 mol. of sodium ethoxide and should be rapidly interrupted. Thus 1.5 g. of nearly pure material were obtained when a solution of sodium ethoxide (0.6 g. of sodium) in alcohol (20 c.c.) was added in one portion to the nitrile (7.3 g.) and benzaldehyde (10 g.) in cold alcoholic solution (20 c.c.). The reaction lasted 10 minutes.

To observe the abnormal production of this isomeride from benzoylmandelonitrile and anisaldehyde, it is desirable to reduce the time of reaction and so check hydrolysis. A solution of sodium ethoxide (1.3 g. of sodium) in alcohol (25 c.c.) was added in one lot to a solution of benzoylmandelonitrile (12 g.) and anisaldehyde (11 g.) in alcohol (30 c.c.). Rise of temperature was checked by shaking the reaction mixture in running water, and after 7 minutes the material was extracted by addition of ether and water. After removal of the solvent, the residual liquor was treated with methyl alcohol and light petroleum. Cooling in ice and salt gave crystals which, once recrystallised from alcohol, weighed 0.9 g. and melted between 118° and 120°. These were identical with the original specimen (Greene and Robinson, *loc. cit.*) (Found: MeO, 7.9, 8.1. Calc. for  $C_{22}H_{18}O_4$ , MeO, 9.0%).

*Abnormal Production of Benzoylbenzoin.*—On three occasions when  $\frac{1}{2}$  mol. of sodium ethoxide was added drop by drop to alcoholic

solutions of benzoyl-*p*-methoxymandelonitrile and benzaldehyde, small quantities of benzoylbenzoin were obtained in a good state of purity. This unexpected result was ascertained in one case by combustion and the method of mixed melting point and in the others by the latter method only. The characteristic prismatic rods of benzoylbenzoin were also readily recognisable under the microscope. The yields of this product, starting in each case from 11.5 g. of benzoyl-*p*-methoxymandelonitrile and 11 g. of benzaldehyde, were 1.6 g. (m. p. 122—125°), 0.7 g. (m. p. 120—123°), and 0.6 g. (m. p. 119—122°), respectively. The condensation of benzoyl-*p*-methoxymandelonitrile with anisaldehyde does not afford a convenient means of preparing benzoylanisoin.

*4'-Methoxybenzoylbenzoin* (V; m. p. 127—128°).—A solution of sodium ethoxide (1.15 g. of sodium) in ethyl alcohol (30 c.c.) was added in one portion to benzoylmandelonitrile (23 g.) and anisaldehyde (22.5 g.) dissolved in ethyl alcohol (30 c.c.). The mixture was shaken in running water for 5 minutes and then worked up in the usual manner. The crystals (3.4 g.) which separated from the ether, recrystallised from 90% alcohol (75 c.c.), had m. p. 125—127°. The ethereal mother-liquor was treated as usual, and the crop recovered from the drying agent (magnesium sulphate) by addition of water, on recrystallisation, gave 4.9 g. of m. p. 124—127°; from the ethereal solution 2.4 g. of m. p. 121—124° were obtained. The pure product melted at 127—128° (Found: C, 76.1; H, 5.3; MeO, 8.5.  $C_{22}H_{18}O_4$  requires C, 76.3; H, 5.2; MeO, 9.0%). A mixture with the isomeride described above melted at 100—104°. *4'*-Methoxybenzoylbenzoin crystallises from alcohol or ether in colourless, prismatic rods and dissolves in cold concentrated sulphuric acid to a brassy yellow solution which, on warming, remains yellow for a time and then suddenly passes through reddish-brown to dark greenish-brown.

A further illustration of the sensitive nature of the general reaction was provided by an experiment in which a cold solution of sodium ethoxide (0.6 g. of sodium) in alcohol (25 c.c.) was, during 3 or 4 hours, gradually added to a cold solution of benzoylmandelonitrile (12 g.) and anisaldehyde (11 g.) in ethyl alcohol (30 c.c.). Some crystals separated during the course of the reaction, which was controlled by water cooling. These were filtered off, washed with water and alcohol, and recrystallised from alcohol. The substance (0.1 g.) had m. p. 120—124°, which was raised to 120—126° by admixture with *4'*-methoxybenzoylbenzoin and depressed by admixture with the other isomeride. The filtrate of the reaction mixture was extracted as usual and gave a syrup from which, by ~~recrystallisation~~, *4*-methoxybenzoylbenzoin (0.3 g.) was obtained.

*Piperonyl- $\alpha$ -furylcarbinyl Benzoate* (III).—This substance was obtained from benzoylmethylenedioxymandelonitrile (28 g.) and furfuraldehyde (23 g.) in alcohol (30 c.c.) by addition in one lot of a solution of sodium ethoxide (1.15 g. of sodium) in ethyl alcohol (30 c.c.). The mixture was shaken in running water for 5 minutes and then extracted as in other cases. From the ethereal solution, a crop was obtained which, after one recrystallisation from 90% alcohol (45 c.c.), gave 3.3 g. of crystals, m. p. 130—132°. A smaller fraction (1.3 g.), m. p. 117—130°, was recovered from the drying agent. In two half-scale experiments the yields were 1.4 g. of m. p. 125—130° and 1.6 g. of m. p. 125—129°. In the former, the reaction was allowed to proceed for 20 minutes before extraction, and this delay seems to have decreased the yield. Increase of the proportion of sodium to 1.1 g. for 14.1 g. of nitrile in a reaction which lasted 15 minutes led to the isolation of an impure product (3.4 g.), m. p. 103—106°.

From the three earlier experiments were obtained 6.6 g. of material, m. p. 131.5—133.5°, and for analysis a portion of this was recrystallised from glacial acetic acid, toluene and rectified spirit. The pure product melted at 132.5—133.5° (Found: C, 68.5; H, 4.1.  $C_{20}H_{14}O_6$  requires C, 68.6; H, 4.0%). The substance crystallised from alcohol in colourless, prismatic rods and when mixed with its isomeride of m. p. 140—141°, melted at 110—115°.

*$\alpha$ -Furoylpiperonylcarbinyl Benzoate* (IV).—This substance was prepared readily and in good yield by the condensation of piperonal (12 g.) with benzoylfurfuraldehydecyanohydrin (11 g.) in ethyl alcohol (40 c.c.). Sodium ethoxide (0.6 g. of sodium) in ethyl alcohol (20 c.c.) was added in one portion and the mixture was shaken in running water. After 25 minutes, the solid was collected, and only a minute quantity was recovered from the mother-liquor. The substance was recrystallised from glacial acetic acid (25 c.c.) and from ethyl alcohol (80 c.c.), and the main crop (4.7 g.) had m. p. 136—138°. For analysis, this material was recrystallised from alcohol, glacial acetic acid, 90% alcohol, toluene, and 90% alcohol, giving 3.1 g. of the pure substance, m. p. 140—141° (Found: C, 68.8; H, 4.1.  $C_{20}H_{14}O_6$  requires C, 68.6; H, 4.0%). The colourless, hexagonal plates dissolve in cold concentrated sulphuric acid to an intense crimson solution tinged with brown.

3:4- and 3':4'-*Methylenedioxybenzoylbenzoins* (I and II).—By reducing the time of reaction hydrolysis has been lessened and more convenient methods of preparing these isomerides are now submitted.

A solution of sodium ethoxide (0.6 g. of sodium) in ethyl alcohol (20 c.c.) was added to benzoylmandelonitrile (12 g.) and piperonal (11 g.) in ethyl alcohol (40 c.c.). The mixture was shaken in

running water for 15 minutes and extracted with ether. The solid residue was crystallised from glacial acetic acid, giving 2.6 g. of material, m. p. 132.5—134.5°, and 1.1 g., m. p. 129—132°. The ethereal solution after the usual treatment gave 1.9 g. of crystals, m. p. 127—131°. A portion of this product, recrystallised once, was identical with authentic 3':4'-methylenedioxybenzoylbenzoin, m. p. 134—135°.

From benzoylmethylenedioxymandelonitrile (14.1 g.) and benzaldehyde (11 g.) dissolved in alcohol (40 c.c.) there were obtained, by addition, in one portion, of a solution of sodium ethoxide (0.6 g. of sodium) in alcohol (20 c.c.), 1.1 g. of a product, m. p. 144—147°, and 146—148° when mixed with 3:4-methylenedioxybenzoylbenzoin (m. p. 147.5—148.5°). In this experiment, the reaction was allowed to continue for 35 minutes.

When the time of reaction and the quantities of nitrile and aldehyde (but not of sodium) were halved, the percentage yield was almost doubled.

This work was carried out at the Universities of St. Andrews and Manchester. The author takes this opportunity of thanking Prof. R. Robinson, F.R.S., for his interest in it, and also the Carnegie Trustees for the award of a scholarship.

#### XLIV.—*The Reaction between Hydroxylamine and Ferric Chloride.*

By ALEC DUNCAN MITCHELL.

HYDROXYLAMINE is a compound of great interest from several points of view. Many years ago Haber showed (*Ber.*, 1896, 29, 2444) that it would oxidise ferrous salts in alkaline solution or suspension, and reduce ferric salts in acid solution, and he suggested that its structure in the two cases might be represented as  $H_3N \cdot O$  and  $H_2N \cdot OH$  respectively. The existence of such dynamic isomerides would account for the above behaviour, which is typical of many of the reactions of hydroxylamine, and, with the object of seeking a further basis for this hypothesis, the author has carried out several kinetic studies, since similar investigations have afforded such evidence in other cases (Mitchell, J., 1923, 123, 629, 2241).

The reactions of hydroxylamine are all very complicated, and, up to the present, only one, the subject of this communication, has been interpreted. It may be stated at once that, possibly because

the acidic solutions involved may exclude one isomeride, the results have no bearing on the main problem, but they are of interest in other respects.

A kinetic study of the reactions of hydroxylamine appeared desirable in that no such examination has hitherto been made. A survey of the literature discloses more than twenty reactions in which the ultimate products have been studied, but the mechanism underlying their formation has usually been ignored. There are two partial exceptions to this statement: (1) Raschig ("Schwefel- und Stickstoff-Studien," 1924) studied the stoichiometrical ratios obtaining at various stages in the course of certain reactions, but did not investigate them kinetically; and (2) Brönsted (*Z. physikal. Chem.*, 1922, **102**, 187) made a rough colorimetric estimate of the effect of a saline solution on the reaction now discussed, and, from the apparent absence of appreciable "salt effect," concluded that reaction takes place between the metallic ion and undissociated hydroxylamine molecule to form a "critical complex." As will be seen later, however, the more accurate method used here indicates a definite negative salt effect (p. 347).

There seemed to be two difficulties in the way of the proposed investigations: (1) few of the reactions proceed quantitatively in one direction, the majority giving varying proportions of by-products, and (2) hydroxylamine reacts more or less readily with most of the reagents which might normally be employed in the estimation of the second reactant or the products. The second difficulty has been obviated in the present instance by analytical methods which are described in the experimental portion of this communication. The first difficulty has been minimised by choosing reactions, such as that under discussion, which appear to give but little by-product. In the present case, the reaction is quantitative under the conditions laid down by Raschig (*Annalen*, 1887, **241**, 190)—considerable excess of ferric salt and of sulphuric acid, and at least five minutes' boiling. These conditions could not, for various reasons, be applied in the present research, but it is believed that the necessary departures from them involve only slight errors. There is no doubt that the difficulties which had to be overcome by Raschig were the slowness of the reaction in its later stages and the possible persistence of an intermediate product. The former difficulty is immaterial in an investigation such as this, and the latter is only of importance in so far as it affects analysis, but the method used is believed to eliminate this effect (p. 346). A consideration of the work of Bray (*J. Amer. Chem. Soc.*, 1919, **41**, 1363) in conjunction with that of Kurtenacker and Neusser (*Z. anorg. Chem.*, 1923, **131**, 27) shows that, using only a bare excess of ferric salt, reaction is incomplete

simply because it becomes extremely slow, and that, using neutral or very feebly acidic solutions, there is slight formation of elementary nitrogen, corresponding to 4%, at most, of the hydroxylamine. Apart from this, these authors find no evidence of side-reactions, and it would therefore appear that the departures from the prescribed conditions do not materially affect the present research. The author's experience confirms the production of traces of nitrogen

FIG. 1.

in the least acidic solutions, and also indicates that, under the conditions which are imposed upon this research—restrictions which often necessarily obtain in kinetic studies—traces of higher oxides of nitrogen are produced (p. 346).

#### *Mechanism of the Reaction.*

The complete reaction under ideal conditions is represented by

and the molar concentrations of the first four species will be repre-

sented by  $a$ ,  $b/2$ ,  $f$ , and  $h$  respectively. It will be seen that, if the suffix 0 represent these at zero-time, and the suffix  $t$  at any specified time corresponding to the reduction of  $x$  moles of ferric iron, then  $a_t = a_0 - x$ ,  $b_t = b_0 - x$ ,  $f_t = f_0 + x$ , and  $h_t = h_0 + 3x/2$ .

A few experiments using ferric chloride and hydroxylamine hydrochloride led to no conclusion as to the order of the reaction. The initial velocity was enormous, but was damped down so rapidly that, unless a reaction of about the tenth order was assumed, one had to ascribe repressing effects to one or more of the products of reaction. Even when the velocity became of a lower order, a reduction of, say, 5%, in the concentrations of ferric iron and hydroxylamine caused the velocity to be reduced to one-half or less (see Expt. 1 as an example). (The reduction of cupric salts by hydroxylamine in the presence of acetic acid and sodium acetate is found to be similar in this respect.)

The initial addition of hydrochloric acid produced much slower reactions, but the damping was still so marked that a second product of reaction was suspected of a repressing effect (see Fig. 1, Expt. 4). Initial addition of ferrous salts also produced a great depression in velocity whether hydrochloric acid had been added or not. (The effects of equi-molar additions of hydrochloric acid or ferrous salts were not quite the same.) When both hydrochloric acid and ferrous salts were present in fair concentration, the reaction was closely termolecular—bimolecular with regard to ferric iron and unimolecular with respect to hydroxylamine. The termolecular velocity coefficient fell off slightly, but this was provisionally attributed to the progressive accumulation of ferrous and hydrogen ions, as reaction in the presence of a large excess of both was too slow for a more rigid test to be practicable. No other type of ordinary velocity coefficient gave any approach to constancy.\*

\* In this connexion may be mentioned an interesting instance of the danger of relying on initial velocities from a few isolated experiments as a clue to the order of reaction: in a few runs with initial hydrochloric acid and hydroxylamine kept constant, the apparent initial velocity (that based on the gross change before the first titration) was roughly proportional to the initial concentration of ferric chloride, which was varied, and the erroneous deduction was drawn that this was involved to only the first order. The explanation is due to the fact that, as will be seen later, the velocity in these experiments is inversely proportional to the concentration of ferrous iron, so that  $\delta x \propto a^2/f$ ; since  $f$  increases from zero to  $\delta x$  in the small interval concerned, its mean concentration is  $\delta x/2$ , so that  $\delta x \propto a^2/\delta x/2$  as an approximation, or  $(\delta x)^2 \propto a^2$  or  $\delta x \propto a$ —thus accounting for the erroneous conclusion. Strictly, one is dealing with an integral summation starting with an infinite velocity for an infinitely short time, but actually the velocity is of a measurable order almost instantly, so that the approximation involved here is sufficiently near the truth to account for the observed facts.

The effects of the products of the reaction in repressing it indicated an equilibrium as an *intermediate* stage in the reaction; and it could be *only an intermediate stage* because the reaction goes to completion, forming the basis of Raschig's method for the estimation of hydroxylamine, so that the ultimate products could not reverse the reaction.

Further evidence bearing on the equilibrium was obtained when certain experiments, the early stages of which were too rapid for detailed measurement at 25°, were carried out at 15.5°. Seven experiments, of various types, all gave the temperature coefficient of 5.9 for 9.5°, which, by exponential proportion, becomes 6.5 for 10°. Just as temperature coefficients of less than unity—or negative coefficients as they would be if expressed more rationally—are interpreted as evidence of intermediate compounds (Eggert, *Z. Elektrochem.*, 1921, 27, 455, and Skrabal, *ibid.*, 1915, 21, 461, on the Landolt reaction, and Hasche and Patrick, *J. Amer. Chem. Soc.*, 1925, 47, 1214, on the reaction between nitric oxide and oxygen), so this abnormally high temperature coefficient is regarded as indicating the existence of an intermediate equilibrium, which is displaced, by a rise in temperature, in a direction more favourable to reaction, this accelerating effect being superimposed upon the normal temperature effect.

No attempt has been made to correct for incomplete ionisation of electrolytes; the corrections which have been made for salt effect (p. 349) in certain cases tend to make a rough correction of this kind, however, and serve to make experiments more comparable.

The recognised methods of treating reaction velocities fail where the indications are that the initial velocity is infinite or of a very high magnitude. It was therefore necessary to obtain expressions, even if they were empirical, which would represent the course of the reaction, before one could draw any conclusions of a quantitative nature, and subsequently a certain amount of theoretical justification was found for them. As a tentative expression the following was used:

$$\frac{dx}{dt} = k_1 \frac{(a-x)^2(b-x)}{(h+3x/2)(f+x)} \quad \dots \dots (1)^*$$

It is here necessary for the purposes of discussion to classify experiments into four types as follows:

(I) Those having only ferric chloride and hydroxylamine hydrochloride initially.

(II) Those having additional hydrochloric acid alone initially.

(III) Those having additional ferrous iron alone initially.

\* The integrals of all the formulæ used here are very cumbersome and their solutions are tedious, so details are omitted.

(IV). Those having both additional hydrochloric acid and ferrous iron initially.

Expression (1) gave for all experiments, except those of type (I), values for  $k_1$  which were reasonably constant in any one experiment, as is shown for two types by Expts. 5 and 18. The values showed a slight tendency to fall as a rule, and, as will be seen in the table, varied from one experiment to another in such a way as to suggest that the second power of  $(h + 3x/2)$  should replace the first power. When this amended expression

$$\frac{dx}{dt} = k_2 \frac{(a - x)^2(b - x)}{(h + 3x/2)^2(f + x)} \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (2)$$

is applied to the experiments the results are as shown in the same table. In this table, the values of  $a$ ,  $b$ ,  $f$ , and  $h$  are expressed in moles per litre and relate to initial conditions; the values of  $k_1$  and  $k_2$  as found from the differential determinations of velocity (see p. 347) are shown as well as those obtained by integration: the latter often obscure marked drifts towards the end of a reaction and thus are not so trustworthy in these circumstances as the differential values, although they are far less subject to experimental error. In experiments of types (I), (II), and (III), where the initial velocity is very great, the integrated values are a more trustworthy guide as to the course of the early stages of the reaction. Although  $k_2$  shows a rise throughout every reaction, it is noteworthy that its order of magnitude is very consistent throughout the whole range of experiments, which cover a wide variety of conditions and are usually continued until over 50% of the possible reaction is completed—this extent is indicated for each experiment in the column “% completed.” As it was highly improbable that this consistency was a mere coincidence, a search was made for a theoretical basis which would account for the general agreement and possibly afford a reason for the anomalies noticed.

If the hypothetical nitroxyl were produced according to the equation  $2\text{Fe}^{+++} + \text{NH}_2\text{OH} \rightleftharpoons 2\text{Fe}^{++} + 3\text{H}^+ + \text{HNO}$  (and subsequently decomposed to nitrous oxide), this would be expected to play a part in the repression of the reaction, and the effect of ferrous and hydrogen ions would be more nearly in proportion to the second and third powers of their respective concentrations. As a matter of fact, the introduction into the formulæ of any function of  $x$ , giving, for example,  $dx/dt = ka^2b/hfx$  or  $dx/dt = ka^2b/h^2fx$ , renders them quite incapable of representing the course of reaction; and the use of the second or third powers of  $f$  or  $h$  respectively is similarly useless. The absence from (2) of any term representing an intermediate compound seems to be capable of explanation as follows.

One has circumstantial evidence for assuming the formation of a complex, thus :

denoting the complex by  $M$  and its concentration by  $m$ , and assuming it to decompose to nitrous oxide according to a unimolecular law, we have for the rate of accumulation of  $M$  :

$$dm/dt = k_3 a^2 b - k_4 h^2 f m - k_5 m \quad . \quad . \quad . \quad (3)$$

and for the rate of diminution of ferric iron :

$$dx/dt = k_3 a^2 b - k_4 h^2 f m = dm/dt + k_5 m \quad . \quad . \quad . \quad (4)$$

(If one deals with the very early stages of reaction, it would be necessary to allow for the fact that a certain amount of hydrogen and ferrous ions is locked up in the complex  $M$ , and is therefore present as such in a concentration less by an amount  $m$  than the values  $(h + 3x/2)$  and  $(f + x)$ ; the error involved by ignoring this is small when  $h_0$  and  $f_0$  are finite, however, and the equations would become extremely complicated.)

After the very early stages of a reaction,  $m$  tends to keep nearly constant, owing to a compensating effect of the three reactions tending to adjust it; one would then have  $dm/dt = 0$ , and  $dx/dt = k_5 m = k_3 a^2 b - k_4 h^2 f m$ . Solving for  $m$  and substituting, one has

$$dx/dt = k_3 k_5 a^2 b / (k_4 h^2 f + k_5) \quad . \quad . \quad . \quad (5)$$

When both  $h_0$  and  $f_0$  are zero,  $dx/dt = k_3 a^2 b$ , independently of any simplifying assumptions, and, since reaction is so rapid, it is certain that  $k_3$  must be very large. Such a condition only obtains in the initial stages, to which expression (5) does not apply, owing to the nature of the assumptions made. The term  $k_4 h^2 f$  in experiments of types (II) and (III) rapidly becomes of a finite order, and in type (IV) is already of a finite order, so that, as soon as  $k_4 h^2 f$  becomes markedly greater than  $k_5$ , one arrives at the same expression as was obtained empirically,  $k_3 k_5 / k_4$  being equal to  $k_2$  in (2). The expressions (3) and (4) are too complicated for complete solution, so that one is unable to find whether they would account for the rise in the value of  $k_2$  or for certain other discrepancies to be discussed later.

It is possible that reaction involves the free undissociated basic molecule:  $2\text{Fe}^{+++} + \text{NH}_3\text{OH} \rightleftharpoons \text{Fe}^{++} + \text{H}^+ + (\text{NOH}, \text{Fe}, \text{H})^{+++}$ . This mechanism would lead to an expression such as (1) but the term  $(b - x)$  would have to be corrected in order to make it correspond to the free base. After the hydrogen-ion concentration reaches a value which is very early attained in experiments of types (I) and (III) and which obtains initially in the other types, this corrected

term becomes approximately  $(b - x)k_h/(h + 3x/2)$ ,  $k_h$  being the hydrolytic dissociation constant of hydroxylamine hydrochloride. An expression similar to (2) therefore results, and, as this expression is not applicable to the early stages, a decision between this possibility and that developed above cannot be made. It is believed, however, that the extremely rapid fall in the initial concentration of free basic molecules in experiments of types (I) and (III) would require an even greater fall in velocity than is actually found, so that the foregoing hypothesis is preferred.

### *Discussion of Results.*

An apparent anomaly is exhibited by Expts. 15 and 23 in type (III), since  $k_1$  rises at first in these cases but falls as a rule, and in this type alone  $k_2$  appears to be zero initially. The latter fact is immaterial in view of the way in which  $k_2$  is derived on theoretical grounds, and it cannot be expected to hold at  $t = 0$ . The fact that  $k_1$  exhibited a different behaviour in these experiments from the more usual behaviour is connected with the circumstance that initial ferrous iron depresses more than initial equi-molar hydrogen ions, as is shown by the curves for Expts. 4 and 15 (Fig. 1), Expts. 22 and 23 being similar. In each case, however, as the curves show, the experiment with more ferrous iron overtakes the other as hydrogen ions accumulate during the progress of the reaction, and then one has the conditions which prevail in type (IV), where hydrogen ions depress to a greater extent than the equi-molar ferrous ions—see Expts. 17 and 18 or 13 and 14. All these peculiarities become normal when one considers the way in which  $(h_0 + 3x/2)(f_0 + x)$  varies differently with increase in  $x$  according as  $h_0$  or  $f_0$  is zero or both finite, and are due ultimately to the fact that the functions of hydrogen ions and ferrous ions in repressing the reaction are different.

There still remains the interesting fact that, even after corrections have been made for salt effect (p. 349), experiments in which ferrous iron is added initially seem to give slightly lower values for  $k_2$  with increasing amounts of ferrous iron. No satisfactory explanation has been found for this behaviour. On the other hand, both  $k_1$  and  $k_2$  are far more satisfactory in experiments in which there is no initial ferrous iron (type II) than in those where there is no initial acid (type III), so that the equations used appear to be more satisfactory for relatively rapid increases of ferrous iron than of hydrogen ions.

With the object of gaining further insight into the mechanism and of obtaining an estimate of the extent to which hydrogen and ferrous ions are diminished owing to the existence of the complex,

six experiments were devised so as to correspond with the various conditions which might obtain in Expt. 2 after it had reached a certain stage. Initially it had  $\alpha = 0.200$ ,  $b/2 = 0.100$ , and the stage chosen was when 0.075 of the ferric iron had been reduced. At this stage, which was attained in 29.5 minutes, one would have  $h = 0.075 \times 3/2$  and  $f = 0.075$  if 3 and 2 atoms of hydrogen and iron respectively remained free in solution according to the stoicheiometric equation. The six experiments were chosen with the above values of  $\alpha$  and  $b$  and with concentrations of  $h$  and  $f$  as shown:

Expt.	$h$ .	$f$ .				
20	0.1125	0.0750	corresponding to	3H <sup>+</sup>	and 2Fe <sup>2+</sup>	remaining free.
24	0.0750	0.0750	" "	2H <sup>+</sup>	" 2Fe <sup>2+</sup>	" "
25	0.0750	0.0375	" "	2H <sup>+</sup>	" Fe <sup>2+</sup>	" "
26	0.0375	0.0375	" "	H <sup>+</sup>	" Fe <sup>2+</sup>	" "
31	0.1125	0.0375	" "	3H <sup>+</sup>	" Fe <sup>2+</sup>	" "
32	0.0375	0.0750	" "	H <sup>+</sup>	" 2Fe <sup>2+</sup>	" "

As can be seen from the curves \* (Fig. 1), the initial velocities are slower in the case of Expt. 20, and faster in all the others, than the reaction from the corresponding point in Expt. 2, the curve in the case of this experiment being plotted with the origin corresponding to the stage concerned. This would indicate that in Expt. 2 there are fewer hydrogen and ferrous ions opposing reaction than in Expt. 20, some being locked up in the complex. On the other hand, in Expt. 2 the complex is already at the concentration imposed by the stabilising effect of the reactions affecting it, whereas, in the earliest stages of the other reactions, it has probably not attained such a condition, so that comparisons are not rigid. Passing to the general course of the curves, it would appear that the conditions in Expt. 2 are such as would be expected from the repressing effect of approximately 2.7 moles of hydrogen ion and 1.7 moles of ferrous ion, for, considering the various values of  $t$  for constant values of  $x$  (which is the correct criterion), its curve is slightly farther from that of Expt. 20 than from a compromise between those of Expts. 24 and 31 which would approximately represent 2.5 and 1.5 moles respectively; as it is also about one-third of the way between those of Expts. 20 and 25, it would appear to correspond to 2.67 and 1.67 moles of hydrogen and ferrous ions respectively; both situations suggest that only about one-third of the hydrogen and ferrous ions which might possibly be locked up in the complex are actually so, or, that two-thirds of the total complex formed have already broken down to final products.

Although the results in the foregoing discussion leave many details

\* In these curves the extent of reduction ( $x$ ) is plotted against time ( $t$ ) which has been reduced in accordance with the correction for salt effect (p. 349).

in an unsatisfactory state, there is little doubt that the general conclusions are not far from the truth, and it is therefore of interest to compare them with certain other workers' views.

Raschig's ideas on the general course of the oxidation of hydroxylamine are put forward in detail in his "Stickstoff- und Schwefel-Studien," 1924. They are, briefly, that the first stage consists in the slow formation of the radical  $\text{NH}\cdot\text{OH}$ , which unites with a similar radical to give  $\begin{array}{c} \text{H}\cdot\text{N}\cdot\text{OH} \\ || \\ \text{H}\cdot\text{N}\cdot\text{OH} \end{array}$ . After this point a variety

of possibilities is supposed to arise and the persistence of any one type of molecule will depend not only on its inherent stability but also on the rapidity with which it may be further oxidised. Thus,

in the next phase one might have  $\begin{array}{c} \text{N}\cdot\text{OH} \\ || \\ \text{N}\cdot\text{OH} \end{array}$  or  $\begin{array}{c} \text{H}\cdot\text{N} \\ | \\ \text{H}\cdot\text{N} \end{array} > \text{O}$  according as

the dihydroxyhydrazine could be further oxidised before it dehydrated or not, and in the latter case further oxidation would give hyponitrous acid,  $\begin{array}{c} \text{H}\cdot\text{N} \\ | \\ \text{HO}\cdot\text{N} \end{array} > \text{O}$ , which would decompose to nitrous

oxide, if nothing were present to oxidise it more rapidly than it could decompose. These views appear to the author to have the great advantage that they explain the variety and varying proportions of the end-products.

The results described herein, however, indicate that the first measurable stage involves, in effect, the removal of two hydrogen atoms from each molecule of hydroxylamine, because undoubtedly two molecules of ferric salt are implicated, and it is difficult to see what (if any) preliminary rapid reaction, save the formation of a "critical complex," could lead to a subsequent measurable termolecular reaction. The molecule thus appears to be oxidised to the stage represented by the hypothetical nitroxyl or nitrous oxide, although the latter is only produced as the result of secondary changes. These views agree, to a certain extent, with the earlier opinion expressed by Raschig, when dealing with the estimation of hydroxylamine by ferric salts, that an intermediate compound (possibly nitroxyl) of moderate stability is produced, which delays the completion of the reaction for analytical purposes (*Z. angew. Chem.*, 1904, 17, 1411).

As will be seen from the experimental portion of this paper, there is no foundation for Brönsted's statement, quoted on p. 337, that the reaction under discussion is not appreciably susceptible to salt effect, although the magnitude is not so great as he appeared to look for. Actually there is a definite negative salt effect, which would, according to Brönsted, indicate reaction between ions of opposite polarity; but it is doubtful whether his hypotheses, which

are based on comparatively simple cases, can be extended to such complicated reactions as the present.

The hydroxylamine was always employed as hydrochloride, which had been recrystallised and freed from excess acid; both this salt and the ferric chloride would give a trace of free hydrochloric acid by hydrolysis, so that, in experiments with no added acid, there would always be a trace of free acid initially, which would slightly affect the earliest velocity coefficients.

#### EXPERIMENTAL.

All the experiments were carried out at 25°, with the exception of those necessary to find the temperature coefficient. Time is expressed in minutes throughout. The details call for no special description except in regard to the analytical method. The course of the reaction was followed by the estimation of unchanged ferric iron. The process was based on two facts: (1) hydroxylamine has no effect on iodine during the short time necessary for titrations provided that considerable mineral acid is present—sulphuric acid sufficient to be in normal concentration throughout the titration was found to fulfil this condition; and (2) ferric iron can be estimated consistently and fairly accurately by titration of iodine liberated from potassium iodide, if a trace of cuprous iodide is present as recommended by Hahn and Windisch (*Ber.*, 1923, 56, 598). The equilibrium which tends to be set up ( $\text{Fe}^{+++} + \text{I}' \rightleftharpoons \text{Fe}^{++} + \text{I}$ ) is displaced by titration of iodine as fast as it is formed, and the presence of the cuprous salt accelerates the reaction (presumably by more rapid reduction of ferric salt and continuous re-formation of cuprous salt) to such an extent that titrations can be completed in the ordinary time instead of lasting for several minutes, as in the absence of cuprous salt. Although the method has been criticised (Rupp, *Apothek. Z.*, 1924, 39, 422), the author's experience is that it is useful and gives results about 1 part in 300 parts high (with titres of 40 c.c.), but this error might be reduced if precautions were taken against the aerial oxidation of the solution containing hydriodic acid and ferrous salts.

The starch-iodine coloration returns after a few minutes in the titrations made during actual runs, and rather less rapidly in controls with ferric salts in the absence of reaction products. The difference is attributed to the presence of traces of nitrous acid.

As the result of many duplicate runs, it may be stated that experiments are reproducible almost invariably within about 0.1 c.c. on titres of usually 30 or 40 c.c.

The behaviour of a complex of the type suggested on p. 342 in such titrations is, of course, uncertain; it might react either as

ferrous or as ferric iron. The latter possibility is improbable, for the apparent rate of initial change would then be far less than the actual, and would subsequently tend to increase temporarily as the complex broke down; the apparent course of the reaction shows such enormous diminution in velocity that it is more likely that the complex reacts as a ferrous compound.

A control was made to ascertain whether hydroxylamine in nearly neutral solution exercised any oxidising effect on ferrous iron, such as it exerts in alkaline solution. The result was definitely negative.

The curves obtained by plotting experimental differential velocities against  $x$  change so rapidly that they are not capable of "smoothing." The velocities shown in the tables were therefore obtained by plotting  $x$  against the square-root or fourth-root of time, according to circumstances. The fairly flat curve thus obtained was smoothed and the values of  $\sqrt{t}$  or  $\sqrt[4]{t}$  corresponding to a series of values of  $x$  were read off, and, from the values thus obtained, a further curve was constructed, on the basis of  $v = \delta x / \delta t$ , showing the relation between  $x$  or  $(a - x)$  and  $v$ . Even this method leaves considerable uncertainty in the early stages of experiments of type I. The integrated velocity coefficients are based on unsmoothed values.

*Salt Effect.*—Experiments similar to No. 4 were made with the addition of  $M/10$ - and  $M/5$ -ammonium sulphate; they gave results uniformly slower in the proportion 1.14 and 1.30, respectively. A similar experiment comparable with No. 2 gave a slightly greater depression. The primary object of this type of experiment was to find what correction, if any, should be applied to experiments of types III and IV (in which the ferrous salt had been added, for convenience, as ferrous ammonium sulphate), in order that they should be comparable with one another and with those of other types. When a definite effect was found, it was essential to make a few other determinations in order to obtain an estimate of that due to ferrous sulphate. An experiment parallel with No. 12, but having  $M/10$ -ammonium sulphate present, in addition to the  $M/10$  already added as the double salt, showed a reduction of velocity in the ratio 1.17 to 1, whereas from the foregoing one would have expected a ratio of 1.30 to 1.14, i.e., 1.14 to 1—a result which is as near as can be expected from the graphical methods which have to be used in the absence of really satisfactory velocity coefficients, and which shows that the salt effect is fairly consistent.

$M/15$ -Aluminium sulphate gave a depression identical with that of  $M/5$ -ammonium sulphate and, therefore, twice as great as the  $M/10$ -ammonium sulphate to which it is equivalent; this result is characteristic of the ion of higher valency.

Zinc ammonium sulphate was chosen as being best suited for comparison with the ferrous ammonium sulphate. For  $M/5$ - and  $M/10$ -solutions it showed depressions in the proportions 1.54 and 1.31 respectively. As these are consistent with the foregoing results, the general trend was adopted as the basis for corrections of all experiments of types III and IV, and the factors by which velocities are multiplied (or times divided) are :

for 0.2000 molar ferrous ammonium sulphate	1.54
0.1000    "    "    "    "	1.30
0.0750    "    "    "    "	1.22
0.0500    "    "    "    "	1.14
0.0375    "    "    "    "	1.11

A comparison of, for example, Expts. 10 and 11 does not indicate the relatively large salt effect which might be expected from a five-fold change in the concentration of the trivalent ferric salt, and, for this reason, no attempt has been made to correct for such salt effect.

(The product  $hf$  increases four-fold, and  $h^2f$  seven-fold during the run.)

### Summary.

1. The rate of reaction *after the early stages* is directly proportional to the concentration of hydroxylamine and to the square of that of ferric chloride, and inversely proportional to the concentration of ferrous salt and to the square of the hydrogen-ion concentration.

2. The most probable interpretation is that reaction proceeds by way of an intermediate equilibrium involving a complex of the type shown:  $2\text{Fe}^{+++} + \text{NH}_2\text{OH}^+ \rightleftharpoons \text{Fe}^{++} + 2\text{H}^+ + (\text{NOH}, \text{Fe}, \text{H})^{+++} \rightarrow \text{N}_2\text{O}$ , etc.

3. The abnormal temperature coefficient of 6.5 for a  $10^\circ$  rise would thus be partly due to a more favourable displacement of the equilibrium.

4. "Salt effect" is negative—reaction velocity is depressed by the addition of indifferent salts.

UNIVERSITY OF LONDON,  
SOUTH KENSINGTON, S.W.

[Received, November 11th, 1925.]

## XLV.—The Structure of the Normal Monosaccharides. Part IV. Glucose.

By EDMUND LANGLEY HIRST.

IN Part I (Hirst and Purves, J., 1923, 123, 1352) the reasons which had led to the general adoption of a butylene oxide formula for normal aldose derivatives were reviewed, the need of more definite chemical evidence was pointed out, and a method for studying the problem was outlined which has since furnished strong evidence that normal derivatives of xylose (*loc. cit.*), arabinose (Hirst and Robertson, J., 1925, 127, 358), and rhamnose (Hirst and Macbeth, *this vol.*, p. 22) are, in fact, amyleno-oxidic and not butylene-oxidic, as hitherto been supposed. In the experiments now to be

described, the method has been extended to the hexose series. The oxidation of tetramethyl glucose, whose structural relationship to the normal methylglucosides and to glucose has been the subject of much investigation, has been studied and as a result it appears that the amylenoxide formula should be ascribed also to normal derivatives of glucose. This is in exact agreement with evidence as to the structure of glucose recently obtained by Charlton, Haworth, and Peat (this vol., p. 89), whose experiments were based on considerations of an entirely different nature. If this structure for glucose be accepted, changes in the nomenclature of certain derivatives will obviously be necessary analogous to the renaming of normal tetramethyl glucose as the 2:3:4:6- instead of the 2:3:5:6-derivative of glucose.

The principal method adopted in the present investigation was to oxidise tetramethyl glucose with nitric acid. The reaction between a normal trimethyl pentose (I) and nitric acid is simple in nature, involving only the oxidation to carboxyl of the reducing and the potential primary alcoholic groups situated respectively at the two ends of the pentose carbon chain. Trimethyl rhamnose (II) also reacted simply, the terminal group  $\cdot\text{CH}(\text{OH})\cdot\text{CH}_3$ , produced by the action of the oxidising agent in forming trimethyl rhamnonic acid, giving quantitatively carboxyl and carbon dioxide. A methylated hexose, however, whether a 1:4- or a 1:5-oxide, presents a very different type of structure and it was to be expected that the course of oxidation would be more complicated. If the amylenoxide structure of tetramethyl glucose (III) be assumed, the first stage in the reaction would be the production of tetramethyl gluconic acid (IV), and its subsequent course would be determined by the action of nitric acid on the group  $\cdot\text{CH}(\text{OMe})\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OMe}$ , with the ketone  $\cdot\text{CH}(\text{OMe})\cdot\text{CO}\cdot\text{CH}_2\cdot\text{OMe}$  as a probable intermediate product. It is well known that ketones of the type  $\text{R}\cdot\text{CO}\cdot\text{R}'$  may be oxidised in different ways according to the experimental conditions. The main product from 2:3:4:6-tetramethyl glucose might therefore be either *d*-dimethoxysuccinic acid (V) or inactive xylotrimethoxyglutaric acid (VI), according as the break occurred between the 4th and 5th or between the 5th and 6th carbon atoms. It is evident that by a similar series of steps, shown in the accompanying scheme, butylene-oxidic tetramethyl glucose (VII) might also give dimethoxysuccinic acid, and it follows that the isolation of this acid alone would not enable precise conclusions to be drawn concerning the structure of tetramethyl glucose. The detection of xylotrimethoxyglutaric acid, on the other hand, would definitely indicate the presence of an amylenoxide linking. It was therefore necessary to establish experimental conditions such that the nature of the

various oxidation products would lead definitely to the allocation of a structural formula.

This was ultimately accomplished by oxidising tetramethyl glucose for a short time with nitric acid of density 1.420. The reaction proceeded smoothly, was easy to control, and led to very little loss of material by side reactions. In this respect the reagent was much more satisfactory than the acid ( $d$  1.2) which had previously been most frequently employed in the sugar group. With the latter, even at comparatively low temperatures, the more prolonged action necessary to effect the requisite oxidation invariably yielded considerable quantities of oxalic acid by a profound decomposition of the molecule. The product isolated in good yield was a mixture containing both  $d$ -dimethoxysuccinic acid and xylotrimethoxyglutaric acid, which were separated from each other by taking advantage of the different rates of formation of their very characteristic crystalline diamides. Dimethoxysuccinamide (Purdie and Irvine, J., 1901, 79, 960) and xylotrimethoxyglutaramide (Hirst and Purves, *loc. cit.*) were thus obtained in a pure condition and their identity was placed beyond doubt by comparison with authentic specimens. It has already been indicated (Hirst and Macbeth, *loc. cit.*) that there appears to be no reason for suspecting any wandering of the methyl groups during oxidation, and it follows, therefore, from what has been said above, that normal tetramethyl glucose must be the 2 : 3 : 4 : 6-derivative possessing the amylene oxide formula (III); the possibility of a propylene or ethylene-oxide structure being entirely excluded by the nature of the products isolated.

The interest attached to this reaction and the desirability of accumulating as much evidence as possible concerning the oxidation of a fully methylated hexose led to a further study of the action of nitric acid and of alkaline potassium permanganate on tetramethyl glucose. The reaction appears to take an entirely different course from that of 2 : 3 : 6-trimethyl glucose when oxidised under precisely similar conditions (Irvine and Hirst, J., 1922, 121, 1222). The latter gave with nitric acid ( $d$  1.2) at 60° a dibasic acid (dimethylsaccharic acid), whereas tetramethyl glucose gives mainly tetramethylgluconic acid with a small quantity of dimethoxysuccinic acid, apparently without going through the intermediate stage of trimethylsaccharic acid. This difference is interesting, especially as butylene-oxidic trimethyl arabinose with a terminal group similar to that present in tetramethyl glucose can be oxidised to dimethoxyglutaric acid (Baker and Haworth, J., 1925, 127, 365). A sufficient number of examples has not, however, been examined to justify any views as to whether this behaviour is the exception or the rule. Prolonged treatment of tetramethyl glucose with nitric acid ( $d$  1.2)

at higher temperatures produces a complex mixture containing much oxalic acid and little or no trimethoxyglutaric acid, the chief constituent being dimethoxysuccinic acid. Oxidation with alkaline potassium permanganate gave oxalic acid and dimethoxysuccinic acid.

Summarising the evidence obtained from these experiments, it appears that the oxidation of amyleno-oxidic tetramethyl glucose with nitric acid leads first to 2:3:4:6-tetramethylgluconic acid. Further oxidation splits the carbon chain either between the 4th and 5th or between the 5th and 6th carbon atoms to give dimethoxysuccinic acid or xylotrimethoxy-glutaric acid, and the relative proportions in which the two changes take place vary with the experimental conditions, the latter change being favoured by oxidation with stronger acid for a shorter time.

#### EXPERIMENTAL.

*Stability of Dimethoxysuccinic Acid in Presence of Nitric Acid.*—Dimethoxysuccinic acid was heated in nitric acid (*d* 1.42) for several hours at 100°. No oxidation and no change in the initial specific rotation,  $[\alpha]_D + 69.5^\circ$  ( $c = 1.375$ ), were observed. Previous experiments have demonstrated the stability of trimethoxyglutaric acid.

*Oxidation of Tetramethyl Glucose with Nitric Acid* (*d* 1.42).—When a solution of tetramethyl glucose (5 g. of carefully recrystallised

material conforming to the accepted standards) in nitric acid (40 c.c.; *d* 1.42) was kept at room temperature, oxidation began after 5 minutes; thereafter the reaction was controlled by gradual heating in such a way that evolution of oxides of nitrogen never became rapid. After  $\frac{1}{2}$  hour, the temperature was raised to 90° and kept at this point for 2 hours; the evolution of gas had then almost ceased. Water (2 vols.) was added, and the excess of nitric acid removed by careful distillation at 40°/9 mm., with the addition of water in the usual manner. The dry oxidation product was a glass soluble with difficulty in methyl alcohol. It contained no oxalic acid. After esterification by boiling with methyl alcohol (50 c.c.) containing 4% of hydrogen chloride, the product was distilled under diminished pressure (for details of the method used, see previous papers). The main fraction (2.65 g.) was a colourless oil, b. p. 135–140°/10 mm. (bath at 150–155°),  $n_D^{20}$  1.4375. The first and last fractions (0.4 and 0.8 g., respectively) showed  $n_D^{20}$  1.4345 and 1.4416.

*Examination of the Oxidation Product.*—The main fraction was soluble in water and all the usual organic solvents.  $[\alpha]_D = +31.5^\circ$  in methyl alcohol (*c* = 2.085) and  $+33^\circ$  in aqueous ethyl alcohol (*c* = 0.8), and the characteristic change in rotation shown by lactones was not observed. The absence of lactonic substances was further shown by the compound titrating as an ester. The physical and chemical properties agreed most closely with those required for a mixture of 60% of methyl *d*-dimethoxysuccinate and 40% of methyl xylotrimethoxyglutarate (Found: C, 47.0; H, 7.05; OMe, 58.9; 0.106 g. required 9.0 c.c. of *N*/10-alkali for hydrolysis. Calc. for the above mixture: C, 47.2; H, 7.0; OMe, 60.9%; 9.5 c.c. The b. p., rotation, and refractive index are also in accord with this view. [Methyl *d*-dimethoxysuccinate has b. p. 135°/12 mm.,  $n_D^{20}$  1.4340,  $[\alpha]_D + 81^\circ$  in methyl alcohol (*c* = 6.26) (compare Purdie and Barbour, J., 1901, 79, 971), and methyl xylotrimethoxyglutarate has b. p. 132°/12 mm.,  $n_D^{20}$  1.4402, and is optically inactive.]

Complete confirmation of these views was obtained by the formation in good yield of crystalline dimethoxysuccinamide and xylotrimethoxyglutaramide by the action of ammonia on the mixed esters. A solution of 1.0 g. in 8 c.c. of methyl alcohol saturated with dry ammonia began, after a few hours, to deposit crystals in characteristic, opaque, white tufts. These were collected at the end of 3 days, and after being washed with alcohol and ether and dried at 105° were found to be pure dimethoxysuccinamide (yield 0.36 g.). The substance was insoluble in cold organic solvents, but slightly soluble in water, in which the value  $[\alpha]_D + 95^\circ$  (*c* = 0.80) was observed. It sublimed in long needles on being heated in a vacuum

(compare Purdie and Irvine, *loc. cit.*), showed no definite m. p., but when heated fairly quickly showed the following sequence of changes: darkened at about 245°, melted partly with decomposition at 269°, and was completely decomposed at 276° (Found: OMe, 34.3. Calc., OMe, 35.2%). Its properties were in exact agreement with those of an authentic specimen of the amide prepared from methyl *d*-dimethoxysuccinate.

The mother-liquor of the dimethoxysuccinamide was kept for a further 4 days. Colour changes took place similar to those observed during the formation of xylotrimethoxyglutaramide (*loc. cit.*), and 7 days from the beginning of the experiment another crop of crystals began to be deposited as flat, transparent prisms, resembling xylotrimethoxyglutaramide in crystalline form. After 12 days, 0.25 g. was collected. This material showed a moderate solubility in water and could be recrystallised from an alcohol-ether mixture. It was optically inactive (tested in 2% solution in water). It melted in air to give a dark blue liquid, m. p. 194–195°, and at 194–195° when mixed with an authentic specimen of the glutaramide prepared from xylose (Found: C, 43.5; H, 7.4; OMe, 41.1. Calc.: C, 43.6; H, 7.3; OMe, 42.3%).

Further quantities of dimethoxysuccinamide were obtained by treating with ammonia in methyl alcohol the first and the last fraction. No oxamide could be detected.

*Oxidation with Nitric Acid (d 1.2) at 75°*.—A solution of 5.5 g. of tetramethyl glucose in 85 c.c. of nitric acid (*d* 1.2) was heated at 75° for 12 hours until the reaction appeared to be complete. The oxidation products (isolated as before after esterification) were (a) methyl oxalate (1 g.), (b) a clear yellow syrup (3.5 g.), b. p. 138–149°/9 mm. (bath at 150–156°),  $n_D^{20}$  1.4415,  $[\alpha]_D + 54^\circ$  in alcohol ( $c = 1.348$ ),  $[\alpha]_D + 53^\circ$  in aqueous alcohol ( $c = 0.50$ ), decreasing to  $+43^\circ$ . This material on treatment with ammonia in methyl alcohol gave a small quantity of oxamide and much *d*-dimethoxysuccinamide. No xylotrimethoxyglutaric acid could be detected. The oxidation products under these conditions form a complex mixture, but consist principally of oxalic acid and dimethoxysuccinic acid. The high refractive index, the drop in rotation shown by the solution in aqueous alcohol, and the titration figures are in agreement with the view that some tetramethylgluconolactone was present in the main fraction (Found: C, 46.5; H, 6.6; OMe, 54.7%; 0.178 g. required 14.2 c.c. of *N*/10-alkali for hydrolysis, partly as lactone, partly as ester). The analysis of the corresponding lead salt is in accord with these views (Found: Pb, 50.0; OMe, 18.6%).

*Oxidation with Nitric Acid (d 1.2) at 60°*.—A solution of 7 g. of tetramethyl glucose in 50 c.c. of nitric acid (*d* 1.2) was heated at

85° until oxidation commenced, the temperature being then lowered to 60° and the reaction allowed to continue for 4½ hours. The product was treated in the way already described and was finally distilled. After a first fraction of 0.85 g., the greater part (4.0 g.) of the material was collected at 142–143°/9 mm. It could not be separated into its components by fractional distillation. The distillate was a neutral, clear syrup which developed acidity in contact with water;  $n_D^{20}$  1.4526,  $[\alpha]_D + 108^\circ$  in benzene ( $c = 1.176$ ). In water the initial value,  $[\alpha]_D + 80^\circ$  ( $c = 1.792$ ), dropped rapidly to 64° after 28 minutes, 54.5° after 83 minutes, 45° after 158 minutes, and 39° after 280 minutes; the final value was 35°. This behaviour is characteristic of  $\delta$ -lactones. Titration with alkali showed that the substance was partly lactonic and partly esteric in character. 0.1502 G. required (a) 5.0 c.c. of  $N/10$ -alkali as lactone, (b) 3.0 c.c. of  $N/10$ -alkali as ester (Found: C, 50.1; H, 7.5; OMe, 53.5%). 0.8 G. dissolved in 6 c.c. of methyl alcohol saturated with ammonia gave crystals of dimethoxysuccinamide (0.05 g.) in a few hours. These observations proved that the methyl ester of trimethoxysaccharolactone, if present at all, must have been there in very minute quantity, and the material under examination appeared to consist of 80% of tetramethylgluconolactone and 20% of methyl dimethoxysuccinate. This mixture requires C, 50.3; H, 7.5; OMe, 54.5% and 0.150 g. would require (a) 5.1 c.c. of  $N/10$ -alkali as lactone, (b) 2.9 c.c. of  $N/10$ -alkali as ester, whilst the b. p. and the initial and final values of  $[\alpha]_D$  are in agreement with those expected.

(For the properties of dimethoxysuccinic acid derivatives, see Purdie and Irvine, *loc. cit.*; for those of tetramethylgluconolactone, see Pryde, J., 1924, 125, 520; Charlton, Haworth, and Peat, *loc. cit.*)

*Oxidation with Potassium Permanganate.*—Tetramethyl glucose (5 g.) was dissolved in water (100 c.c.) rendered just alkaline with potassium hydroxide, and to the solution, heated at 75°, was added gradually potassium permanganate (25 g.) dissolved in hot water. The colour of the permanganate solution disappeared quickly at first, but very slowly towards the end. After filtering and passing carbon dioxide through the filtrate to remove free alkali, the solution was evaporated to small bulk at 50°/12 mm. The greater portion of the potassium was removed by means of perchloric acid and after elimination of the remaining water the product (partly free acid and partly potassium salt) was esterified with acid methyl alcohol. On isolating and distilling the ester, 0.6 g. was obtained as a first fraction. This was almost entirely methyl oxalate (the identity of which was confirmed by transforming it into oxamide). The main fraction

(2 g.) showed b. p. 130—135°/9 mm. (bath at 145°),  $n_D^{20}$  1.4342,  $[\alpha]_D + 43^\circ$  ( $c = 1.68$ ) in methyl alcohol [Found: OMe, 55.5; CO<sub>2</sub>Me (by titration), 64%]. When it was treated with ammonia in methyl alcohol, oxamide was first formed followed by much dimethoxysuccinamide (50% by weight of the ester used; properties as above). It was evident, therefore, that the products were essentially oxalic acid and dimethoxysuccinic acid, the amount of trimethoxyglutaric acid being negligible.

The author wishes to record his thanks to Mr. J. M. Smith, M.Sc., of Armstrong College, for valuable assistance in preparing certain of the compounds required in this investigation.

[Received, December 12th, 1925.]

### XLVI.—3 : 4- and 2 : 5-Dimethoxyphenylhydrazine.

By WILLIAM HENRY PERKIN, jun., and LEON RUBENSTEIN.

IN a paper published a short time since (Blaikie and Perkin, J., 1924, 125, 296; compare Kermack, Perkin, and Robinson, J., 1922, 121, 1872), the synthesis was described of several derivatives of indole containing one methoxyl group in the benzene nucleus.

The present investigation was planned as a continuation of that research and it was hoped that it might be found possible to synthesise dimethoxy-derivatives of indole and to convert these into carboline and indole-diazines related to harmine and harmaline. We also desired to prepare and study more particularly such dimethoxy-derivatives of indole and tetrahydrocarbazole as

and to compare their reactions with those of brucine with the object of obtaining further evidence bearing on the question of the positions of the methoxy-groups in that alkaloid (compare Lions, Perkin, and Robinson, J., 1925, 127, 1159). Unfortunately, the preparation of phenylhydrazines of the type  $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{NH}\cdot\text{NH}_2$  required for these experiments, from the corresponding anilines, proved to be a matter of unusual difficulty, and it is probably for this reason, and

because they are so unstable when they have been obtained, that there is no mention of these important substances in the literature. These hydrazines, and especially the 2:5-dimethoxy-derivative, do not yield satisfactory condensation products with ketones such as cyclohexanone or  $\alpha$ -ketoglutaric acid and moreover the conversion of these hydrazones into the corresponding derivatives of indole or tetrahydrocarbazole by means of the usual acid reagents, alcoholic hydrochloric or sulphuric acid, glacial acetic acid, etc., is accompanied by the formation of so much tar that the preparation of these derivatives in any quantity was found to be impossible. Other methods must therefore be sought for the synthesis of these substances, and the present communication is confined to a brief description of the dimethoxyphenylhydrazines which have been prepared and of some indole and tetrahydrocarbazole derivatives which we have succeeded in obtaining in small quantities.

When 3:4-dimethoxyaniline hydrochloride (Fargher, J., 1920, 117, 869) dissolved in acetic acid is treated with methyl nitrite, it yields brown needles of 3:4-dimethoxybenzenediazonium chloride, and this is converted by ammonium sulphite and ammonia into red crystals of ammonium 3:4-dimethoxydiazobenzenesulphonate. This salt is readily reduced by zinc dust to ammonium 3:4-dimethoxyphenylhydrazinosulphonate, the nearly colourless needles of which rapidly decompose on exposure and yield 3:4-dimethoxyphenylhydrazine (m. p. 81°) on treatment with sodium acetate. This very unstable substance combines with cyclohexanone, and the syrupy hydrazone gives with alcoholic hydrochloric acid a small yield of 6:7-dimethoxy-1:2:3:4-tetrahydrocarbazole (III; m. p. 98°).

In a second series of experiments, 3:4-dimethoxyphenylhydrazine was condensed with ethyl pyruvate, and the syrupy hydrazone gave, with alcoholic hydrochloric acid, so small a yield of 5:6-dimethoxyindole-2-carboxylic ester (m. p. 172°; compare I) that the substance could not be further investigated. We next prepared 2:5-dimethoxyphenylhydrazine hydrochloride from 2:5-dimethoxyaniline hydrochloride (Mühlhausen, *Annalen*, 1881, 207, 254) by a process similar to that just described in the case of the 3:4-derivative, and, on treatment with sodium acetate, this yielded 2:5-dimethoxyphenylhydrazine (m. p. 85°). Both the hydrochloride and the free base are, however, so unstable and condense with ketones with such difficulty that the investigation could not be continued.

Included in this communication is a brief account of 2-carboxy-7-methoxyindole-3-acetic acid (IV) and 2-carboxy-5-methoxyindole-3-acetic acid (V) obtained respectively by condensing *o*-methoxyphenylhydrazine and *p*-methoxyphenylhydrazine with  $\alpha$ -ketoglutaric

acid and treating the products with alcoholic hydrochloric or sulphuric acid.

On testing the various methoxy-derivatives described in this communication for the brucine reaction—the orange to red coloration produced on adding a drop of nitric acid to the solution of a trace of brucine in glacial acetic acid—it was found that the monomethoxyindole derivatives give only a yellow coloration. On the other hand, 6 : 7-dimethoxytetrahydrocarbazole (III) gives an immediate pink coloration which becomes deep red on warming and, in the case of 5 : 6-dimethoxyindole-2-carboxylic ester, the yellow colour produced at first becomes wine-red on warming. The behaviour of these substances seems to support the view of Lions, Perkin, and Robinson (*loc. cit.*, p. 1161) that brucine contains the two methoxyl groups in the *o*-position to each other.

#### EXPERIMENTAL.

3 : 4-Dimethoxyphenylhydrazine,  $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{NH}\cdot\text{NH}_2$ .—Finely powdered 3 : 4-dimethoxyaniline hydrochloride (20 g.; compare Fargher, *loc. cit.*) is added to glacial acetic acid (90 c.c.), and dried methyl nitrite passed into the well-stirred mixture, the temperature being maintained between  $10^\circ$  and  $15^\circ$ . The deep brown solution is poured into dry ether (500 c.c.), and the 3 : 4-dimethoxybenzenediazonium chloride thus precipitated in brown needles is immediately dissolved in ice-water and the solution added drop by drop and at  $0^\circ$  to a well-stirred, saturated ammonium sulphite solution (60 c.c.) containing ammonia (45 c.c.;  $d$  0.880). The deep red product is kept for a few hours, and the red crystals (14 g.) of ammonium 3 : 4-dimethoxydiazobenzenesulphonate are collected (Found: N, 15.7; S, 12.0.  $\text{C}_8\text{H}_{13}\text{O}_5\text{N}_3\text{S}$  requires N, 16.0; S, 12.1%). This substance is mixed with glacial acetic acid (10 c.c.), and zinc dust (3.7 g.) gradually added, the temperature being kept between  $45^\circ$  and  $50^\circ$ . The pale brown mixture is diluted with water, the zinc precipitated as sulphide and removed by filtration in an atmosphere of hydrogen sulphide to prevent oxidation. The yellow solution is concentrated by distillation under reduced pressure; ammonium 3 : 4-dimethoxyphenylhydrazinosulphonate (9.5 g.) then separates in greyish-white crystals with a metallic lustre (Found: N, 15.7; S, 12.0.  $\text{C}_8\text{H}_{15}\text{O}_5\text{N}_3\text{S}$  requires N, 15.6; S, 12.1%).

This salt (12 g.) is boiled under reflux with alcoholic hydrochloric

acid (30 c.c. of 15%) for  $\frac{1}{2}$  hour. The mixture of 3:4-dimethoxyphenylhydrazine hydrochloride and ammonium chloride which separates from the deep red solution is collected, extracted with boiling alcohol, and filtered off; the filtrate deposits the hydrazine hydrochloride (4.5 g.) in grey prisms which, after recrystallisation from alcohol, melt at  $162^{\circ}$  (decomp.) (Found: N, 13.7.  $C_8H_{13}O_2N_2Cl$  requires N, 13.7%). 3:4-Dimethoxyphenylhydrazine hydrochloride has a strong odour of the phenylhydrazine and must be rapidly dried on porous porcelain over sulphuric acid, since it readily decomposes in contact with air, becoming a dark mass. It gradually loses hydrogen chloride under reduced pressure and the crystals dissolve in water or alcohol to solutions which rapidly become red.

3:4-Dimethoxyphenylhydrazine separates, on the addition of sodium acetate to the aqueous solution of the hydrochloride, in colourless needles, m. p.  $81^{\circ}$ , which rapidly decompose in contact with air.

6:7-Dimethoxytetrahydrocarbazole (III).—3:4-Dimethoxyphenylhydrazine hydrochloride (2.5 g.) is added to alcohol (15 c.c.) containing cyclohexanone (1.2 g.) and sodium acetate (1.4 g.). The mixture is boiled under reflux during 2 hours and poured into water; the hydrazone then separates as a syrup which does not solidify on standing or cooling. This syrup is washed with water, boiled with alcoholic hydrochloric acid (12 c.c. of 20%) for a few minutes, and the dark solution poured into water; the 6:7-dimethoxytetrahydrocarbazole that separates crystallises from dilute alcohol in pale yellow prisms, m. p.  $98^{\circ}$  (Found: C, 72.5; H, 7.6; N, 6.3.  $C_{14}H_{17}O_2N$  requires C, 72.7; H, 7.4; N, 6.1%).

Ethyl 5:6-Dimethoxyindole-2-carboxylate (compare I).—3:4-Dimethoxyphenylhydrazine hydrochloride (2.5 g.) was added to a solution of ethyl pyruvate (1.2 g.) and finely powdered sodium acetate (1.3 g.) in alcohol (25 c.c.). After boiling for 2 hours, the red solution was diluted with water; the oily hydrazone that separated did not solidify on cooling. It was washed with water and boiled for a few minutes with alcoholic hydrochloric acid (10 c.c. of 20%); on adding water, ethyl 5:6-dimethoxyindole-2-carboxylate separated in a very crude condition. This was ultimately obtained pure, crystallising from alcohol in yellow prisms, m. p.  $172^{\circ}$  (Found: C, 62.5; H, 6.0; N, 5.7.  $C_{13}H_{15}O_4N$  requires C, 62.7; H, 6.0; N, 5.7%), but the amount available did not allow of the preparation of the acid in a pure state.

2:5-Dimethoxyphenylhydrazine.—The diazotisation of 2:5-dimethoxyaniline in dilute aqueous hydrochloric acid was not feasible owing to the effervescence which accompanies the reaction even at low temperatures. Finely divided 2:5-dimethoxyaniline hydro-

chloride (20 g.; compare Mülhausen, *loc. cit.*) is added to glacial acetic acid, and dry methyl nitrite passed into the well-stirred mixture at 10°. The deep brown solution is gradually poured into dry alcohol-free ether with stirring; 2 : 5-dimethoxybenzenediazonium chloride is then precipitated in small, yellow needles and is very unstable. The ether is decanted, the crystals are rapidly washed with ether and dissolved in ice-cold water (60 c.c.), and the solution is added drop by drop to a well-cooled saturated solution of ammonium sulphite (60 c.c.) containing ammonia (40 c.c.; *d* 0.880). After remaining for a few hours, the deep red mixture is filtered, when *ammonium 2 : 5-dimethoxydiazobenzenesulphonate* remains as brick-red crystals. This substance may be crystallised from a little water, in which it is rather readily soluble (Found : N, 15.7; S, 12.1.  $C_8H_{13}O_5N_3S$  requires N, 16.0; S, 12.1%). This sulphonate (26 g.) was mixed with glacial acetic acid (23 c.c.) and water (7 c.c.), and zinc dust (7.5 g.) added at 40–50°, a little at a time. The solution, which gradually became lighter in colour, was kept at 50° for an hour, diluted with water, the zinc removed as sulphide in an atmosphere of hydrogen sulphide, and the filtrate concentrated under reduced pressure; the *ammonium 2 : 5-dimethoxyphenylhydrazinosulphonate* (19 g.) that separated as a grey, crystalline solid was recrystallised from hot alcohol (Found : N, 15.6; S, 12.1.  $C_8H_{13}O_5N_3S$  requires N, 15.6; S, 12.1%).

When this sulphonate (25 g.) was boiled under reflux with alcoholic hydrochloric acid (60 c.c. of 15%), a precipitate consisting of *2 : 5-dimethoxyphenylhydrazine hydrochloride* and ammonium chloride separated from the deep purple solution. After a few minutes, the hydrolysis was complete, more alcohol was then added and some animal charcoal, the boiling liquid filtered and concentrated; the hydrazine hydrochloride was then obtained in colourless crystals (9.5 g.) which darken above 250° (Found : C, 48.2; H, 6.0; N, 13.8.  $C_8H_{13}O_2N_2Cl$  requires C, 48.0; H, 5.9; N, 13.7%). This hydrochloride is very soluble in water and moderately soluble in alcohol and rapidly decomposes on exposure to air. *2 : 5-Dimethoxyphenylhydrazine* separated in needles on the addition of sodium acetate to the aqueous solution of the hydrochloride; after drying on porous porcelain over sulphuric acid, it melted at 84°.

*2-Carboxy-7-methoxyindole-3-acetic Acid* (IV).— $\alpha$ -Ketoglutaric acid (25 g.; compare Blaise and Gault, *Compt. rend.*, 1908, 147, 199) was dissolved in water (200 c.c.) containing sodium acetate (12 g.) and glacial acetic acid (10 c.c.), and *o*-methoxyphenylhydrazine hydrochloride (25 g.; Blaikie and Perkin, *J.*, 1924, 125, 315) in water (100 c.c.) then added. After the turbid solution had been

kept for a few hours, the yellow methoxyphenylhydrazone of  $\alpha$ -ketoglutaric acid (35 g.) was collected. It separated from benzene in yellow prisms, m. p.  $168^{\circ}$  (decomp.).

This hydrazone (15 g.) was boiled under reflux with alcoholic hydrochloric acid (25 c.c. of 15%) for  $\frac{1}{2}$  hour. The hot, very dark coloured solution was filtered from the ammonium chloride, and the filtrate kept for several hours, crystallisation being assisted by occasional scratching. The crystals were collected, washed with small quantities of alcohol, and recrystallised three times from alcohol, from which *ethyl 2-carbethoxy-7-methoxyindole-3-acetate* separated in grey needles, m. p.  $106^{\circ}$ , b. p.  $245-255^{\circ}/11$  mm. with slight decomposition (Found: C, 63.1; H, 6.0; N, 4.8.  $C_{16}H_{19}O_5N$  requires C, 62.9; H, 6.2; N, 4.6%). This ester was boiled with 10% aqueous sodium hydroxide for 2 hours and the filtered solution acidified; the *2-carboxy-7-methoxyindole-3-acetic acid* that separated crystallised from alcohol in brown needles, m. p.  $253^{\circ}$  (decomp.) (Found by titration: equiv., 251. Calc. for a dibasic acid  $C_{12}H_{11}O_5N$ : equiv., 249).

*2-Carboxy-5-methoxyindole-3-acetic Acid* (V).—*p*-Methoxyphenylhydrazine (Blaikie and Perkin, *loc. cit.*; 9.6 g.), dissolved in water (20 c.c.) containing potassium acetate (6 g.), was boiled under reflux for 2 hours with a solution of  $\alpha$ -ketoglutaric acid (8 g.) in a mixture of alcohol (30 c.c.) and water (5 c.c.). The product was filtered off and the alcohol evaporated; the *p*-methoxyphenylhydrazone of  $\alpha$ -ketoglutaric acid then remained as an oil which did not solidify on cooling and rubbing. The oil was boiled under reflux with alcoholic sulphuric acid (25 c.c. of 20%), mixed with water and ether, the tar which had separated removed by filtration, and the ethereal solution washed with water, dried, and evaporated. Since the syrupy ester did not crystallise, it was boiled under reflux with sodium hydroxide (10%) for an hour, cooled, and acidified; a gum then separated which gradually hardened and after repeated recrystallisation from alcohol, *2-carboxy-5-methoxyindole-3-acetic acid* was obtained in pale yellow needles, m. p.  $265^{\circ}$  (Found: N, 5.9; equiv. by titration, 250.  $C_{12}H_{11}O_5N$  requires N, 5.7%; equiv., 249).

[Received, December 15th, 1925.]

# XLVII.—*The System Ferrous Oxide-Phosphoric Acid-Water and Some of its Oxidation Products.*

By SYDNEY RAYMOND CARTER and NORMAN HOLT  
HARTSHORNE.

IN addition to the promised work (J., 1923, 123, 2223) on the ferrous phosphates, this paper describes a study of the oxidation of some of the ferrous-phase complexes, which has thrown fresh light on the composition of the neutral ferric phosphates.

The following ferrous phosphates are described in the literature:  $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$ , or  $3\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$ , occurs in nature as *vivianite* and has been prepared by Becquerel (*Ann. Chim. Phys.*, 1833, 54, 149), Debray (*ibid.*, 1861, 61, 437), Horsford (*Sitzungsber. Akad. Wiss. Wien*, 1873, 67, 466), and Evans (*Pharm. J.*, 1897, 4, 141).  $\text{Fe}_3(\text{PO}_4)_2 \cdot 6\text{H}_2\text{O}$ , or  $3\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$ , has been obtained by Gautier (*Compt. rend.*, 1893, 116, 1491). Two acid phosphates are described, viz.,  $\text{FeHPO}_4 \cdot \text{H}_2\text{O}$ , or  $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$ , by Debray (*loc. cit.*), and  $\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ , or  $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ , by Erlenmeyer (*Annalen*, 1878, 194, 176). Kunz-Krause (*Ber. Deut. pharm. Ges.*, 1923, 33, 20) describes a substance, containing ferrous and ferric iron and phosphoric acid, which is found in certain arable soils. This he assumes to be a basic ferrous ferric phosphate.

## EXPERIMENTAL.

As in the case of the ferric phosphates (*loc. cit.*), the system was studied at 70°. The equilibrium mixtures were prepared by dissolving excess of Swedish iron wire (99.75% Fe) in solutions of phosphoric acid, obtained from the same source as that used in the ferric phosphate investigation. This operation, the subsequent stirring to attain equilibrium, and the collection of the liquid and solid phases were performed in an atmosphere of carbon dioxide in an apparatus (Fig. 1) in which the rubber stoppers were coated with paraffin wax or collodion and the connexions were made with thick-walled pressure tubing carefully wired on. The iron wire, in lengths of about  $\frac{1}{2}$  inch, was placed in the flask A, and the air in the apparatus was then displaced by passing carbon dioxide, admitted through the tube B, for about 2 hours, care being taken to clear all "pockets" such as stirrer bearings. The carbon dioxide was obtained from ordinary commercial cylinders and in some cases was sufficiently pure to be used directly, but in others the gas was passed through chromous chloride solution to remove the small quantity of oxygen present, then through sodium bicarbonate solution to remove hydrochloric acid, and finally

through strong sulphuric acid. (One sample of chromous chloride solution of about 250—300 c.c. was required for a series of experiments lasting several months and during this time no alteration in the characteristic blue colour of the solution was observed. We attribute this to the fact that the solution was kept in contact with amalgamated zinc, which appears effectively to regenerate the chromous chloride after it has been oxidised, hydrochloric acid, presumably, being formed.)

Phosphoric acid solution of the required strength, freshly boiled and still hot, was run into the flask through the tap-funnel C. The mixture was then stirred with the mercury-sealed stirrer, D,

FIG. 1.

until sufficient solid phase had formed, the flask being meanwhile maintained at approximately  $70^{\circ}$  by means of the water-bath, E, and undue evaporation of water prevented by the condenser, F. The stirrer was then stopped and its bearing sealed by the rubber stopper, H, to withstand pressure. By closing the clip, G, and admitting more carbon dioxide to the flask, a portion of the mixture was forced up the tube J and into the solubility tube, K, which was one of a series of four, the remainder (not shown) being connected, in a manner similar to K, to an extension of the tube L. By suitable adjustment of screw clips (*e.g.*, M) the mixture could be admitted to one or other of these solubility tubes, the displaced carbon dioxide escaping through the mercury seals, N, etc. The tubes were supported in the thermostat, O, fitted with a glass window and maintained at  $70^{\circ} \pm 0.1^{\circ}$  by an ordinary gas-regulator.

A suitable quantity of mixture having been transferred to K, the composition of the remainder in A was altered by the addition of a few c.c. of either water or syrupy acid and the next solubility tube was filled, and so on. Four mixtures of slightly different compositions were thus obtained from one sample of iron. The object in not dissolving the iron directly in the solubility tubes was to avoid the excessive frothing which occurred when this was attempted. The flask A was of such a shape and size that the froth could not rise: further the method ensured that the mixtures were free from undissolved iron which might have interfered with the collection of phase samples and would probably have rendered the attainment of equilibrium slow and uncertain.

The mixtures were stirred for at least a week, usually longer, and from the regularity of the results it is inferred that equilibrium had then been attained. In deciding the time allowed for stirring we had to be guided by our experience of the ferric system, since it would have been impracticable, on account of the risk of oxidation, to open the solubility tubes for the purpose of withdrawing samples for trial analyses. During the stirring the pressure of the carbon dioxide in the apparatus was maintained slightly above atmospheric in order to minimise the effect of leaks (great care, however, was taken to exclude these) and diffusion through the rubber connexions, and to counterbalance any reduction in pressure due to cooling caused by a fall in level of the thermostat water.

The apparatus for collecting the phase samples was essentially the same as that used in collecting the moist solid phase in the ferric system (*loc. cit.*), with the addition of arrangements for maintaining an atmosphere of carbon dioxide in and around the filter. The figure shows it connected to the solubility tube by means of the collecting tube P, which normally was closed with a piece of glass rod. Before this connexion was made, the collecting apparatus was cleared of air by a current of carbon dioxide admitted at Q, and the jacket, R, containing the weighing-bottle, S, was also cleared, by gas entering through the tube, T, the coiled portion of which, immersed in the thermostat, served to heat the gas and thus prevent cooling of the jacket. Connexion was then made as quickly as possible, the final arrangement being shown in the figure. By suitable adjustment of the gas pressure in different parts of the apparatus the mixture of liquid and solid phases was then blown over into the weighed filter, U (any overflow being caught in the trap, V), and was filtered. The liquid phase was caught in the weighing-bottle, S. During filtration an atmosphere of carbon dioxide was maintained in R by means of T, entry of air being minimised by the loose-fitting cork cover, W.

The liquid and moist solid phases were analysed by the methods used in the ferric system. In calculating the percentage of ferrous oxide, it was assumed that the whole of the iron was present in this state, although actually it was always found that the mixtures were oxidised to some extent, usually less than 1%. This point is discussed in the following section.

Analyses of the solid phases in the dry state were also made. The drying was accomplished in some cases by washing with dry ether alone, in an atmosphere of carbon dioxide. The apparatus used consisted of a filter flask in the neck of which a wide straight adapter and a tube for admitting carbon dioxide were supported by means of a rubber stopper. The side tube of the flask carried a mercury bubbler. A filter was made up in the adapter by means of two porcelain filter plates with a layer of asbestos between them, and the neck of the adapter was fitted with a rubber stopper carrying a tube for admitting carbon dioxide, a dropping-funnel, and a capillary tube which could be closed by a screw clip fitted to a rubber extension. The air was removed from the filter flask by means of carbon dioxide and with a steady stream of this passing through the filter, the moist solid was rapidly transferred to the adapter, the stopper carrying the dropping-funnel, etc., being removed as long as was necessary to accomplish this. The air was then quickly blown out of the adapter by carbon dioxide, the capillary tube serving as outlet. This was then closed and by increasing the pressure of the carbon dioxide as much liquid as possible was expressed from the moist solid. By alternately releasing and raising the pressure by operating the clip on the capillary tube, ether could be admitted from the dropping-funnel and forced through the solid.

In cases where ether could not readily be made to pass through the solid the following procedure was adopted. The solid was shaken for a few moments in a large weighing-bottle with water, containing two or three drops of concentrated hydrochloric acid (to remove any crust of ferric salt), which was then decanted and the process repeated with two or three washings of water, alcohol, and dry ether, respectively. The solid was finally dried in a stream of carbon dioxide.

#### *Results.*

The results are in Table I and are plotted by the triangular method in Fig. 2. Analyses of the dry solids are in Table II. In the second column of Table I figures are given for the percentage of iron present in the ferric state in some of the mixtures. This was determined by rapidly dissolving the contents of the overflow trap V (Fig. I) in water acidified with hydrochloric acid and

titrating a portion of the solution with potassium dichromate directly and then titrating another equal portion, after reduction by stannous chloride. The method gave only a very approximate value, since the first stages of oxidation are probably confined to the liquid phase (in the four-component system FeO-Fe<sub>2</sub>O<sub>3</sub>-P<sub>2</sub>O<sub>5</sub>-H<sub>2</sub>O the ferrous salts must have some region of existence as solid phases in the presence of ferric iron) and the samples taken consisted of both solid and liquid phases in varying relative amounts.

Moreover, an appreciable degree of oxidation probably occurred before the first titration could be completed. The figures were useful, however, as a rough test of the inertness of the atmosphere maintained over the mixtures during stirring. The high values given by mixtures 5 and 26 were due to the use of carbon dioxide which was subsequently found to contain 1% of oxygen. As already stated, the oxidation was neglected when the ferrous oxide

FIG. 2.

percentages were being calculated, since any attempt to determine the oxidation in liquid and moist solid phases separately, and make the necessary allowances, would have increased the already great difficulties in collecting the phase samples, besides being fraught with uncertainty as to whether the results would really represent the condition before the solubility tubes were opened. As justification for our procedure we may point to the regularity with which most of the solubility points lie on smooth curves and to the evidence afforded by the conjugation lines for the composition

of the solid phases, this evidence being confirmed by analysis of the dry solids.

The third column in Table I gives the densities of the liquid phases. The values were obtained by comparing the weights of the samples with their volumes at room temperature, estimated to 0.25 c.c. by the graduations on the side of the weighing-bottle S (Fig. 1). Since the average volume of a sample was near 20 c.c., the figures are accurate to about 1 part in 80.

With regard to the solid phases, within the range of acid concentrations studied, no neutral salt such as vivianite exists. It probably has a small range of existence in the region below the point corresponding to 7.38%  $P_2O_5$  of mixture 1, but we have found it impossible to study this region on account of the increased susceptibility to oxidation which occurs as the acid concentration diminishes. Starting with the dilute-acid region, the first solid phase found,  $2FeO, P_2O_5, 5H_2O$ , or  $FeHPO_4, 2H_2O$ , has, as far as we are aware, not been described before. Its composition is confirmed by the analysis of the dry solid (Table II) and its crystalline form is shown in the photomicrograph reproduced in Fig. 3. We are indebted to Dr. Leonard Hawkes, Head of the Geology Department at Bedford College, for the following crystallographic analysis under the microscope. Biaxial; positive; axial angle  $2V_r = ca. 60-70^\circ$ ; dispersion of optical axis  $\rho > \nu$  (?); optical axial plane parallel to the length axis of the prism. Examination was rendered difficult on account of the elongated habit and consequent tendency to settle on the slide in one position only.

The next solid phase,  $2FeO, P_2O_5, 3H_2O$  or  $FeHPO_4, H_2O$ , was described by Debray (*loc. cit.*), but doubt was subsequently cast on this author's work by Erlenmeyer (*loc. cit.*). We, however, have confirmed its existence both by the graphical method and by analysis of the dry solid (Table II). The figures are not so satisfactory as the analyses of the other dry solids owing to the very small amount of material available, but they are sufficiently conclusive. We have obtained it in two distinct forms which have slightly different solubility curves. This is shown clearly in Fig. 2, where this portion of the isotherm is drawn separately on an enlarged scale. The form showing the greater solubility is very finely divided and the particles are almost destitute of crystalline form while showing a characteristic elongated shape. A specimen of those in equilibrium with mixture 16 is shown in Fig. 4. The average length of the particles in this photomicrograph, which may be taken as representative of the whole series, is estimated to be 0.014 mm. Evidence for the composition of this solid is based solely on the conjugation lines, since all efforts to dry the

solid failed, no doubt on account of its extremely fine state of division.

The form showing the lower solubility is definitely crystalline. The type of the crystals in equilibrium with mixtures 9, 10, and 11 is shown in Fig. 5. The crystals are plates having, usually, six sides. The average diameter of those in the figure, measured in the direction of greatest length, is about 0.1 mm. Evidence for the composition of this form is based chiefly on the analysis of the dried solid in equilibrium with mixture 9 (Table II), the evidence of the conjugation lines from mixtures 10 and 11, which apparently lie at an invariant point, being inconclusive.

Mixtures 6, 7, and 8 gave a crystalline solid phase which was quite unlike any of the others in appearance. Unfortunately in no case was there sufficient material for analysis. The crystals are shown in Fig. 6. From the position of the liquid-phase points on the diagram (Fig. 2) we have concluded that it is another habit of the crystalline compound  $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$  and accordingly have included the analytical figures in that section of Table I. The average length of the crystals (Fig. 6) was about 0.1 mm.

It appeared at first that the deposition of one form or the other was fortuitous. Subsequent perusal of the experimental notes showed, however, that in those cases where a suitable mixture (*i.e.*, one having convenient proportions of solid and liquid phases) was obtained at once in the reaction flask A (Fig. 1) and was transferred immediately to the solubility tubes, the more soluble form was obtained, whereas if further additions of iron or phosphoric acid solution were necessary, or if during the dissolution of the iron the temperature was raised or lowered (as was sometimes done to break up cakes of solid formed over-night in the reaction flask, or for other practical reasons), then the less soluble crystalline form resulted. Qualitative observations have shown that the salt has a very small temperature coefficient of solubility; moreover, its solubility is not greatly altered by varying the concentration of acid (see Fig. 2). If we assume that the molecules aggregate much more rapidly than they subsequently arrange themselves to form crystals, it is clear that the form first deposited will be an irregular aggregate, *i.e.*, an amorphous or quasi-amorphous solid. Moreover, since the solubility is scarcely affected by temperature and concentration, the aggregates may remain undisturbed for a long period unless these conditions are altered considerably. The aggregated form has more free energy than the crystalline variety and will be metastable and more soluble. The theory that the difference in solubility is connected in any way with the difference in particle size (given above) may be dismissed,

since the particles were probably too large for this factor to be operative (compare Hulett, *Z. physikal. Chem.*, 1901, **37**, 385, who found differences in the solubility of particles of diameter 0.002 mm. and less) and in any case the mixtures were stirred sufficiently long (8, 10, and 33 days) for the larger particles to grow at the expense of any small enough to give an abnormal solubility.

The solid phase in the mixtures richest in acid was the compound  $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$  or  $\text{Fe}(\text{H}_2\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ , described by Erlenmeyer (*loc. cit.*). Its composition is amply confirmed both by the conjugation lines (Fig. 2) and by analysis of the solid in equilibrium with mixture 22 (Table II). Typical crystals are shown in Figs. 7 and 8. It has a positive temperature coefficient and crystallises spontaneously within 24 hours from appropriate liquid phases which are allowed to cool to room temperature.

The colour of the liquid phases throughout the isotherm was the pale green characteristic of the ferrous ion. The solids were also pale green. The formation of complexes, which takes place in the ferric system, does not therefore appear to occur here.

#### *Oxidation of the Mixtures.*

It has already been stated that the mixtures poor in acid were particularly susceptible to oxidation. This showed itself in the formation of reddish-brown crystals which were deposited to a greater or less extent after the mixtures had been stirred for some days, and appeared to exist in stable contact with the ferrous phosphate already present. In mixture 1, the solid phase consisted almost entirely of these crystals and therefore it was obviously useless for the purpose of the ferrous isotherm to analyse the moist solid. It was, however, of interest to find out the composition of the crystals and it was fortunately found possible to separate them from admixed ferrous phosphate by the brief action of dilute hydrochloric acid. This was discovered by watching the behaviour of the mixture under the microscope, when, on adding a drop of hydrochloric acid, the ferrous phosphate dissolved almost immediately while the brown crystals appeared to be unaltered. The solid was therefore washed, by shaking with dilute hydrochloric acid for some minutes, transferred to a filter, and washed under pressure successively with a little more dilute acid, water, alcohol, and dry ether. A little of the solid, immediately dissolved in hydrochloric acid, gave only a very faint response to the test for ferrous iron. It was therefore not a ferrous-ferrous phosphate. It gave a strong ferric reaction. Analysis of the remainder gave  $\text{Fe}_2\text{O}_3$ , 42.2;  $\text{P}_2\text{O}_5$ , 37.7.  $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$  requires  $\text{Fe}_2\text{O}_3$ , 42.8;  $\text{P}_2\text{O}_5$ , 38.0%, and  $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4.25\text{H}_2\text{O}$  requires  $\text{Fe}_2\text{O}_3$ , 42.3;

$P_2O_5$ , 37.5%. The result thus agrees very closely with the latter formula, but we consider that, failing further evidence, it is better to regard it as incompletely dried  $Fe_2O_3 \cdot P_2O_5 \cdot 4H_2O$ .

The naturally occurring strengite has this composition, and Erlenmeyer (*loc. cit.*) claims to have prepared a neutral phosphate of this composition; his analytical figures, however, are not very conclusive, as we pointed out in our earlier paper. Crystals of our compound are shown, as dark, rectangular prisms, side by side with ferrous phosphate in Figs. 3 and 6.

Since in the ferric system we had not observed a solid which resembled these brownish-red crystals in appearance, it seemed evident that they were only stable in the presence of ferrous iron and that if oxidation were completed, the solid would change. To test this point, a mixture was prepared in the region of existence of  $2FeO \cdot P_2O_5 \cdot 5H_2O$  and was stirred at  $70^\circ$  in a solubility tube, the bearing of which was not sealed by mercury. From time to time the solid phase was examined microscopically, and the liquid tested for ferrous iron. Water was added as required to make up for loss due to evaporation through the stirrer bearing. The brown ferric salt was present from the first, and after 8 days constituted the whole of the solid phase, all the greenish-white, ferrous phosphate having disappeared. The liquid phase, however, still showed a strong ferrous reaction. After a further 8 or 9 days the brown colour of the solid had given place to a pale pink shade, resembling that of the ferric phosphates encountered in our previous work. Under the microscope, the solid was seen to be very much broken but definitely crystalline, many of the crystals having a characteristic kite-like shape. These are shown in Fig. 9, where a well-formed specimen will be seen in the middle of the picture. At this stage the liquid phase still showed a fairly strong ferrous reaction. Stirring was continued for another week without any change occurring in the appearance of the solid, but the liquid phase now gave a very weak ferrous reaction. The mixture was then left unstirred for another fortnight; it was then completely oxidised. It was stirred for a few hours to ensure equilibrium and the liquid and the solid (dry) were analysed. The liquid contained a trace of  $Fe_2O_3$  and 7.09% of  $P_2O_5$ . The solubility curve of the ferric phosphates (*loc. cit.*, p. 2230) shows that the quantity of  $Fe_2O_3$  corresponding to 7.09%  $P_2O_5$  is measurable, being about 0.1%. This slight difference in solubility may, however, be attributed to the solid in that case having been amorphous, whereas here it was crystalline, and therefore we conclude that the same compound was concerned in both cases. The reason for obtaining the crystalline form by oxidation of a ferrous mixture

FIG. 3.— $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$  and  $\beta\text{-Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$  (short dark prisms).  $\times 10$ .

FIG. 8.— $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ .  $\times 43$ .

FIG. 9.— $\alpha\text{-Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ .  $\times 90$

[To face page 372.]

probably lies in the gradual decrease in solubility which occurs during the process or in other factors inherent in it, which affect the velocity of crystallisation as opposed to aggregation and are evidently absent or suppressed when ferric oxide is treated with dilute phosphoric acid.

Analysis of the solid phase gave  $\text{Fe}_2\text{O}_3$ , 42.25;  $\text{P}_2\text{O}_5$ , 37.5, 37.6%, which, within the probable limits of experimental error, is the same as the composition found for the brown crystals. There are thus two neutral ferric phosphates having the composition  $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$  in the four-component system  $\text{Fe}_2\text{O}_3$ -FeO- $\text{P}_2\text{O}_5$ - $\text{H}_2\text{O}$  at  $70^\circ$ . We will call the pink the  $\alpha$ -form and the brown the  $\beta$ -form. Under the conditions studied, the  $\alpha$ -form is stable in the absence, or in low concentrations, of ferrous iron, whilst the  $\beta$ -form exists in the presence of medium to quite high concentrations: indeed, judging from the readiness with which it crystallises from ferrous mixtures, in spite of all efforts to maintain an inert atmosphere, it may be inferred that in this region the range of existence of solutions in equilibrium with a ferrous salt only is very limited.

The difference between the  $\alpha$ - and the  $\beta$ -salt may be explained in a similar way to that applied in the case of the neutral ferric phosphates at  $25^\circ$  (*loc. cit.*). As we mentioned there, the work of Weinland and Engraber showed that the pink ferric phosphates were probably complex ferri-phosphates. Thus we may suppose that the pink  $\alpha$ -form has the constitution  $[\text{Fe}(\text{PO}_4)_2]\text{Fe}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$ , while the brown  $\beta$ -salt is a true ferric phosphate,  $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$ . Support for the latter supposition is given by the colour changes which ferrous phosphate solutions undergo on oxidation: the original green colour changes to brown and finally to pink. The intermediate brown colour may well be due to the ferric ion, and it is the  $\beta$ -form which can exist at this stage.

It is now seen that we were in error in our earlier work in attributing five molecules of water to the solid phase in equilibrium with the weakly acid solution at  $70^\circ$ . That such a hydrate does exist appears to have been confirmed by Weinland and Engraber, and in our own work at  $25^\circ$  there seems to be little doubt that it was present. At  $70^\circ$ , however, the  $\alpha$ -salt with four molecules of water is stable, at least in the region in which the above oxidation experiment terminated.

#### Summary.

1. The system  $\text{FeO}$ - $\text{P}_2\text{O}_5$ - $\text{H}_2\text{O}$  has been studied at  $70^\circ$ , between the concentrations 7.38 and 57.51%  $\text{P}_2\text{O}_5$ . Within this range the stable solid phases are the acid salts  $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$ ,  $2\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$ , and  $\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ , the first of which has, as far as is known, not been described before.

2. By the oxidation of phases poor in acid, two neutral ferric phosphates, both having the composition  $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$ , are deposited. The brown  $\beta$ -form exists in contact with liquid phases having high to medium concentrations of ferrous iron; at lower concentrations, the pink  $\alpha$ -form becomes stable.

The authors wish to express their indebtedness to Dr. J. F. Spencer for much helpful advice and to Mr. A. Watson for carrying out many of the analyses.

## XLVIII.—Condensations involving Reactive Methyl Groups in Heterocyclic Bases.

By JAMES ERNEST HUMPHRIES.

THE reactions described below, *viz.*, the condensation of quinaldine, *p*-toluquinaldine, and  $\alpha$ -picoline and of their quaternary salts with Michler's hydrol and a nitrosoamine, are further examples of the reactivity of methyl and methylene groups towards the groups  $\text{:C:O}$  and  $\text{:N:O}$ . Fosse (*Ann. Chim. Phys.*, 1906, 8, 18) found that, in presence of acetic acid as condensing agent, Michler's hydrol (4:4'-tetramethyldiaminobenzhydrol) reacted with the methylene group of such compounds as acetoacetic ester, acetylacetone, etc. Quinaldine and  $\alpha$ -picoline condense readily with the hydrol under the same conditions, yielding the compounds

The condensations can also be effected by zinc chloride. The methiodides of the heterocyclic bases react more readily than the bases themselves and under conditions in which the latter are not affected, *viz.*, in alcoholic solution. The condensation products are similar to the *leuco*-compounds of the triphenylmethane dyes and are readily oxidised by lead peroxide and acetic acid to red dyes.

The quaternary salts do not react with benzenediazonium sulphate, but condense readily with *p*-nitrophenylnitrosoamine, in cold alcoholic solution. The resulting compounds were phenylhydrazones, *e.g.*,  $\text{C}_9\text{H}_6\text{N}(\text{MeI}) \cdot \text{CH} \cdot \text{N} \cdot \text{NH} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ . This reaction differs from that of Adams (*Chem. Zentr.*, 1923, 94, I, 1591), who added simultaneously solutions of potassium hydroxide and diazotised aniline to an aqueous solution of quinaldine methiodide and obtained the azo-compound,  $\text{C}_9\text{H}_6\text{N} \cdot \text{CH}_2 \cdot \text{N} \cdot \text{N} \cdot \text{C}_6\text{H}_5$ .

The bases themselves and their hydrochlorides do not react with

the nitrosoamine, so that in both reactions the reactivity of the  $\alpha$ -methyl group is enhanced by converting the tertiary base into a quaternary compound.

#### EXPERIMENTAL.

*Condensations with Michler's Hydrol.*—(1) *Quinaldine*. A solution of equimolecular quantities of the hydrol and quinaldine in glacial acetic acid was warmed on a water-bath until the intense blue colour changed to deep red (1 hour). Ammonium hydroxide then precipitated a dark green oil which, isolated by means of ether, was obtained in pale-yellow needles, m. p.  $131^\circ$  (Found: N, 10.7.  $C_{27}H_{29}N_3$  requires N, 10.6%).

The condensation product (1 mol.) was dissolved in hydrochloric acid (3 mols.) and enough water to make a 2% solution; acetic acid (2 mols.) was added and the whole cooled to  $0^\circ$ . Then, with rapid stirring, freshly prepared lead peroxide (1 mol.) was quickly added. The solution became intensely red. The lead was removed as sulphate, and the oxidation product obtained by addition of sodium hydroxide and extraction with chloroform. A red, amorphous powder was precipitated from the dried chloroform extract on adding ether. The *oxalate* was analysed (Found: N, 8.0.  $C_{30}H_{32}O_6N_3$  requires N, 7.95%).

The oxidation product dyes silk violet. Its salts are red, but the pseudo-base,  $C_9H_6N \cdot CH : C(C_6H_4 \cdot NMe_2)_2$ , is brown.

(2) *p-Toluquinaldine*. The condensation product (m. p.  $152^\circ$ ) was similar to that formed from quinaldine (Found: N, 10.1.  $C_{28}H_{31}N_3$  requires N, 10.3%).

(3)  $\alpha$ -*Picoline*. The condensation was carried out as in (1) and pale yellow crystals, m. p.  $187^\circ$ , were obtained (Found: N, 12.1.  $C_{23}H_{27}N_3$  requires N, 12.2%).

(4) *p-Toluquinaldine methiodide*. The condensation, which also proceeds in glacial acetic acid, was effected by boiling an alcoholic solution of the reactants for a few minutes. On concentrating the solution, copper-red needles, m. p.  $160^\circ$  (decomp.), were obtained (Found: I, 23.2; N, 7.6.  $C_{29}H_{34}N_3I$  requires I, 23.05; N, 7.6%).

The corresponding methochloride, obtained by condensing *p*-toluquinaldine methochloride and the hydrol, was oxidised as in (1), but the deep-red, amorphous dye which was formed could not be obtained pure.

*Condensations with p-Nitrophenylnitrosoamine.*—When equal molecular quantities of benzenediazonium sulphate and *p*-toluquinaldine methiodide were mixed in alcoholic solution at the ordinary temperature, the solution turned red and golden-yellow plates, m. p.  $133^\circ$ , of the *periodide* of *p*-toluquinaldine methiodide

immediately began to separate (Found: N, 2.55; I, 69.1.  $C_{12}H_{14}NI_3$  requires N, 2.5; I, 68.9%). This was readily reduced to the methiodide by sulphur dioxide or stannous chloride, and was also formed by warming the methiodide and iodine in glacial acetic acid.

No condensation took place when the methiodide was replaced by the methonitrate of *p*-toluquinaldine.

(1) *p*-Toluquinaldine methiodide. The nitrosoamine was prepared by Schraube and Schmidt's method (*Ber.*, 1894, 27, 514). Equimolecular quantities of the nitrosoamine and the methiodide, each in alcoholic solution, were mixed at 0°. The crystalline precipitate was recrystallised from methyl alcohol, reddish-brown needles, m. p. 244°, being thus obtained (Found: N, 12.3; I, 28.6.  $C_{18}H_{19}O_2N_4I$  requires N, 12.5; I, 28.35%).

That the new compound was the *p*-nitrophenylhydrazone of 2-formyl-6-methylquinoline was proved in the following way. *p*-Toluquinaldine methiodide was condensed with *p*-nitrosodimethylaniline (Kaufmann and Vallette, *Ber.*, 1912, 45, 1738), yielding the Schiff's base,  $C_{10}H_{10}N(MeI) \cdot CH:N \cdot C_6H_4 \cdot NMe_2$ , in green needles, m. p. 207 (decomp.). This was hydrolysed by boiling with dilute hydrochloric acid, and *p*-nitrophenylhydrazine added. The hydrazone so found was identical with the product of the nitrosoamine condensation.

(2) *Quinaldine methiodide*. The product formed red needles, m. p. 250° (Found: I, 29.4.  $C_{17}H_{15}O_2N_4I$  requires I, 29.3%).

(3) *Quinaldine ethiodide* gave red needles, m. p. 262° (Found: I, 28.5.  $C_{18}H_{17}O_2N_4I$  requires I, 28.3%).

(4)  $\alpha$ -*Picoline methiodide* gave yellow needles, m. p. 260° (Found: I, 33.4.  $C_{13}H_{13}O_2N_4I$  requires I, 33.1%).

In the last three cases the identity of the product was confirmed as in the case of (1).

The author wishes to thank Dr. W. H. Mills, F.R.S., for his valued advice.

UNIVERSITY OF ABERDEEN.

## XLIX.—*The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part I.*

By JAMES ALLAN and ROBERT ROBINSON.

THE nitration of veratrole in cold acetic acid solution proceeds extremely smoothly and 4-nitroveratrole is obtained in almost theoretical yield. Careful search reveals no trace of 3-nitro-

veratrole or of 4:5-dinitroveratrole in the product. An ether of guaiacol, other than veratrole, will naturally yield two nitro-derivatives in relative amounts which depend on the ratio of the directive powers of the groups RO and MeO.

Since the meta-directing influence of the alkyloxy-group is zero, we may assume that Directive Power of OR/Directive Power of OMe = % of (A) formed in the reaction/% of (B) formed in the reaction. In order to obtain numbers which can be compared, the directive power of MeO is taken to be 100. In every case nitration was carried out in cold glacial acetic acid solution, and the composition of the product determined by the method of thermal analysis with the aid of data derived from mixtures of substances of the types (A) and (B), which were prepared by appropriate alkylation of 4- and 5-nitroguaiacols, respectively. The directive powers found in this way were: MeO, 100; EtO, 135; Pr<sup>n</sup>O, 128; Pr<sup>i</sup>O, 150; *n*-C<sub>4</sub>H<sub>9</sub>O, 123; CH<sub>2</sub>PhO, 113. It is interesting to note that Sonn and Patschke (*Ber.*, 1925, 58, 1698) \* have observed the order CH<sub>2</sub>·CH·CH<sub>2</sub>·O > EtO > Pr<sup>n</sup>O > MeO for the orienting influence of these groups in the course of the preparation of ethers of β-resorcyraldehyde by the Gattermann synthesis.

## EXPERIMENTAL.

*Mixtures of 4-Nitro-2-ethoxyanisole and 5-Nitro-2-ethoxyanisole.*—5-Nitroguaiacol was prepared by the method of Pollecöff and Robinson (*J.*, 1918, 113, 648) and in the nitration of 2-methoxyphenyl carbonate it was found advantageous to continue stirring at 0° for 3·5 hours. The ethylation of 5-nitroguaiacol was carried out by Ludwig's method (*Monatsh.*, 1900, 21, 100) and also by the xylene-ethyl sulphate-potassium carbonate process. The yield was 65% and the m. p. 102°. 5-Nitro-2-ethoxyanisole (Freyss, *Bull. Soc. ind. Mulhouse*, 1901, 70, 375), m. p. 85°, was similarly obtained in 60% yield from 4-nitroguaiacol. The freezing points were determined in a double-jacketed glass tube with the usual precautions. Nucleation and stirring were practised and the thermometer was graduated in fifths of a degree, but could be read accurately to the nearest 0·1°. As in all subsequent cases, the entire range of composition was examined and a portion of the curve selected for closer study either because the readings

\* The work here described was carried out in 1922—1923 and the numerical results were disclosed when Part IV of this series was read at a meeting of the Society in June, 1925 (compare *J. Soc. Chem. Ind.*, 1925, 44, 659r).

were more free from ambiguity in that region, or because the nitration mixture has a freezing point lying well inside the section.

The following data were employed in the present instance, the first number of each pair representing the percentage of 5-nitro-2-ethoxyanisole in the mixture: 31.5, 83.7°; 37.8, 79.5°; 42.4, 75.4°; 50.9, 66.3°; 54.1, 62.6°; 55.6, 60.1°.

*Nitration of 2-Ethoxyanisole.*—2-Ethoxyanisole, b. p. 213° (Tiemann and Koppe, *Ber.*, 1881, 14, 2018) (10 g.) mixed with purified acetic acid (30 g.) was nitrated by the gradual addition of nitric acid (12.5 c.c.;  $d$  1.42) in acetic acid (30 g.). The mixture was mechanically stirred and cooled in a freezing mixture; the highest temperature reached was 12°. After 45 minutes, the product crystallised and the temperature remained stationary at  $-1^\circ$ ; water was then added, the solid collected, well washed and dried (yield 95%). The product (A) was crystallised from methyl alcohol (50 c.c.), and equilibrium ensured by keeping for 5 hours at 16°. The pale yellow crystals were collected, thoroughly drained under pressure, and dried (10.68 g.) (B). 7.1652 G. of (B) mixed with 0.5 g. of 4-nitro-2-ethoxyanisole froze at 66.0°. Hence from the graph, (B) contains 4.82 g. of 4-nitro-2-ethoxyanisole and 5.85 g. of 5-nitro-2-ethoxyanisole. In order to determine the composition of (A) it is necessary to estimate the solubilities of the isomerides in methyl alcohol at 16° and in presence of each other. 4-Nitro-2-ethoxyanisole (6.1860 g.) and 5-nitro-2-ethoxyanisole (3.8571 g.) were allowed to saturate methyl alcohol (25 c.c.) at 16°. The solid residue weighed 9.13 g. and its f. p. was 81.5°, corresponding to 34.9% of 5-nitro-2-ethoxyanisole. Combining these results, it appears that (A) contains 42.5% of 4-nitro-2-ethoxyanisole and 57.5% of 5-nitro-2-ethoxyanisole. That (B) contained the two isomerides only was shown by the fact that 7.1652 g. of (B) mixed with 1.0 g. of 4-nitro-2-ethoxyanisole froze at 68.9°. This corresponds to 51.4% of 4-nitro-2-ethoxyanisole, whereas the percentage calculated from the assumed composition of (B) is 51.9. This result and similar ones recorded below also guarantee the correct location of the points on the graph corresponding to the observed freezing points. The directive power of EtO relative to MeO (100) is therefore 135 in this series.

4:5-Dinitro-2-ethoxyanisole.—The mixture of mononitro-2-ethoxyanisolcs was dissolved in cold nitric acid ( $d$  1.42) and next day the product was precipitated by water and collected; it crystallised from alcohol in very pale yellow needles, m. p. 150° (yield almost quantitative) (Found: N, 11.6.  $C_9H_{10}O_6N_2$  requires N, 11.6%). The m. p. of this methoxyethoxy-compound appears anomalous, since the related dimethoxy- and diethoxy-compounds melt at

132° and 113° respectively. By successive reduction with zinc dust in aqueous alcoholic hydrochloric acid solution, addition of sodium acetate and of a solution of phenanthraquinone in aqueous sodium bisulphite, and boiling, a flocculent, yellow precipitate of 3-methoxy-2-ethoxyphenanthraphenazine is obtained. Crystallised from xylene, the substance has m. p. 231°, gives a deep magenta solution in sulphuric acid, and fluoresces violet in benzene (Found : N, 8.2.  $C_{23}H_{18}O_2N_2$  requires N, 7.9%).

6'-Nitro-3' (or 4')-methoxy-4' (or 3')-ethoxyphenyl-4 : 5-thiotriazocatechol Methyl Ethyl Ether.—Jones and Robinson (J., 1917, 111, 910) obtained a compound,  $C_{16}H_{16}O_6N_4S$ , by the action of hydrogen sulphide on 4 : 5-dinitroveratrole in aqueous alcoholic ammonia. This substance was shown to be a nitro-derivative, reducible to a related diazotisable amine, and it was considered to be 6-nitro-veratryl-4 : 5-thiotriazoveratrole (I).

We have applied the reaction under similar conditions to 4 : 5-dinitro-2-ethoxyanisole and have thus obtained a yellow compound which was crystallised by the addition of alcohol to its solution in nitrobenzene. The substance closely resembles nitroveratryl-thiotriazoveratrole and appears to be homogeneous. The yellow, rectangular plates, m. p. 175°, are sparingly soluble in alcohol or ether and moderately readily soluble in benzene or chloroform (Found : C, 51.6; H, 4.4; S, 7.8.  $C_{18}H_{20}O_6N_4S$  requires C, 51.4; H, 4.8; S, 7.6%).

In these substances the  $SN_3$  group is associated with 24 valency electrons and on the electronic theory of valency a reasonable assumption regarding the constitution of the thiotriazo-nucleus is that it contains the bipolar ion (II), where each straight line in thin type represents two electrons.

It is very probable, however, that the nucleus has aromatic character and this requires a contribution of four electrons from the  $SN_3$  group towards an aromatic sextet, two more being derived by fusion with the benzene nucleus. By analogy with glyoxaline these four electrons should be derived from the nitrogen atom joined to sulphur and from the double bond joining the other nitrogen atoms, giving the expression (III). Here, the sulphur atom is favourably situated for the purpose of increasing its covalency with the nitrogen atom and thus neutralising both its

own electrical charge and that on the ring members. The formula (II) is derived from an *o*-thionitrosoazobenzene derivative by a process of internal addition precisely analogous to that assumed by Burkhardt and Lapworth (J., 1925, 127, 1749) for the first stage of the reaction between nitrosobenzene and ethyl methylenemalonate. In the case we have discussed, the place of the unsaturated ester is taken by the thionitroso-group and the place of the nitroso-group by the azo-group.

4-Nitro-2-propoxyanisole, prismatic needles, m. p. 106° (Found : C, 56.6; H, 6.1.  $C_{10}H_{13}O_4N$  requires C, 56.9; H, 6.2%) and 5-nitro-2-propoxyanisole, hexagonal tablets, m. p. 72° (Found : C, 56.9; H, 6.5%) were obtained in 70% and 65% yield, respectively, from 5-nitroguaiacol and 4-nitroguaiacol by the action of propyl iodide and potassium hydroxide in boiling alcoholic solution during 5–6 hours.

Mixtures of 4-nitro-2-propoxyanisole and 5-nitro-2-propoxyanisole had the following freezing points, the first number of each pair representing the percentage of 4-nitro-2-propoxyanisole in the mixture : 31.5, 55.5°; 34.2, 59.9°; 36.7, 63.5°; 41.0, 69.6°; 44.2, 73.4°; 50.5, 79.3°; 53.6, 82.4°; 57.0, 84.6°.

*Nitration of 2-Propoxyanisole.*—2-Propoxyanisole (10 g.), b. p. 220–225° (Cahours, *Compt. rend.*, 1877, 84, 1195, gives 240–245°), dissolved in pure acetic acid (45 g.) was nitrated below 9° by the gradual addition with stirring of a mixture of nitric acid (15 c.c.; *d* 1.42) and acetic acid (35 g.). After one hour the product was precipitated by water, collected, washed and dried (A; 96% yield). This material was crystallised from 70 c.c. of 80% ethyl alcohol and after attaining equilibrium at 16° the solid was isolated (B) (10.79 g.). (B) froze at 75.2°, corresponding to 46.2% of 4-nitro-2-propoxyanisole. This was verified by adding 0.5213 g. of 4-nitro-2-propoxyanisole, when the f. p. was 77.6°, corresponding to 48.7% of 4-nitro-2-propoxyanisole (calc., 48.7%). A mixture of the isomerides (11.8861 g.), f. p. 78.5° (corresponding to 49.75% of 4-nitro-2-propoxyanisole) was allowed to reach equilibrium with 80% alcohol (40 c.c.) at 16°. The isolated solid froze at 80.0° (corresponding to 51.25% of 4-nitro-2-propoxyanisole) and the alcohol dissolved 0.5151 g. From these results it may be calculated that (A) contains 43.9% of 4-nitro-2-propoxyanisole and 56.1% of 5-nitro-2-propoxyanisole. The directive power of  $Pr^2O$  is, accordingly, 128.

4 : 5-Dinitro-2-propoxyanisole, obtained in theoretical yield from the mono-nitration product of 2-propoxyanisole by the action of nitric acid (*d* 1.42), crystallises from alcohol in needles, m. p. 143° (Found : C, 47.0; H, 5.0.  $C_{10}H_{12}O_6N_2$  requires C, 46.9; H, 4.7%).

4-Nitro-2-isopropoxyanisole, pale yellow, prismatic needles, m. p.  $83^{\circ}$  (Found: C, 56.7; H, 6.1.  $C_{10}H_{13}O_4N$  requires C, 56.9; H, 6.2%) and 5-nitro-2-isopropoxyanisole, yellow prisms, m. p.  $53^{\circ}$  (Found: C, 57.0; H, 6.3%), were obtained like the ethyl and propyl compounds previously described, but in this case the yields were only 30% and 15%, respectively. The freezing points of mixtures of the isomerides were the following, the first number of each pair giving the percentage of 5-nitro-2-isopropoxyanisole: 24.6,  $69.7^{\circ}$ ; 30.4,  $66.7^{\circ}$ ; 35,  $63.7^{\circ}$ ; 39.5,  $60.2^{\circ}$ ; 48.1,  $53.8^{\circ}$ .

*Nitration of 2-isopropoxyanisole.*—Guaiacol was converted into its isopropyl ether by boiling in alcoholic solution with an equivalent of potassium hydroxide and isopropyl iodide. The yield of a colourless oil, b. p.  $210-215^{\circ}$ , was 90% (Found: C, 71.6, 71.6; H, 8.4, 8.2.  $C_{10}H_{14}O_2$  requires C, 72.3; H, 8.4%). Somewhat low results in carbon estimations appear to be normal in the case of these ethers. Thus Cahours (*loc. cit.*) found C, 71.7 for 2-propoxyanisole. The nitration (of 8 g.) was carried out in the usual manner, giving a product (A) in 92% yield which was crystallised from 45 c.c. of 80% alcohol. After standing at  $15^{\circ}$ , the solids (B) were isolated (7.6978 g.). A mixture of 6.5663 g. of (B) with 2.4954 g. of 4-nitro-2-isopropoxyanisole froze at  $57.0^{\circ}$ , corresponding to 56.0% of 4-nitro-2-isopropoxyanisole. Hence (B) contains 39.3% of 4-nitro-2-isopropoxyanisole. A further 0.34 g. of 4-nitro-2-isopropoxyanisole was added and the f. p. was then  $58.2^{\circ}$ , corresponding to 57.8% (calc., 57.6%) of the 4-nitro-derivative. 60 C.c. of 80% alcohol dissolved 2.3089 g. of a mixture of 4-nitro-2-isopropoxyanisole (5.0 g.) and 5-nitro-2-isopropoxyanisole (4.641 g.) at  $15^{\circ}$  and the residue was isolated. 6.3365 G. of this product mixed with 4-nitro-2-isopropoxyanisole (1.1973 g.) had f. p.  $61.3^{\circ}$ , corresponding to 61.75% of the 4-nitro-derivative. From the above data it may be calculated that (A) contains 40.0% of 4-nitro-2-isopropoxyanisole and the directive power of  $Pr^{\beta}O$  is 150.

4:5-Dinitro-2-isopropoxyanisole, prepared from the mixture of mononitro-derivatives of 2-isopropoxyanisole in the usual manner, is much more readily soluble in alcohol than the propoxy-isomeride and crystallises in rectangular plates, m. p.  $129^{\circ}$  (Found: C, 46.8; H, 5.0.  $C_{10}H_{12}O_6N_2$  requires C, 46.9; H, 4.7%).

4-Nitro-2-n-butoxyanisole, m. p.  $74^{\circ}$  (Found: C, 58.3; H, 7.0.  $C_{11}H_{15}O_4N$  requires C, 58.7; H, 6.7%), and 5-nitro-2-n-butoxyanisole, pale yellow prisms, m. p.  $56^{\circ}$  (Found: N, 6.6.  $C_{11}H_{15}O_4N$  requires N, 6.2%), were obtained in the usual manner in 60% and 55% yield, respectively. The freezing points of mixtures of the isomerides are the following, the first number of each pair indicating the percentage of 4-nitro-2-n-butoxyanisole: 25.5,  $39.8^{\circ}$ ; 28.3,

37.5°; 33.2, 32.6°; 36.5, 30.4°; 39.6, 33.2°; 42.7, 35.3°; 45.1, 35.7°; 46.9, 35.5°; 50.7, 39.6°; 52.2, 41.8°; 53.8, 44.1°.\* A compound, f. p. 35–36°, appears to be formed containing 44% of the 4-nitro-isomeride. The eutectic on the side of the 4-nitro-isomeride is near 35° and on the side of the 5-nitro-isomeride it is near 30°.

*Nitration of 2-n-Butoxyanisole.*—The *n*-butyl ether of guaiacol was obtained in almost quantitative yield in the usual manner. It is a colourless oil, b. p. 236–239° (Found: C, 72.8; H, 8.8.  $C_{11}H_{16}O_2$  requires C, 73.3; H, 8.9%), and, on nitration in acetic acid below 12°, gave a mixture of mononitro-derivatives (A) in 96% yield. This material was dissolved in 65 c.c. of 80% alcohol and, on cooling, an oil separated and subsequently crystallised. After keeping at 16°, the product (B) was collected, well drained, and pressed, and finally dried at 95° during an hour. (B) (8.5006 g.) mixed with 4-nitro-2-*n*-butoxyanisole (0.3088 g.) froze at 37.3°, corresponding to a mixture containing 49.0% of the 4-nitro-isomeride. On adding 0.3054 g. of the 4-nitro-isomeride, the f. p. observed was 39.6°, corresponding to 50.7% of the 4-nitro-isomeride (calc., 50.7%). Further addition of 4-nitro-2-*n*-butoxyanisole (0.2977 g.) gave a mixture found to contain 52.1% of the 4-nitro-isomeride (calc., 52.2%). A mixture of 4-nitro-2-*n*-butoxyanisole (6.0833 g.) and 5-nitro-2-*n*-butoxyanisole (6.5902 g.) was crystallised from 80% alcohol (50 c.c.) and, after standing at 16°, the solid was isolated and found to weigh 11.2734 g. and to freeze at 38.5°, corresponding to 49.75% of the 4-nitro-isomeride.

From the above data it follows that (A) contains 44.8% of 4-nitro-2-*n*-butoxyanisole and 55.2% of the 5-nitro-isomeride. Consequently the directive power of *n*- $C_4H_9\cdot O$  is 123.

4:5-Dinitro-2-*n*-butoxyanisole, obtained by further nitration of the mixed mononitro-derivatives in excellent yield, crystallises from alcohol in faintly yellow needles, m. p. 97° (Found: C, 48.7; H, 4.9.  $C_{11}H_{14}O_6N_2$  requires C, 48.9; H, 5.2%).

4-Nitro-2-benzyloxyanisole was obtained in 75% yield from 5-nitroguaiacol by the action of benzyl chloride and potassium hydroxide in boiling alcoholic solution. It crystallises from alcohol in one of two forms, m. p. 93° and m. p. 98° (Found in material, m. p. 93°: C, 64.7; H, 5.2, and in material, m. p. 98°: C, 64.7; H, 5.1.  $C_{14}H_{13}O_4N$  requires C, 64.9; H, 5.0%).

5-Nitro-2-benzyloxyanisole, m. p. 82°, was similarly obtained from 4-nitroguaiacol in 55% yield (Found: C, 64.9; H, 5.0%). The

\* In this case and also that of the benzyloxy-series, sharper and more consistent readings were obtained if, after thorough nucleation, stirring ceased when the cooling became very slow in the neighbourhood of the freezing point.

freezing points of mixtures of the isomerides were the following, the first number of each pair indicating the percentage of 5-nitro-2-benzyloxyanisole: 17.1, 85.0°; 23.7, 80.0°; 33.6, 72.9°; 37.2, 69.2°; 41.3, 65.2°; 46.0, 57.2°.

*Nitration of 2-Benzyloxyanisole.*—2-Benzyloxyanisole (9.766 g.) dissolved in acetic acid (65 c.c.) was nitrated by the gradual addition of a mixture of nitric acid (20 c.c.;  $d$  1.42) and acetic acid (35 c.c.) with cooling in ice and stirring. The temperature rose momentarily to 18°, but quickly fell to 8°. After an hour, water was added and the product (A) collected, washed and dried (yield 98%). The material was crystallised from 80% alcohol (80 c.c.) at 16°, and the solid (B) completely freed from adherent mother-liquor and dried (11.1332 g.). A mixture of (B) (6.3452 g.) and 4-nitro-2-benzyloxyanisole (2.0015 g.) froze at 67.0° and therefore contained 39.5% of 5-nitro-2-benzyloxyanisole. On adding more 4-nitro-2-benzyloxyanisole (0.451 g.), the f. p. was 69.1°, corresponding to 37.3% of the 5-nitro-isomeride in the mixture (calc., 37.5%). Alcohol (50 c.c. of 80%) was saturated at 16° by the addition of 4-nitro-2-benzyloxyanisole (5.0 g.) and 4-nitro-2-benzylanisole (4.2528 g.). The solvent contained 0.3972 g. of the mixed isomerides, whilst the separated material had f. p. 59.5° and thus contained 44.8% of 5-nitro-2-benzyloxyanisole. From the above data it appears that (A) contained 53.0% of 5-nitro-2-benzyloxyanisole and 47.0% of the 4-nitro-isomeride and that the directive power of  $\text{CH}_2\text{PhO}$  is 113.

The authors wish to thank the Department of Scientific and Industrial Research for grants which have enabled one of them to take part in the research.

L.—*The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part II. The Nitration of some 2-Benzyloxyanisoles substituted in the Benzyl Group.*

By ALBERT EDWARD OXFORD and ROBERT ROBINSON.

IN this communication the method described in the preceding paper is applied to the determination of the directive powers of the *m*- and *p*-nitrobenzyloxy- and *m*-methoxybenzyloxy-groups.

2-*m* (or *p*)-Nitrobenzyloxyanisole is much more difficult to

nitrate than is 2-benzyloxyanisole and it is evident that the introduction of the nitro-group has the effect of depressing the reactivity of the molecule as a whole. This effect is, however, felt to a greater relative extent by the benzyloxy-group than by the methoxyl. In Part I it is shown that the directive power of the benzyloxy-group (MeO, 100) is 113 and we now find that the *m*-nitrobenzyloxy- and *p*-nitrobenzyloxy-groups have, within the limits of experimental error, identical directive powers, namely, 67. Obviously the true value should be smaller still, because a portion of the inhibitory effect of the nitroxyl has been experienced by the methoxyl group. Since the nitro-group exerts its influence to an equal extent from the meta- and para-positions in the benzyl nucleus, it is not an alternating effect but, in all probability, a general polar effect which is under observation. The existence of general electrical effects is widely recognised, but it must be emphasised that, no less than in the case of the alternating effects, a knowledge of the mechanism of the reaction is necessary before a conclusion can be reached as to whether a particular process should be facilitated or hindered. An example will illustrate our meaning. Olivier (*Rec. trav. chim.*, 1922, 41, 646) has shown that the hydrolysis of *o*-, *m*-, and *p*-nitrobenzyl chlorides in aqueous alcohol is much slower than that of benzyl chloride or any of its chloro-, bromo-, or methyl derivatives and this is another clear case of the general electrical effect of the nitro-group. The fact that the nitrophenols and nitrobenzoic acids, compared with phenol and benzoic acid, respectively, are strong acids shows that the nitro-group increases the affinity for the negative charge, whilst the weak basic nature of the nitroanilines, compared with aniline, shows that the introduction of a nitro-group decreases the affinity for the positive charge. An important exemplification of the latter point is found in the high chemical reactivity of nitro-substituted diazonium salts. Now, under the conditions of Olivier's experiments, the most acceptable view of the mechanism of the hydrolysis is that which postulates partial or complete dissociation of the nitrobenzyl chlorides at some stage and possibly as a result of oxonium salt formation with water or alcohol. Any such process will be inhibited if the affinity of the substituted benzyl group for the positive charge is diminished. Hence, on this mechanism, the theory of the general electrical effect of the nitro-group requires that the hydrolysis of a nitrobenzyl chloride should be slower than that of benzyl chloride. If, however, the benzyl chlorides were hydrolysed through the intermediate formation of a complex anion which subsequently recovered neutrality by ejecting chloridion, then the nitro-group, by increasing the affinity for the negative charge, would

facilitate the process.\* Conversely, the introduction of nitro-groups into a molecule should retard the formation of complex kations such as those resulting from the attack of an aromatic compound by a diazonium ion, and this is in accordance with experience. It is a short step to the general case of aromatic substitution in which the nucleus is attacked by the positive end of a polarised complex rather than by a positive ion, and the same principles apply. If an aromatic nucleus, A, reacts with a complex,  $\oplus B-C\ominus$ , then the charge on B is transferred to the nucleus and the bipolar ion,  $\oplus A-B-C\ominus$ , is produced. Circumstances, such as the introduction of nitroxyl, which reduce the affinity of A for the positive charge must retard the process. In our experiments, the nitro-groups gave rise to no alternating effect whatever, but it should be noted that the system is a complex one summarised as : modifying group—activating centre—point of reaction. That is, the effect of the nitro-groups on the reacting nucleus is only experienced through an oxygen atom, which must be regarded as the effective key-atom. In Olivier's experiments very weak alternating effect (in the expected sense) is superposed on the powerful general effect, whilst Harrison (private communication) has shown that the hydration of 3 : 4'-dinitrotolane yields nothing but 3-nitrophenyl 4-nitrobenzyl ketone, (*m*-) $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$  (*p*-), in accordance with the rule of alternate polarities. The general conclusion may be drawn that the alternating polar effect of a nitroxyl group cannot be discerned beyond the limits of the conjugated (crotonoid) system of which it forms a part. We had planned the determination of the directive powers of *m*- and *p*-methoxybenzyloxy-groups, but for reasons explained on p. 391 the latter estimation has not yet been made. The *m*-methoxybenzyloxy-group has the directive power 92 (MeO, 100;  $\text{CH}_2\text{Ph} \cdot \text{O}$ , 113) and it will suffice to note at this stage that the result is in harmony with the effect which a *m*-methoxy-group has in enhancing the ionisation\* constants of some substituted benzoic acids (*e.g.*, anisic acid,  $K = 3.2 \times 10^{-5}$ ; veratric acid,  $K = 3.8 \times 10^{-5}$ ).

\* The hydrolysis of *p*-iodoxynitrobenzene by alkalis (Vorländer and Büchner, *Ber.*, 1925, 58, 1291) with formation of nitrobenzene and an iodate is a most interesting example of a combined alternating and general effect resulting in the ready production of a complex anion which recovers neutrality by ejecting iodate ion

*p*-Dinitrobenzene does not undergo a similar reaction and this suggests that an important factor in the situation is the heavy iodine atom, which is doubtless capable of adding electrons to its outer shell.

## EXPERIMENTAL.

2-*m*-Nitrobenzyloxyanisole,  $\text{OMe} \cdot \text{C}_6\text{H}_4 \cdot \text{O} \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ .—*m*-Nitrobenzyl bromide, m. p. 59–60°, was obtained in 96% yield by the action of bromine (32 g.) on a mixture of *m*-nitrobenzyl alcohol (31 g.) and red phosphorus (4 g.). A mixture of guaiacol (10 g.), *m*-nitrobenzyl bromide (17 g.), and alcoholic sodium ethoxide (430 c.c. of 0.5*N*) was refluxed for 1.5 hours, and the solid that was precipitated by addition of water was dried and crystallised from alcohol and then twice from light petroleum; it formed small, pale yellow needles, m. p. 47.5–48° (Found: C, 64.8; H, 5.0; N, 5.7.  $\text{C}_{14}\text{H}_{13}\text{O}_4\text{N}$  requires C, 64.8; H, 5.1; N, 5.4%).

4-Nitro-2-*m*-nitrobenzyloxyanisole,

The guaiacol carbonate process for the preparation of 5-nitroguaiacol, for some unascertained reason, gave very poor results in this series of experiments and we therefore obtained the substance by the nitration of acetylguaiacol and subsequent hydrolysis (Paul, *Ber.*, 1906, 39, 2779). The ether of the nitroguaiacol was prepared by the method described for the *m*-nitrobenzylation of guaiacol, except that the reaction mixture was boiled for 2 hours. The substance was crystallised from acetic acid and then twice from alcohol, separating in almost colourless, microscopic plates, m. p. 164.5–165° (Found: C, 55.4; H, 4.3.  $\text{C}_{14}\text{H}_{12}\text{O}_6\text{N}_2$  requires C, 55.3; H, 4.0%). All the *m*-nitrobenzyloxy-derivatives were more readily soluble in organic solvents than the corresponding *p*-nitrobenzyloxy-compounds.

5-Nitro-2-*m*-nitrobenzyloxyanisole.—The potassium salt of 4-nitroguaiacol which separates from the product of hydrolysis of 4-nitroveratrole (Pollecioff and Robinson, *J.*, 1918, 113, 645) proved to be homogeneous and was brought into reaction with an equivalent quantity of *m*-nitrobenzyl bromide in boiling alcoholic solution (400 c.c. for 12 g. of the salt) during 1.25 hours. The crude product, m. p. 140°, was twice recrystallised from alcohol, separating in colourless, microscopic plates, m. p. 140.5–141.5° (Found: C, 55.5; H, 4.2%).

*Method of Determination of Freezing Points.*—The material was placed in a thick-walled test-tube (8.5 × 1.5 cm.) provided with a standard Anschütz thermometer (graduated in fifths of a degree, but capable of being read accurately with the aid of a telescope to the nearest 0.05°) and a stirrer of stout silver wire. This vessel was surrounded by an air-jacket and the whole could be heated or cooled in a covered bath of sulphuric acid. The substances to be tested were finely powdered and dried for 10–12 hours at temperatures a few degrees below their m. p. About 1.3 g.

usually sufficed to cover the bulb of the thermometer. The temperature of the outer bath was kept at 20° above the m. p. of the material until this was completely fluid and thereafter at 2° below the f. p., which was ascertained in a rough preliminary experiment or by extrapolation. The liquid in the inner tube was slowly stirred until its temperature was 1.5–2° below the true f. p.; crystallisation was then induced by more vigorous stirring or by scratching; the temperature then rose to a maximum and remained at that temperature, the f. p., for 0.5–3 minutes, slow stirring being continued. In the neighbourhood of the eutectic, the degree of supercooling had a considerable effect on the observed f. p. and, on the other hand, as the mixture approached the eutectic it was less difficult to induce crystallisation. In every case several determinations of each f. p. were made and the mean of the most trustworthy values, the extreme variation not exceeding 0.3°, was calculated. It is not good practice to take the highest value and ignore the remainder, since this high value may have been obtained by some deviation from standard procedure.

*Mixtures of 4-Nitro-2-m-nitrobenzyloxyanisole and  
5-Nitro-2-m-nitrobenzyloxyanisole.*

% 5-nitro-isomeride.	F. p.	% 5-nitro-isomeride.	F. p.
0.0	165.3°	50.2	137.0°
11.47	160.35	55.0	130.9
20.56	156.0	60.1	128.7
29.77	151.4	65.5	129.1 (?)
34.85	148.45	70.3	127.5
39.59	145.1	80.7	133.5
45.47	140.55	92.0	139.1
50.19	136.7	100.0	142.65
54.44	132.2		

Obtained by adding the 5-nitro-isomeride to the 4-nitro-isomeride.

Obtained by adding the 4-nitro-isomeride to the 5-nitro-isomeride.

*Nitration of 2-m-Nitrobenzyloxyanisole.*—The ether (2.170 g.) dissolved in pure acetic acid (25 c.c.) was nitrated by the addition of boiled nitric acid (10 c.c.; *d* 1.42) in one portion, the mixture being mechanically stirred and efficiently cooled by water at 14°. Subsequent operations were exactly the same as those described below in the case of the *p*-nitrobenzyloxy-isomeride. The yield was 98.4% of that theoretically possible and in this case the correction applied to the f. p. was + 0.1°. The corrected f. p. of the nitration product (A) was 145.1° and from the graph this is found to correspond to 39.6% of the 5-nitro-isomeride (Lagrange interpolation formula—39.7%). The corrected f. p. of a mixture (B) of 1.2372 g. of (A) and 0.2520 g. of the 4-nitro-isomeride was 149.65°. From the graph this corresponds to 32.7% of the 5-nitro-isomeride (L.I.F.—32.9%) and hence (A) contained 39.4% (39.6%) of the

5-nitro-isomeride. The best value for the % of 5-nitro-2-*m*-nitrobenzyloxyanisole in the nitration product appears to be 39.6. Hence the directive power of the *m*-nitrobenzyloxy-group is 67. This was confirmed by taking 0.9579 g. of (B) and adding 0.2808 g. of the 5-nitro-isomeride, thus bringing the % of the latter to 48.1. From the graph, the f. p. should be 138.4° (Found: 138.2°).

*Mixtures of 4-Nitro-2-p-nitrobenzyloxyanisole and 5-Nitro-2-p-nitrobenzyloxyanisole.*—The compounds were obtained exactly like the isomerides and in excellent yields. They were crystallised thrice from benzene and obtained in pale yellow, flat needles, sparingly soluble in most organic solvents. The 4-nitro-isomeride has m. p. 167—168° (Found: C, 55.5; H, 4.0.  $C_{14}H_{12}O_6N_2$  requires C, 55.3; H, 4.0%) and the 5-nitro-isomeride has m. p. 163.5—164.5° (Found: C, 55.3; H, 4.1%).

% 5-nitro-isomeride.	F. p.	% 5-nitro-isomeride.	F. p.

		89.5	160.0
		100.0	165.0

Obtained by adding the 5-nitro-isomeride to the 4-nitro-isomeride.

Obtained by adding the 4-nitro-isomeride to the 5-nitro-isomeride.

*Nitration of 2-p-Nitrobenzyloxyanisole.*—The *p*-nitrobenzyl ether of guaiacol was obtained like the *m*-nitrobenzyl ether and crystallised from alcohol in pale yellow, glistening leaflets, m. p. 63.5° (Found: C, 64.9; H, 5.0.  $C_{14}H_{13}O_4N$  requires C, 64.8; H, 5.1%). The substance is readily soluble in ether, benzene, chloroform, or acetic acid, sparingly soluble in cold methyl or ethyl alcohol and in hot light petroleum. Lyman and Reid (*J. Amer. Chem. Soc.*, 1920, 42, 615) quote the m. p. (63.6°) of the substance but give no further details. A solution of the ether (3.4 g.) in acetic acid (30 c.c.) was mechanically stirred, cooled in ice, and boiled nitric acid (3 c.c.;  $d$  1.42) mixed with acetic acid (3 c.c.) was gradually introduced. After 2 hours, unchanged substance was recovered, whereas 2-benzyloxyanisole was readily nitrated under similar conditions. Next, the theoretical amount of nitric acid was added to an approximately 10% solution of the ether in acetic acid, and the mixture heated on the steam-bath to 90° without a colour change. One drop of nitric acid was then added and in a minute the liquid suddenly became red and in a short time a considerable amount of a yellow solid crystallised. The addition of a second molecular proportion of nitric acid produced no effect and the temperature

was then raised to 100° for 15 minutes, giving a clear solution. Water was added and the product collected, washed, and dried in the air and at 120° for 2 hours (Found: C, 55.2; H, 4.0. Calc.: C, 55.4; H, 4.0%). On analysis (f. p. 145-95°) this material was found to contain 42% of the 5-nitro-isomeride, and this conclusion was confirmed by addition of the 4-nitro-isomeride and the determination of the f. p. of the mixture.

*Nitration at 14°.* Boiled nitric acid (10 c.c.;  $d$  1.42) was added to a stirred solution of the ether (2.422 g.) in acetic acid (30 c.c.) cooled by water at 14°. In about a minute crystallisation occurred without a change in the colour of the liquid, and after 15 minutes water was added and the product collected, washed, and dried at 80-100° for 10 hours. The yield was 99.1% of that theoretically possible. The f. p. of the crude product was 147.0° and in order to apply a correction for traces of impurities the following procedure was adopted. The finely powdered product (1.5 g.) was heated with pure methyl alcohol (10 c.c.) until the latter boiled; the mixture was then cooled, finally in water at 10°. The solid was collected, 10 c.c. of methyl alcohol being employed for washing the flask and an equal volume for washing on the filter. The material dried at 100° for 1 hour lost very little weight and had f. p. 147.2°. A repetition of the process gave a mixture, f. p. 147.0°. Hence the corrected f. p. of the nitration product is 147.4°. From the graph we find that the corresponding % of the 5-nitro-isomeride is 39.8 (L.I.F.—39.8). The corrected f. p. of a mixture of the nitration product (1.1706 g.) and the 4-nitro-isomeride (0.2419 g.) is 152.0°. Using the interpolation formula, this corresponds to 32.5% of the 5-nitro-isomeride or 39.2% of the 5-nitro-isomeride in the nitration product. The best value for the composition of the mixture obtained by nitration of 2-*p*-nitrobenzyloxyanisole is 4-nitro-2-*p*-nitrobenzyloxyanisole 60.5% and 5-nitro-2-*p*-nitrobenzyloxyanisole 39.5%, whence the directive power of the *p*-nitrobenzyloxy-group is 67. On this assumption, the f. p. of a mixture of the nitration product (0.3842 g.) and the 5-nitro-isomeride (0.7388 g.) should be 154.5° on a branch of the curve not previously employed (Found: 154.25°). An artificial mixture of the two isomerides containing 39.5% of the 5-nitro-isomeride had f. p. 147.25° [Found: Nitration product, f. p. 147.0°; f. p. (corr.) 147.4°].

2-*m*-Methoxybenzyloxyanisole.—Guaiacol (4.9 g.) and *m*-methoxybenzyl bromide (8 g.) (Lapworth and Shoesmith, J., 1922, 121, 1392) were added to a solution of sodium ethoxide (from 0.9 g. of sodium) in 95% alcohol (300 c.c.), and the mixture heated in the steam-bath for 10 minutes. The product was isolated by extraction

with ether after addition of water, and 4.0 g., b. p. 220°/22 mm., m. p. 28—31°, were obtained. By crystallisation from light petroleum the m. p. was raised to 31.5° (Found: C, 74.0; H, 6.5.  $C_{15}H_{16}O_3$  requires C, 73.7; H, 6.6%).

4-Nitro-2-m-methoxybenzyloxyanisole, crystallising from alcohol in short, pale yellow, glistening needles, m. p. 116—117° (Found: C, 62.2; H, 5.4.  $C_{15}H_{15}O_5N$  requires C, 62.3; H, 5.2%), and 5-nitro-2-m-methoxybenzyloxyanisole, crystallising from alcohol in very pale yellow, slender needles, m. p. 98.5—99.5° (Found: C, 61.8; H, 5.5%), were prepared by methods closely resembling those employed for the nitrobenzyl ethers of 5- and 4-nitroguaiacols. The yields were good.

Mixtures of 4-Nitro-2-m-methoxybenzyloxyanisole and 5-Nitro-2-m-methoxybenzyloxyanisole.—The following freezing points were observed, the first number of each pair indicating the percentage of the 5-nitro-isomeride in the mixture: 0.0, 114.85° (1); 11.78, 109.8° (2); 18.57, 106.8° (3); 21.52, 105.3° (4); 31.00, 100.35° (5); 34.20, 98.3° (6); 41.55, 93.1° (7); 50.20, 85.6° (8); 53.91, 82.5° (9); 62.23, 75.2° (10). In applying the Lagrange interpolation formula, the values (1), (2), and (3) were ignored, because in these cases supercooling to the extent of 3° or 4° was necessary. A smooth curve can be drawn through points corresponding to the values (1) to (9) inclusive, and (10) is probably on the other side of the eutectic.

Nitration of 2-m-Methoxybenzyloxyanisole.—The nitration was carried out like that of 2-p-nitrobenzyloxyanisole, except that the temperature was 0° and the flask was kept over-night in melting ice. The yield from 1.9642 g. of the ether was 2.3020 g. (99.0%) and the pale yellow, dry product had m. p. 78—94° (Found: C, 62.4; H, 5.3; N, 5.3. Calc.: C, 62.3; H, 5.2; N, 4.8%). The f. p. of the nitration product was 87.05°, whilst mixtures of the nitration product (1.6128 g.) with 0.2398 g. and 0.3608 g. of the 4-nitro-isomeride froze at 92.85° and 95.4°, respectively. Careful examination of these figures by graphical and algebraic methods, taking into consideration the fact that the f. p. 92.85° is close to a determined point (7) 93.1°, shows that the best value for the composition of the nitration mixture is 48.0% of 5-nitro-2-m-methoxybenzyloxyanisole and 52% of 4-nitro-2-m-methoxybenzyloxyanisole. The directive power of the *m*-methoxybenzyloxy-group is accordingly 92.

2-p-Methoxybenzyloxyanisole.—A solution of anisyl alcohol (5 c.c.) in benzene (30 c.c.) was saturated with hydrogen chloride. The reaction was very rapid. The solution decanted from the aqueous layer was dried by calcium chloride and, the excess of hydrogen

chloride having been removed in a current of dry air, added to a boiling solution of sodium ethoxide (from 1.0 g. of sodium) and guaiacol (6.5 g.) in absolute alcohol (300 c.c.); the mixture was then refluxed for 1.5 hours. The neutral ether, isolated in the usual manner, crystallised from light petroleum in rosettes of white needles, m. p. 94—96° (Found: C, 73.4; H, 6.5.  $C_{15}H_{16}O_3$  requires C, 73.7; H, 6.6%). Despite repeated efforts, satisfactory conditions for the nitration of this compound could not be established. It has not, therefore, been possible to make use of the data recorded below.

*4-Nitro-2-p-methoxybenzyloxyanisole.*—This substance, prepared like the 5-nitro-isomeride described below, was crystallised from alcohol and then repeatedly from light petroleum, separating in very pale yellow, glistening needles, m. p. 129—130° (Found: N, 4.9.  $C_{15}H_{15}O_5N$  requires N, 4.8%).

*5-Nitro-2-p-methoxybenzyloxyanisole.*—The *p*-methoxybenzylation of 4-nitroguaiacol was carried out in the usual manner, with *p*-methoxybenzyl bromide, but the yield was poor. After crystallisation from aqueous alcohol the substance melted at 108° with softening at 100°. Better results were obtained by the following method. Anisyl alcohol (4 c.c.) was converted into chloride in benzene solution as described above, and the liquid decanted from the aqueous layer shaken vigorously for one hour with a solution of the potassium salt (10 g.) of 4-nitroguaiacol in dilute aqueous sodium hydroxide (300 c.c.). The neutral product was extracted with ether, isolated, and crystallised from alcohol and then from light petroleum, separating in pale yellowish-brown, short needles, m. p. 109° with slight softening at 100° (Found: C, 62.2; H, 5.4.  $C_{15}H_{15}O_5N$  requires C, 62.3; H, 5.2%).

Mixtures of the 4- and 5-nitro-2-*p*-methoxybenzyloxyanisoles had the following f. p., the first number of each pair indicating the percentage of the 4-nitro-isomeride: 0.0, 107.8°; 7.01, 103.7°; 19.14, 96.0°; 21.97, 93.4°; 23.20, 91.05°; 29.32, 85.75°; 38.11, 82.2°; 43.64, 91.05°. In this case, it was necessary to resort to seeding, as otherwise the degree of supercooling required was 3° or more.

We are greatly indebted to the Department of Scientific and Industrial Research for grants which enabled one of us to take part in the work and to the Chemical Society for a grant which has met part of the cost of this investigation.

[Received, December 19th, 1925.]

LI.—*The Relative Directive Powers of Groups of the Form RO and RR'N in Aromatic Substitution. Part III. The Nitration of some p-Alkyloxy-anisoles.*

By ROBERT ROBINSON and JOHN CHARLES SMITH.

THE nitration of quinol dialkyl ethers in cold acetic acid solution results in an almost theoretical yield of the pure mononitro-derivatives and the composition of the product can therefore be determined with considerable accuracy by the method of thermal analysis. Satisfactory methods for the preparation of 2-nitro-4-methoxyphenol and 3-nitro-4-methoxyphenol and of the ethyl, propyl, and *p*-nitrobenzyl ethers of each of these substances have been devised and the f. p.'s of mixtures of the isomeric pairs of nitroquinol dialkyl ethers have been determined. Examination of the products of nitration of quinol methyl ethyl ether, quinol methyl propyl ether, and quinol methyl *p*-nitrobenzyl ether with the aid of the diagrams so obtained shows that the directive powers of ethoxyl and propoxyl relative to methoxyl are higher than those observed in the catechol series, whilst the *p*-nitrobenzyloxy-group is weaker in the quinol than in the catechol series. Furthermore, whereas propoxyl is weaker than ethoxyl in the catechol series, it is now found to be stronger than ethoxyl in the quinol series. The theoretical implications of these results are discussed in the following communication.

EXPERIMENTAL.

*2-Nitro-4-methoxyphenol.*—The product (90% yield) of the action of nitric acid (1 mol.; *d* 1.42) on quinol dimethyl ether dissolved in acetic acid at 30° had m. p. 71.5° and was homogeneous (Mühlhauser, *Annalen*, 1881, 207, 253, gives 71.5°, and Vermeulen, *Rec. trav. chim.*, 1905, 25, 12, gives 72—73°, as the m. p. of nitroquinol dimethyl ether). After reduction and attempted condensation with phenanthraquinone, no phenazine could be obtained and consequently 2:3-dinitroquinol dimethyl ether, one of the products of the further nitration of nitroquinol dimethyl ether (Nietzki and Pechberg, *Ber.*, 1890, 23, 1211), was not present. The nitrations examined quantitatively in the course of this work were conducted at a lower temperature and it may be safely concluded that no dinitro-derivatives were produced. Under the following conditions, the hydrolysis of nitroquinol dimethyl ether gives a 96% yield of recrystallised 2-nitro-4-methoxyphenol (compare Kauffmann and Fritz, *Ber.*, 1910, 43, 1215; Pollecoff and Robinson, *J.*, 1918, 113,

647). A mixture of nitroquinol dimethyl ether (40 g.), sodium hydroxide (80 g.), and water (700 g.) was refluxed in a copper flask heated in an oil-bath for 54 hours, the liquid being agitated by means of a moderately rapid stream of air. Water (400 c.c.) was then added, the condenser removed, and boiling continued for 30 minutes or until the issuing steam condensed to clear drops on a test-tube filled with cold water. The mixture was cooled to about 60°, acidified with hydrochloric acid, and distilled in a current of steam. The product was collected, dried, and crystallised from light petroleum, separating in red prisms, m. p. 79—80°.

2-Nitro-4-methoxyphenol is also the product of the hydrolysis of nitroquinol dimethyl ether by means of hydrobromic acid. Combined with the fact that nitroveratrole under similar conditions gives 5-nitroguaiacol (Cardwell and Robinson, J., 1915, 107, 255), this indicates the order  $o > m > p$  for the influence of a nitro-group on the ease of hydrolysis of methoxyl by acids. A mixture of nitroquinol dimethyl ether (5 g.) and saturated aqueous hydrobromic acid (15 g.) was heated on the steam-bath for 6 hours. Subsequently 2-nitro-4-methoxyphenol (3.0 g.), m. p. 72—74° (recrystallised, m. p. 79—80°), and nitroquinol (0.5 g.), m. p. 132°, were isolated and identified. The theory of the hydrolysis of methoxyl groups by acids is necessarily complex. In the Friedel-Crafts reaction with phenol ethers the order of influence of the carbonyl group on the ease of hydrolysis of methoxyl is  $o > p > m$ . On the other hand, in euxanthone diethyl ether, we find  $m > o$ , in harmony with the nitroveratrole case. In contrast, the hydrolysis of phenolic ethers by alkaline solutions, as affected by the positions of groups like nitroxyl, gives uniform results— $o, p > m$ .

*Quinol Monomethyl Ether.*—The method of Ullmann (*Annalen*, 1903, 327, 116) for the semi-methylation of quinol was found to give poor yields and the following process was adopted after numerous trials. A solution of quinol (110 g.) in sodium hydroxide (100 g.) and water (700 c.c.), contained in a flask filled with hydrogen, was cooled to 12° and vigorously shaken after the addition of neutral methyl sulphate (120 c.c.) in one portion. After about 5 minutes the mixture was cooled and the dimethyl ether collected (33 g., m. p. 56°). The filtrate and washings were acidified with hydrochloric acid and cooled to about 8° for about 1 hour, thereafter the monomethyl ether was collected, washed with ice water, and dried (45 g., m. p. 52—54°). The aqueous solution was extracted with ether and the residue after evaporation of the solvent yielded to benzene a further 30 g. of less pure quinol monomethyl ether, m. p. 41—46°. For our purposes, it was necessary to ensure the absence of quinol from the product. The material was dissolved

in benzene and any quinol which crystallised was separated; the solution was then distilled and a product, m. p. 53—54°, collected at 243—246°. This was redissolved in benzene, and the solution repeatedly shaken with small quantities of cold water. The ether was then again distilled, b. p. 243—244°, m. p. 56°. No coloration was developed in alkaline solution in contact with air. The substance crystallised from light petroleum has m. p. 56°, but when heated to about 200° and quickly cooled, the m. p. is 53°, changing in a week or two to 55°. Crystals, m. p. 56°, also change on keeping and the m. p. becomes 55°. Although these changes are small, the phenomenon is a real one.

*Ethyl p-Methoxyphenyl Carbonate.*—Ethyl chloroformate (95 c.c.) was added, with shaking and cooling in running water, to a solution of quinol monomethyl ether (124 g.) in water (300 c.c.) and sodium hydroxide (40 g.), and after 30 minutes the product was isolated by means of ether. The yield of a colourless, readily crystallising oil, b. p. 157°/17 mm., was 186 g. (93%). As traces of quinol monomethyl ether might have been produced in the distillation, the substance was washed with 0.05*N*-sodium hydroxide, dilute hydrochloric acid and water, and finally dried in a vacuum. The large, prismatic crystals had m. p. 21° (Found: C, 61.1; H, 6.2.  $C_{10}H_{12}O_4$  requires C, 61.2; H, 6.2%). This ester is rather stable, 5 minutes' treatment with boiling 10% aqueous sodium hydroxide being necessary to effect complete solution.

*Ethyl 3-Nitro-4-methoxyphenyl Carbonate,*  
 $OMe \cdot C_6H_3(NO_2) \cdot O \cdot CO_2Et$ .—

Nitric acid (25 c.c.; *d* 1.52) was added to a solution of ethyl *p*-methoxyphenyl carbonate (25 g.) in acetic acid (25 c.c.), and the mixture heated on the steam-bath until the onset of a vigorous reaction manifested by the copious evolution of red fumes and a rise of temperature to 103°. After being maintained at 100° for 6 minutes, the liquid was cooled, water added, and the solid collected, washed, and dried (27.5 g. or 90%). The m. p. was 66°, and was raised only to 66.5° by crystallisation from light petroleum (Found: C, 49.7; H, 4.9; N, 5.9.  $C_{10}H_{11}O_6N$  requires C, 49.8; H, 4.6; N, 5.8%). Slightly impure specimens are pale yellow and give a violet coloration with cold aqueous sodium hydroxide.

*3-Nitro-4-methoxyphenol.*—This substance, previously prepared by Klemenc (*Monatsh.*, 1914, 35, 91) from its acetyl derivative, is best obtained in the following manner. A mixture of ethyl 3-nitro-4-methoxyphenyl carbonate (10 g.), sodium hydrogen carbonate (4 g.), methyl alcohol (17 c.c.), and water (17 c.c.) was boiled under reflux for 15 minutes, and the methyl alcohol then distilled from

the solution. The cooled, red liquid was acidified with hydrochloric acid; the yellow oil obtained quickly crystallised (6.7 g. or 95%). The m. p. was 97—99°, and 98—100° after crystallisation from benzene. The substance is dimorphous and when melted and suddenly cooled it solidifies to an orange mass which in a few seconds changes with a crackling sound to yellow needles. In one experiment the temperature rose to 99°. The phenomenon is readily observed in a capillary tube and the unstable modification appeared to melt at about 85°. The potassium salt of this nitrophenol immediately after drying is violet and readily soluble in acetone but, when kept for some days or ground in a mortar, it becomes crimson and sparingly soluble, even in boiling acetone. The whole point of the method adopted for the preparation of this substance resides in the avoidance of the use of powerful alkaline reagents in the hydrolysis, since the methoxyl in the *o*-position to the nitro-group is readily attacked, and even by hot sodium carbonate to an extent which would vitiate our results.

*3-Nitro-4-ethoxyanisole*.—2-Nitro-4-methoxyphenol (10 g.) was treated in alcoholic solution with potassium ethoxide (from 2.34 g. of potassium), and after the solvent had been evaporated the red potassium salt was dried at 130° in a vacuum for 2 hours. It was then mixed with absolute alcohol (50 c.c.) and ethyl iodide (9 c.c.) and heated in a pressure bottle at 100° for 3 hours. The alcohol was removed by distillation and the product washed with successive quantities of 1% aqueous sodium hydroxide and with water, collected and dried (10.3 g. or 86%). The crude product had m. p. 38—39° and after crystallisation from methyl alcohol and from light petroleum the substance was obtained in short, yellow prisms, m. p. 39.5° and f. p. 39.0° after drying in a vacuum at 100° for 1 hour (Found: C, 54.6; H, 5.7; N, 7.2.  $C_9H_{11}O_4N$  requires C, 54.8; H, 5.6; N, 7.1%).

*2-Nitro-4-ethoxyanisole*.—A solution of potassium ethoxide (from 1.95 g. of potassium) in alcohol\* (15 c.c.) was added to one of 3-nitro-4-methoxyphenol (8.45 g.) in alcohol (20 c.c.), and after the introduction of ethyl iodide (5 c.c.) the mixture was boiled under reflux for 1 hour; the original deep red colour had then given place to orange. The isolation was like that of the isomeride described above and there resulted 9.5 g. (95%) of yellow needles, m. p. 36—38.5°. The purest specimens had m. p. 37—39°, f. p. 38.4°, and were obtained by crystallisation from methyl alcohol and light petroleum (Found: C, 54.7; H, 5.8; N, 7.1%). When quickly cooled from

\* In this case, the reaction is relatively facile and the use of ethyl alcohol is not disadvantageous. The ether was also prepared with methyl alcohol as the solvent.

100°, the substance melted sharply at 37°, but 1 hour later the m. p. was 37—39°.

*Freezing Points of Mixtures of 3-Nitro-4-ethoxyanisole and 2-Nitro-4-ethoxyanisole.*—Although these substances have a rapid rate of crystallisation, this is not the case with mixtures of them, especially near the eutectic, and the f. p.'s are ascertained only with great difficulty. In some examples the time taken to reach the maximum temperature after crystallisation had begun was no less than 20 minutes. Accurate standardisation of the procedure was therefore an urgent necessity. The external water-bath was contained in a Dewar vessel, and its temperature maintained 0.5° lower than that of the mixture. The mixture was supercooled 1.5°, nucleated from a trace of solid left on the thermometer stem, and stirred at the rate of 1 revolution per second. The temperature could be estimated to the nearest 0.02°. The eutectic could not be accurately located, since in this region a double f. p. was observed. The following mean values were selected, the first number of each pair indicating the percentage of 3-nitro-4-ethoxyanisole in the mixture: 0.0, 38.4°; 7.8, 34.7°; 18.2, 28.0°; 25.4, 24.35°; 31.6, 21.25°; 38.1, 17.5°; 40.75, 15.9°; 41.5, 14.15°; 43.1, 14.5°; 45.9, 12.1° (14.2°); 48.0, 11.8° (14.1°); 50.6, 13.9°; 57.6, 19.1°; 63.3, 22.3°; 67.8, 24.7°; 68.5, 25.2°; 75.7, 28.8°; 81.0, 31.1°; 84.3, 32.3°; 94.1, 36.3°; 100.0, 39.0°.

As a confirmation a mixture was made of 3-nitro-4-ethoxyanisole (1.0643 g.) and 2-nitro-4-ethoxyanisole (0.6413 g.) and found to freeze at 21.9°. From the graph, 21.9° corresponds to 62.4% of the 3-nitro-isomeride (calc., 62.4%).

*Nitration of 4-Ethoxyanisole.*—Fiala (*Monatsh.*, 1884, 5, 233) has prepared 4-ethoxyanisole and states that its m. p. is 39°. Using pure quinol monomethyl ether and ethyl iodide, b. p. 72.4°, we find that the crystallised product has m. p. 36—37°, b. p. 216—217°/754 mm. (Found: C, 70.9; H, 8.0. Calc.: C, 71.0; H, 8.0%). The nitric acid employed in the nitrations described in this communication had  $d$  1.42 and was distilled and freed from oxides of nitrogen by means of a current of air. The acetic acid also was purified and froze at 16°. A mixture of acetic acid (3 c.c.) and nitric acid (1.77 g.; 1 mol.) was gradually introduced by means of a capillary tube below the surface of a stirred solution of 4-ethoxyanisole (2.91 g.; 1 mol.) in acetic acid (6 c.c.) cooled to 4°. As no change of colour occurred, the temperature was allowed to rise to 6° after about 10% of the acid had been added. A yellow colour developed and the mixture was then cooled to 0—1° and the remainder of the nitric acid added during 20 minutes, after which stirring and cooling at 0° were maintained for 20 minutes. The temperature was then allowed

to reach 10° for 5 minutes. A further molecular proportion of nitric acid dissolved in acetic acid (1.5 c.c.) was introduced with similar precautions, and the mixture at 0° was then diluted with water (60 c.c.) at 2°. After being stirred for a few minutes, the mixture was kept for an hour. The oil had solidified and the clear supernatant liquid could be siphoned away without loss of the product. The material was then washed successively with water (20 c.c.) at 30°, twice with very weak aqueous sodium bicarbonate (10 c.c.) at 30°, and finally thrice with water at 30°. In each case stirring was resorted to and the washings were removed after solidification of the oil by cooling to about 5°. After drying to constant weight (3.565 g., 94.6%) in a vacuum, the specimen (a) was prepared for determination of the f. p. by heating in a vacuum at 100° for 30 minutes (Found: N, 7.2. Calc.: N, 7.1%). Further nitrations of 5 g. of 4-ethoxyanisole in an identical fashion gave 6.28 g. (b; 97%) and 6.23 g. (c; 96%) of the mixed isomerides.

The results of analysis are set out in the following table.

Specimen.	Grams of mixture taken.	Weight of 3-nitro-isomeride added.	F. p.	% of 3-nitro-isomeride indicated.	% of 3-nitro-isomeride in the nitration product.
(a) 1	2.6640	0	21.8°	62.2	62.2
2	—	1.4448	28.6	75.5	62.1
(b) 1	3.6087	0	21.95	62.4	62.4
2	—	1.5058	27.7	73.5	62.4
3	2.4048 of last mixture, f. p. 27.7°	2.2597	33.5	86.5	62.9
(c) 1	3.2733	0	21.9	62.4	62.4
2	—	0.9945	26.4	70.9	62.1
3	—	1.6532	28.4	75.0	62.4
					Mean 62.36

In order to ascertain what change of composition, if any, was entailed in the isolation processes, a mixture of the isomerides, f. p. 23.2°, was dissolved in the appropriate quantities of nitric and acetic acids so as to imitate the result of an actual nitration. Isolation and washing were carried out as described above, but before drying the whole series of operations was repeated. The dried material then froze at 23.4°. Two such treatments therefore only change the f. p. by 0.2° and if it is assumed that one isolation process raises the f. p. by 0.1°, the corrected composition of the product of nitration is 62.2% of the 3-nitro-isomeride and 37.8% of the 2-nitro-isomeride. Hence the directive power of ethoxyl relative to methoxyl (100) is 163 in the quinol series.

*3-Nitro-4-propoxyanisole*,  $\text{OMe-C}_6\text{H}_3(\text{NO}_2)\cdot\text{OPr}^a$ .—The propyl iodide employed in the preparation of this substance and of its isomeride had b. p. 101.2—101.7° (Found: I, 74.7, 74.7. Calc.:

I, 74.7%), and the propyl alcohol also was fractionated—b. p. 96.9—97.9°.

A mixture of 2-nitro-4-methoxyphenol (16.9 g.), potassium propoxide (from 3.85 g. of potassium), propyl iodide (20 c.c.), and propyl alcohol (50 c.c.) was boiled under reflux for 11 hours. The solvent was then removed in a vacuum at 100°, and the residue yielded to ether 10 g. (48%) of a dark brown liquid, m. p. 10-22°. This boiled at 127° under less than 1 mm. pressure and the clear yellow distillate had m. p. 10-35°. Repeated crystallisation from methyl alcohol at -15° raised the m. p. to the constant value of 10.7° (Found: C, 56.9; H, 6.4; N, 6.6.  $C_{10}H_{13}O_4N$  requires C, 56.9; H, 6.2; N, 6.6%). In a second experiment, exactly the same results were obtained.

Attempts to improve the above process by employing the silver salt of the nitrophenol in place of the potassium salt were wholly unsuccessful. The silver salt of 2-nitro-4-methoxyphenol was prepared from the sodium salt and silver nitrate in aqueous solution. The material was dried in a vacuum (Found: Ag, 39.4.  $C_7H_8O_4NAg$  requires Ag, 39.1%) and was remarkably stable towards alkyl iodides. Boiling methyl and ethyl iodides produced no effect in 10 minutes, and the action of boiling propyl iodide alone for 12 hours or in solution in ether, benzene, ethyl acetate, methyl, ethyl or propyl alcohol also gave negative results or very poor results.

*2-Nitro-4-propoxyanisole.*—This ether was obtained in 85% yield by the usual method applied to a methyl-alcoholic solution boiling during 12 hours. In all such processes the solvent chosen should be such that alcoholysis of alkyloxy-groups in the *o*- or *p*-positions to nitroxyl cannot introduce impurities. The pure substance, crystallised from methyl alcohol and from light petroleum, has f. p. 32.0° (31.98° in a second preparation) (Found: C, 57.0; H, 6.4; N, 6.7%).

*Mixtures of 3-Nitro-4-propoxyanisole and 2-Nitro-4-propoxyanisole.*

—The following values of the f. p.'s were employed for the construction of a graph, and the first number of each pair indicates the percentage of 2-nitro-4-propoxyanisole in the mixture: 100.0, 32.0°; 95.9, 30.55°; 92.6, 29.5°; 86.5, 27.45°; 80.5, 25.1°; 74.9, 22.9°; 68.6, 20.2°; 63.7, 18.0°; 57.5, 15.0°; 53.1, 12.8°; 48.0, 10.35°. The readings for the mixtures containing less than 48% of the 2-nitro-isomeride were too indefinite to be of practical value.

*Nitration of 4-Propoxyanisole.*—4-Propoxyanisole (Fiala, *Monatsh.*, 1884, 5, 234) was obtained in 85% yield in the usual manner and has b. p. 135°/15 mm. and m. p. 26—27°. The nitration was carried out in precisely the same way as that of 4-ethoxyanisole but, as the product was a liquid at 0°, it was necessary after the washings to allow the complete settling of the droplets before removing the

supernatant fluid. The washed product was siphoned with the aid of methyl alcohol through a Pregl micro-filter into a weighed tube, and the methyl alcohol and water were removed by a current of filtered air at 50° and finally at 110° in a vacuum. In two experiments (a) and (b) the yields were 97% and 98%, respectively [Found in (a): N, 6.7. Calc.: N, 6.6%]. The results of the analysis are tabulated below.

Specimen.	Grams of nitration product.	Weight of 2-nitro-isomeride added.	F. p.	% of 2-nitro-isomeride indicated.	% of 3-nitro-isomeride in the nitration product.
(a) 1	1.1478	0.6043	15.1°	58.0	64.1
2	—	1.0971	19.5	67.1	64.3
3	—	1.6141	22.25	73.2	64.5
(b) 1	1.0771	0.6128	15.6	58.9	64.5
2	—	0.9326	18.85	65.6	64.2
3	—	1.2782	21.05	70.5	64.5
					Mean 64.35

As a check the following experiment was carried out. A mixture of 2-nitro-4-propoxyanisole (1.5173 g.) and 3-nitro-4-propoxyanisole (0.5560 g.) containing 73.2% of the former isomeride was made and this was found to have f.p. 22.25°, agreeing with the value read from the graph. This mixture (0.6 g.) added to that (a 3) of the same f. p. mentioned in the above table (1.0 g.) gave a product, f.p. 22.25°.

Corresponding to the above results, the directive power of the *n*-propoxy-group in the quinol series is 180.

**3-Nitro-4-*p*-nitrobenzyloxyanisole.**—2-Nitro-4-methoxyphenol (1.06 mols.), potassium propoxide (1.04 mols.), and *p*-nitrobenzyl bromide (1 mol.) were employed in the preparation of this substance in boiling propyl-alcoholic solution. The yield was 98% of the theoretical calculated on the *p*-nitrobenzyl bromide employed. The substance crystallises from benzene in yellow needles, m. p. 153°, f. p. 152.8° (Found: C, 55.3; H, 4.0; N, 9.2.  $C_{14}H_{12}O_6N_2$  requires C, 55.2; H, 4.0; N, 9.2%).

**2-Nitro-4-*p*-nitrobenzyloxyanisole** was prepared in the usual manner in methyl-alcoholic solution and the yield was 96%. After recrystallisation from benzene, the substance was heated at 100° for an hour; it then melted at 120–125° with sudden evolution of benzene. After heating in a vacuum at 130–135° for 30 minutes in a slow current of air, the substance melted at 123.5° and froze at 123.0° (Found: C, 55.3; H, 4.3; N, 9.2%). The compound is more sparingly soluble in benzene than its less fusible isomeride.

**Mixtures of 3-Nitro-4-*p*-nitrobenzyloxyanisole and 2-Nitro-4-*p*-nitrobenzyloxyanisole.**—The outer bath of the cryometer was a large beaker of sulphuric acid. The following values of the f. p. were employed in the analysis below and the first number of each

pair represents the percentage of 2-nitro-4-*p*-nitrobenzyloxyanisole in the mixture: 100.0, 123.0°; 93.9, 120.25°; 87.9, 117.5°; 83.65, 115.65°; 78.2, 112.95°. The corresponding curve is almost a straight line. Nearer to the eutectic it was not found possible to obtain concordant readings, but the following mean values indicate the form of the curve: 74.25, 111.5°; 70.2, 109.9°; 67.6, 109.0°; 66.7, 108.4°; 59.8, 111.6°; 55.7, 114.4°; 49.4, 123.0°.

4-*p*-Nitrobenzyloxyanisole.—*p*-Methoxyphenol (1.05 mols.), potassium hydroxide (1.02 mols.), and *p*-nitrobenzyl bromide (1 mol.) in boiling methyl-alcoholic solution gave a 95% yield of the ether. The substance is sparingly soluble in cold methyl or ethyl alcohol, readily soluble in benzene, and crystallises from ethyl alcohol in large, yellow prisms, m. p. 87.5° (Found: C, 64.7; H, 5.1; N, 5.4.  $C_{14}H_{13}O_4N$  requires C, 64.8; H, 5.1; N, 5.4%).

In view of the interest which has been evinced in regard to the bright yellow colour of nitroquinol dimethyl ether, it should be noted that this quinol methyl *p*-nitrobenzyl ether is more intensely coloured than either of the nitroquinol methyl *p*-nitrobenzyl ethers. This clearly indicates that the colour of nitroquinol dimethyl ether is due, not to any quinonoid rearrangement, but to the interaction of the *p*-dialkyloxybenzene nucleus and the nitroxyl functioning independently. The direct attachment of the nitro-group to the quinol nucleus depresses its reactivity and should have a bathochromic effect.

Nitration of 4-*p*-Nitrobenzyloxyanisole.—A mixture of acetic acid (12 c.c.) and nitric acid (12 c.c.; *d* 1.42) was added in one portion to a well-stirred solution of 4-*p*-nitrobenzyloxyanisole (3.0 g.) in acetic acid (30 c.c.). The temperature remained at 22° for 30 seconds, then rose to 25°, and the product began to crystallise. Water (150 c.c.) was added after 15 minutes, and the solid collected after 30 minutes and washed with water. The material (*a*) was dried at 80–90° for 10 hours and then weighed 3.45 g. (98%) (Found: N, 9.3. Calc.: N, 9.2%). A second specimen (*b*) was similarly obtained by nitration at 15–20° in 99% yield, and a third (*c*) by nitration at 16–21° in 99% yield.

Specimen.	Weight of nitration product.	Weight of 2-nitro-isomeride added.	F. p.	% of 2-nitro-isomeride indicated.	% of 2-nitro-isomeride in nitration product.
(a, b, c)	—	—	(109–110.5°)	—	(68–72.5)
(a)	0.7201	0.8143	117.2°	87.1	72.5
	—	1.4556	119.0	91.0	72.8
(b)	1.1561	0.9747	116.25	85.2	72.7
	—	1.7854	118.1	89.2	72.5
(c)	1.0287	0.8636	116.0	84.6	71.7
					Mean 72.4

A mixture of 2-nitro-4-*p*-nitrobenzyloxyanisole (0.9930 g.) and 3-nitro-4-*p*-nitrobenzyloxyanisole (0.1808 g.) contains 84.6% of the 2-nitro-isomeride and has f. p.  $116.0^{\circ}$ , confirming the graph in that region. When 1.17 g. of this mixture was added to 1.4 g. of the mixture (from c) given in the above table as of f. p.  $116.0^{\circ}$ , the f. p. was  $116.0^{\circ}$ . From the above data it appears that the directive power of the *p*-nitrobenzyloxy-group in the quinol series is 38.

An error of  $0.1^{\circ}$  in the f. p. causes an error of 0.2 in the percentage obtained from the graph and one of 0.4 in the calculated percentage composition of the mixture. In the case of ethoxyl an error of  $0.1^{\circ}$  in the f. p. produces an error of 0.27—0.3 in the calculated percentage composition of the nitration product, and in the case of propoxyl an error of  $0.1^{\circ}$  in the f. p. would cause an error of 0.24 in the percentage composition read from the graph and an error of 0.5 in the calculated percentage composition of the nitration product.

The authors wish to express their gratitude to the Royal Commissioners of the Exhibition of 1851 for a scholarship which enabled one of them to take part in the research, and also to the Chemical Society for a grant which has defrayed a part of the cost of the materials employed.

### LII.—*The Relative Directive Powers of Groups of the Forms RO and RR'N in Aromatic Substitution. Part IV. A Discussion of the Observations Recorded in Parts I, II, and III.*

By JAMES ALLAN, ALBERT EDWARD OXFORD, ROBERT ROBINSON, and JOHN CHARLES SMITH.

IN order to avoid misconception as to the point of view adopted as a working hypothesis in this series of memoirs, a brief discussion of the fundamental principles is necessary.

It is recognised that certain ions, for example, those from sodium chloride, exhibit a high affinity for their charge and are relatively inert in the matter of co-valency formation, whereas other ions, for example, those from hydrogen cyanide or benzenediazonium hydroxide, have an intrinsic lower affinity for their charge and are active in the production of new bindings by co-valency. In effect, the former class are chemically inactive, the latter class active and, following Abegg and Bodländer, Kauffmann and Briggs, we can recognise in the two types diffuse and intense valency fields respec-

tively. Lapworth has recently contributed a valuable classification of reagents as *anionoid* or *kationoid* according as they behave in the same way as active negative or positive ions (Paper read at the Manchester Literary and Philosophical Society on March 3, 1925; see abstract, *Nature*, **115**, 625). Ethylene, butadiene and benzene are anionoid, their *active* free valency has a negative polar character, and it is obvious that the ethers and amines are even more definitely anionoid. The systems which one of us has called *crotenoid* (Robinson, *J. Soc. Chem. Ind.*, 1925, **44**, 456) are strongly anionoid, the natural character of the unsaturated carbon being reinforced by direct union with an *onium* element. Lapworth points out that, when ethylene polarises, the implication is that the unsaturated carbon with a positive charge is in the more natural or stable condition and is surrounded by a diffuse field. The active unsaturated carbon with a negative charge is in a less natural condition, and this is justly held to be related to the observation that, except  $C_2H^*$ , no hydrocarbon radicals have been observed to occur with a negative charge in Thomson's vacuum tube experiments. Independent of these acute comparisons, the development of the theory of crotenoid systems (Decker, *Ber.*, 1905, **38**, 2893; Hamilton and Robinson, *J.*, 1916, **109**, 1029; Robinson, *ibid.*, p. 1038; *Mem. Manchester Phil. Soc.*, 1920, **64**, 4; Robinson and Robinson, *J.*, 1917, **111**, 958; 1918, **113**, 640; Kermack and Robinson, *J.*, 1922, **121**, 427) required the assumption that the reactive carbon atoms in phenols and amines and their derivatives acquire a negative charge in the course of polarisation, the postulated precedent of all reactions. In the case of a phenol ether the mechanism of activation is represented by the annexed expressions.

The oxygen, by means of its free electrons, increases its co-valency with the ring  $C_a$  (process *a*).  $C_a$  recovers its normal co-valency by giving up correspondingly electrons to  $C_b$  (process *b*) (*o*-substitution) or by relinquishing  $C_aC_b$  co-valency electrons to  $C_bC_c$  (process *c*).  $C_c$  must then relinquish  $C_bC_c$  co-valency electrons to the sole use of  $C_d$  (process *d*) (*p*-substitution). In the activated form the oxygen is positively charged and is exhibiting oxonium character, a rôle in which it far more closely resembles, in its general stability, the satisfied ions ( $Cl^+$ ,  $Na^+$ ) than does the negatively charged

\* As usual, a group derived from acetylene is exceptional.

carbon atom. The latter is intensely reactive and easily forms new co-valencies (compare *J. Soc. Chem. Ind.*, *loc. cit.*, for the details of the mechanism of diazo-coupling on this hypothesis). This type of activation involves the displacement of electrons in a particular direction, *e.g.*, from left to right in the figures. Furthermore, since the oxygen acquires a smaller negative charge or an actual positive charge, the process must be the more facile the more highly negatively charged is the oxygen atom before the activation. This explains the descending order of reactivity in the series :

and in the series :

In the acetoxy- and acetylamino-groups, conjugation gives the atom attached to the nucleus a positive charge (compare Rây and Robinson, *J.*, 1925, 127, 1618). It remains to add that the aromatic nucleus has a special stability of its own which Armit and Robinson (*J.*, 1925, 127, 1604) consider to be due to the possession of a stable electronic structure, the aromatic sextet. Electronic displacements are resisted by the sextet and it is a fact that the activation of a benzenoid centre in conjunction with any external group is feeble compared with that of an ethenoid complex in similar circumstances. Thus nuclear alkylation by the action of an alkyl halide on a crotenoid base occurs only with the more active aromatic systems. In the course of this investigation our views on the part played by the phenomenon of conjugation in organic chemistry have been more clearly focussed and it now appears possible to classify conjugated systems without arbitrary assumptions. Among the unit reactive groupings from which more complex structures may be derived, especial interest attaches to the highly unsaturated centres \* typified by  $\text{C}=\text{C}$ ,  $\text{C}=\text{O}$  ( $\text{C}\equiv\text{N}$ ,  $\text{N}=\text{O}$ , etc.), and  $-\text{O}-$  ( $-\text{NR}-$ ). Of these,  $\text{C}=\text{O}$  alone is kationoid. Certain groupings,  $\text{C}-\text{R}$ , to which definite conditions are attached, must be included. Combining the unsaturated groups two at a time in every possible way, we get :

(1)  $\text{C}=\text{C}-\text{C}=\text{C}$ ; *butadienoid*; polarisation—  $+|\text{C}=\text{C}-\text{C}=\text{C}|^-$ ; reactivity—*anionoid*.

Examples are isoprene, aromatic hydrocarbons.

\* Certain special structures (ketens, acetylenes) are not considered and it is not suggested that the classification is a complete one.

(2)  $\text{C}=\text{C}-\text{C}=\text{O}$ ; *crotonoid*; polarisation—  $+\left|\text{C}=\text{C}-\text{C}=\text{O}\right|^-$ ; reactivity—kationoid.

Examples are methylenemalononic ester, mesityl oxide.

(3)  $\text{C}=\text{C}-\text{O}-$ ; *crotenoid*; polarisation—  $-\left|\text{C}=\text{C}-\text{O}-\right|+$ ; reactivity—anionoid.

Examples are ethyl  $\beta$ -aminocrotonate, dimethylaniline, resorcinol.

(4)  $-\text{O}-\text{C}=\text{O}$ ; neutralised system; polarisation—

reactivity—feebly kationoid at C and special characters (see below).

Examples are esters, amides, dianisylideneacetone.

(5)  $\text{O}=\text{C}-\text{C}=\text{O}$ , *quinonoid*, and (6)  $-\text{O}-\text{O}-$ , *peroxidic*, are heterogeneous systems which we do not propose to discuss.

Many more complex combinations of the unsaturated units are possible and especially it will be recognised that all the systems may be expanded by the inclusion of further  $\text{C}=\text{C}$  groups. In addition there are derived forms of which the following are the most important.

(7)  $\text{O}=\text{C}-\text{C}-\text{X}$ , where X is an atom or group independently capable of separating with a positive charge; *semi-crotonoid*;

polarisation—  $-\left|\text{O}=\text{C}-\text{C}-\text{X}\right|+$ ; reactivity—dissociation; often followed by rearrangement of the negative ion and anionoid character exhibited by the carbon atom previously joined to X. The process is analogous to the dissociation of a carboxylic acid.

Examples are acetone, 2 : 4-dinitrotoluene, ethyl  $\alpha$ -bromoacetate.

(8)  $\text{C}=\text{C}-\text{C}-\text{Y}$ , where Y is an atom or group independently capable of separating with a negative charge; *allyloid*; polarisation—

$+\left|\text{C}=\text{C}-\text{C}-\text{Y}\right|^-$ ; reactivity—kationoid.

Examples are phenyl allyl ether (Claisen and Tietze, *Ber.*, 1925, 58, 275), geraniol.

(9)  $\text{O}-\text{C}-\text{Y}$  occurs in  $\text{MeO}\cdot\text{CH}_2\text{Cl}$ , etc.

*The General Polar Effect.*—Conjugation occurs by virtue of electronic displacements which produce an alternating polar effect\* as

\* An alternating polar effect in a chain  $\text{A}^-\text{B}^+\text{C}^-\text{D}^+\text{E}^-$  does not mean and never has meant either to Lapworth or to Robinson that the atoms are alternately positively and negatively charged. The phrase is taken to imply that evidence exists that in certain reactions, due to separate polarisations, A, C, or E may exhibit anionoid character and, on the other hand, one of the centres B or D may exhibit kationoid character. The alternation of

an inevitable consequence of the laws of valency operating in relation to changes in co-valency. Electronic displacements which do not involve co-valency changes require no alternation and may be continuous but diminishing in degree along a chain (compare Lapworth and Robinson, *Nature*, 1923, 112, 722). Such displacements should occur in almost all types of molecules and will be propagated by electrostatic induction (Lewis, *J. Amer. Chem. Soc.*, 1916, 38, 762; "Valence and Structure of Atoms and Molecules," pp. 84, 143; Thomson, *Phil. Mag.*, 1923, 46, 497; Lowry, *Trans. Faraday Soc.*, 1923, 18, 293; Lucas and Jameson, *J. Amer. Chem. Soc.*, 1924, 46, 2475). We concur \* with Lucas and Moyse (*ibid.*, 1925, 47, 1459), for instance, in their application of the theory to the case of the addition of hydrogen bromide to  $\Delta^2$ -pentene. The general effect of charged centres is obvious and Thomson (*loc. cit.*) has suggested both practical and theoretical methods of estimating the disposition of electrostatic doublets in various types of atomic combinations. In addition, the general effect of a group R can often be estimated by a consideration of the strength of the acid  $R \cdot CO_2H$ . All the evidence goes to show that hydrogen has a greater attraction for electrons than has the methyl group; we shall find it more convenient to express this statement in the converse form. This effect is represented, as in former cases (Malkin and Robinson, *J.*, 1925, 127, 370), by a straight arrow showing the direction in which the electrons are displaced. As an example of the interaction of the two types of electron displacement, we consider the carboxylic

acids  $R \cdot CO_2H$ . The polarisation  $\overset{\text{O}}{\underset{(b)}{\parallel}}\text{C} \overset{\text{O}}{\underset{(a)}{\leftarrow}}\text{H}$  proceeds until the positive charge† on the hydroxyl oxygen increases to such an extent that the proton is weakly held and can be removed by solvent molecules. The two oxygen atoms then divide the negative charge and assume identical functions. The displacement (a) is clearly the more fundamental process, but (b) is, however, a necessary

---

stable and less stable octets was suggested by Kermack and Robinson (*loc. cit.*) as a possible, admittedly speculative, explanation of the tendency underlying the exhibition of this property. This suggestion was never intended to be regarded as a *mechanism* of activation, for which Kermack and Robinson retained an electronic translation of the theory of partial dissociation of conjugated complexes as developed by Robinson and Robinson (*loc. cit.*).

\* Except, naturally, in considering that clear cases of the operation of continuous electron displacement dispose of the necessity for recognising the other type of displacement which occurs in conjugated systems.

† Positive and negative are taken to mean also less negative and less positive respectively. Similarly, a smaller attraction is relatively a repulsion, and *vice versa*.

accessory in providing a means of adjustment of the disturbed co-valency of the carbon atom.

Contrasting  $R \rightarrow C \begin{smallmatrix} O \\ \parallel \\ OH \end{smallmatrix}$  and  $R' \leftarrow C \begin{smallmatrix} O \\ \parallel \\ OH \end{smallmatrix}$  it is apparent that the group  $R$  in repelling electrons *competes* with  $OH$  and to some extent inhibits the process (a), whilst the opposite is true of a group  $R'$  which attracts electrons. Thus  $R' \cdot CO_2H$  is a stronger acid than  $R \cdot CO_2H$ . The case of the phenols is simpler and again  $R' \cdot OH$  should be a stronger acid than  $R \cdot OH$ . Conjugation  $R \begin{smallmatrix} \curvearrowright \\ \parallel \\ OH \end{smallmatrix} C=O$  is also a factor, weakening an acid. This system does not exclude the consideration of the effect of a steric factor\* (Flürsheim, J., 1909, 95, 718) and is in excellent agreement with the available data.

The whole of the foregoing can be independently justified and we proceed to consider how these principles apply to the results recorded in the preceding communications.

In the ethyl ether of guaiacol we have the condition

because the methyl group exercises a greater repulsion on electrons than hydrogen does. Therefore the polarisation of the crotenoid system, including the oxygen of the ethoxyl group, is facilitated as compared with the other system, not represented, which includes the oxygen of the methoxyl group. It follows that ethoxyl should have a higher directive power than methoxyl † (Found :  $EtO$ , 135;  $MeO$ , 100). The substitution of methyl for a second hydrogen atom should still further increase the directive power (Found :  $Pr^oO$ , 150). It is very interesting, however, that in the catechol series  $EtO$ , among  $n$ -alkyloxy-groups, appears to reach a maximum directive power (Found :  $EtO$ , 135;  $Pr^oO$ , 128;  $n-C_4H_9O$ , 123). This phenomenon we regard as due to the fact that as the chain lengthens a greater proportion of the general effect is distributed over the molecule and a smaller proportion, therefore, is effective through the attached atoms of the chain. Thus the ratio Directive

\* Possibly also an electrical effect exercised across the intervening space rather than through the chain.

† The case of  $OH$  itself as against  $OMe$  cannot be considered on similar lines on account of the possibility of ionisation or removal of the proton from  $OH$  by the reagent.

power  $RO/\text{Directive power } MeO$  can be expressed as  $y + a/x + a$ ,\* where  $R$  is a higher alkyl group,  $y$  is its directive power apart from  $a$ ;  $x$  is the directive power of methoxyl apart from  $a$ ,  $a$  is a quantity depending on the general polar effect of the excess methylene groups in  $R - Me$  and is that portion of the effect which, owing to its distribution over the molecule, goes to assist the polarisation of the crotonoid system, including the oxygen of the methoxyl groups. As  $a$  increases, the ratio will approach some minimum value greater than 1. Our results can be interpreted on the assumption that the terminal methyl group of a  $n$ -propyl group exercises a general effect which is largely distributed over the molecule and only to a small extent transmitted through the attached chain. In the series of catechol experiments it is important to observe that the general effect must assist both conjugations, and the interest of parallel experiments in the quinol series is that this is no longer true. Thus in  $p$ -ethoxyanisole,

it is clear that the conjugations of the crotonoid systems themselves involve electronic displacements in opposing directions. The argument used in the catechol series still holds; ethoxyl should have a greater directive power than methoxyl, but if a portion of the general effect of the additional  $CH_2$  of the ethoxyl is distributed, we can write: Directive power of  $EtO/\text{Directive power of } MeO = y' + a'/x' - a'$ . It might accordingly be anticipated that ethoxyl would have a higher relative directive power in the quinol than in the catechol series (Found:  $EtO$  in catechol series, 135;  $EtO$  in quinol series, 163). Furthermore, as  $a'$  increases, the value of the ratio  $(y' + a')/(x' - a')$  must also increase, and the theory, which predicts a lower value for  $Pr^oO$  as compared with  $EtO$  in the catechol series, also requires in the quinol series that  $Pr^oO$  should be greater than  $EtO$  (Found:  $Pr^oO$  in quinol series, 180). In the benzyl ether of guaiacol we encounter one of the postulated conjugated systems (allyloid):

\* The form of this expression is justified if  $x$ ,  $y$ ,  $a$  are taken as representing the number of occasions in unit time on which the different factors concerned lead to effectual polarisations.

In such a case the whole chain is not to be regarded as *one* conjugated system. The allyloid system \* tends to assist the oxygen atom to acquire a negative charge, and this assists the related crotonoid system to function † (Found :  $\text{CH}_2\text{Ph}\cdot\text{O}$ , 113;  $\text{MeO}$ , 100).

In the *m*-methoxybenzyl group (directive power, 92), the methoxyl group has the general effect anticipated on the basis of Thomson's deductions concerning the situation of electrostatic doublets, and the whole group exercises less repulsion on electrons than the methyl group does. This is far more pronounced with *m*- and *p*-nitrobenzyloxy-groups (directive powers, 67). The identity of the directive powers of these two groups was unexpected and led us to adjust our views on conjugation in the direction now indicated. It must not, however, be hastily concluded that the nitro-group produces no alternating effect, even in these experiments, since the fact that *p*-nitrobenzoic acid is slightly stronger than the *m*-isomeride indicates a weak alternate effect. In the *m*-nitrobenzyloxy-group, we might have a slightly stronger general effect and a weaker alternating effect (crotonoid-type) than in the *p*-nitrobenzyloxy-group, and these small variations may balance. However this may be, the results show that if the nitro-group does produce an alternating effect it must be a very small one and this is normal because the reaction examined is one in which the substance exhibits anionoid character and conjugation of nitroxyl with the aromatic nucleus leads to the exhibition of kationoid properties. In the catechol series, for a group like the *p*-nitrobenzyloxy-group we have : Directive power of group/Directive power of  $\text{MeO} = (z - b)/(x - b)$  and in the quinol series the ratio becomes  $(z' - b')/(x' + b')$ . Thus in the quinol series such a group should have a smaller relative directive power than in the catechol series (Found for the *p*-nitrobenzyloxy-group : in the catechol series, 67; in the quinol series, 38). In connexion with these deductions, it is important to notice that there

\* It should be noted that the distribution of affinity in the butadienoid, crotonoid and allyloid systems on our electronic basis coincides with the requirements of Flürscheim's theory, but this is not the case in the crotonoid and semi-crotonoid types.

† The occurrence in some substances of quite complex combinations of general and alternate effects can be foreseen. Thus *p*-isopropoxybenzoic acid should be weaker than anisic acid or even than *p*-*n*-propoxybenzoic acid :

Here we have a general effect reinforcing a crotonoid system the polarisation of which produces a general effect (a), or a conjugation effect (b), or both; these upon influencing the carboxyl as explained above.

are no side reactions to complicate the issue and that in all cases we have measured the whole effective directive power of the groups concerned. Consequently the small differences between  $x$  and  $x'$ ,  $y$  and  $y'$ , and  $z$  and  $z'$  are not likely to affect the validity of our conclusions. We do not claim that the interpretation is more than an approximation to the truth.

The point of view now adopted is one from which the general problem of orientation in aromatic substitution can be surveyed and we regard it as necessary to approach the subject in the following stages, which are of diminishing importance.

- (1) Consideration of the circumstances of the reaction and especially whether the reagent is anionoid or kationoid.
- (2) Consideration of the conjugated systems.
- (3) Consideration of the general effect of attached groups on the conjugated systems.

We will confine ourselves to the cases such that there is no attached group conjugated with the nucleus and the reagent is kationoid ( $\text{Br}_2$ ,  $\text{HNO}_3$ , etc.). In other words, we contemplate a normal benzenoid (butadienoid) system exhibiting anionoid character and wish to deduce from fundamental principles the nature of the effect of attached groups. In the case of a group, A, which repels electrons more than hydrogen does we have the arrangement (I). Here the crowding of electrons

round  $C_a$  will facilitate, by repelling  $C_aC_\beta$  co-valency electrons, the polarisation of that particular butadienoid system which starts with  $C_a$ . The electron will be captured by  $C_\beta$  (process  $a$ ;  $o$ -substitution) or, if not, a  $C_aC_\beta$  co-valency electron will become a  $C_\betaC_\gamma$  co-valency electron (process  $b$ ).  $C_\gamma$ , to recover its normal co-valency, must then correspondingly relinquish an electron to  $C_\delta$  (process  $c$ ;  $p$ -substitution). An alternative statement is that the ring carbon atom around which the density of electrons is greatest most easily becomes the positive end of a conjugated polarised complex. The applications will be obvious—toluene and *tert*-butylbenzene are in the same category. In the case of a group B, which has a *strong*

attraction for electrons (II), it is easy to see in a general way that the circumstances are reversed, but in order to make the argument clear we take an extreme instance such that B has a definite positive charge. The electrical field emanating from B then produces positive electrification in diminishing degree over the portion of the molecule represented. One consequence is that all displacements of electrons in activation will tend to be towards B, and this inhibits para-substitution. Of all the remaining possible displacements (*a*, *b*, *c*, *d*, *e*), that indicated by (*a*) is the most likely to lead to reaction, because reaction depends on the acquirement of a negative charge and of all the carbon atoms which can be activated C<sub>1</sub> has the smallest positive charge. A less degree of electron displacement, therefore, will activate C<sub>1</sub> than will suffice for C<sub>6</sub>. In order of preference we find in this case *m*-substitution, *o*-substitution, *p*-substitution, whilst displacement of the group B is also possible. An alternative statement is that the carbon atom (C<sub>6</sub>) furthest removed from the positive charge is least positive or most negative and most easily acquires a more positive charge and therefore most readily functions as the positively charged end of a polarised ethenoid or butadienoid complex. We cannot lay down any rules in regard to the required strength of the positive charge on B. The nitrogen of the nitro-group is positively charged if we accept the formulation  $\text{=}\overset{\text{I}}{\underset{\text{I}}{\text{O}}}\text{--N=}\overset{\text{I}}{\underset{\text{I}}{\text{O}}}\text{--}$  in which each line represents an electron pair and it would appear that this group is effective even when separated from the nucleus by one carbon atom (Holleman, *Rec. trav. chim.*, 1895, **14**, 121).

Substitution in the *m*-position might also occur in a benzyl-ammonium ion.

The carbon atoms of the carboxyl, carbonyl and trichloromethyl groups can also be regarded as positively charged on the basis of independent evidence. This theory seems to harmonise better than any other which has been advanced with the facts of substitution in polycyclic aromatic groups, but a separate discussion of this subject is necessary. In the case of a group C (III) which in some phases attracts and in others repels electrons we anticipate predominating *o-p*-substitution because the phase in which electrons are repelled provides a favourable opportunity for activation leading to anionoid character, whereas the other phase in no way contributes to activation and in fact inhibits it.

In the case (I) a negative charge is distributed over the nucleus and anionoid character is intensified, leading to ready reaction, whilst in case (II) the distributed positive charge inhibits the substitution of anionoid character. We can in fact estimate the

approximation of a group X to the types A or B by observing the ease of substitution of X-Ph as compared with that of benzene.

LIII.—*The Relative Directive Powers of Groups of the Form RO and RR'N in Aromatic Substitution. Part V. The Nitration of p-Methoxydiphenyl Ether.*

By THOMAS RUSSELL LEA and ROBERT ROBINSON.

THE three methoxydiphenyl ethers were prepared with the object of examining quantitatively the products of their fission by potassium, but the reaction proved to be a complex one and its study was deemed unlikely to furnish the desired information. In the course of our experiments, however, an observation was made which has a direct bearing on the subject of the present series. *p*-Methoxydiphenyl ether yields a single nitro-derivative (I) the constitution of which follows from its hydrolysis to *o*-nitro-*p*-phenoxyphenol (II).

This proves that the directive powers of phenoxy and *p*-methoxyphenoxy are small compared with that of the methoxy group and the result is in harmony with the theoretical conceptions outlined in the preceding memoir. The weak directive powers of the acyloxy and phenoxy groups are undoubtedly due to the same cause, namely, that the oxygen atom is conjugated on both sides.

Using the electrical conductivity analogy, the effect has been described as a "side tracking by a neighbouring system of high capacity" (*Chemistry and Industry*, 1925, 44, 118). On Flürscheim's theory of alternating affinity demand, a similar explanation of the weakness of the phenoxy group could be elaborated, but a consistent application of this hypothesis would appear to suggest that the acetoxy group should have a strong directing influence. Yet *o*-methoxyphenyl acetate is nitrated exclusively in the para-position

with respect to the methoxyl group. The following scheme illustrates this contrast :

### EXPERIMENTAL.

*m*-Methoxydiphenyl Ether.—A mixture of *m*-methoxyphenol (15.5 g.), bromobenzene (15.5 g.), potassium hydroxide (6.2 g.), and copper bronze (0.1 g.) was heated under reflux (oil-bath at 240°) for 2.5 hours. The product was isolated by steam distillation, the excess of bromobenzene being first collected. The benzene extract of the distillate was washed with aqueous sodium hydroxide and water, dried, and distilled finally in a vacuum. The substance, b. p. 175°/20 mm., could not be crystallised (Found: C, 77.9; H, 6.2.  $C_{13}H_{12}O_2$  requires C, 78.0; H, 6.0%). The yield was 19.0 g.

*p*-Methoxydiphenyl Ether.—This compound was prepared by the method described above for the resorcinol derivative and the yield was the same. The substance, b. p. 186°/32 mm., crystallised at -10°, but melted again at room temperature (Found: C, 77.8; H, 6.1%).

3-Nitro-4-methoxydiphenyl Ether (I).—A mixture of nitric acid (15 c.c.; *d* 1.42) and acetic acid (15 c.c.) was gradually added to a solution of *p*-methoxydiphenyl ether (5 g.) in acetic acid (20 c.c.) maintained at about 15° by cooling. Fifteen minutes after the addition of the nitric acid, water was added and the solid collected, washed, and dried (5.8 g.). The substance crystallised from alcohol in pale yellow prisms, m. p. 73—74° (Found: C, 63.7; H, 5.2.  $C_{13}H_{11}O_4N$  requires C, 63.7; H, 4.9%). No other product of the reaction could be isolated. In a similar manner, *o*-methoxydiphenyl ether (Ullmann and Sponagel, *Ber.*, 1905, **38**, 2211) (5 g.) gave 4.9 g. of a solid product which crystallised from alcohol in long, colourless needles, m. p. 70—71° (Found: C, 63.5; H, 4.7%). In this case, however, only 2.8 g. crystallised from alcohol and an oil was precipitated by the addition of water to the alcoholic mother-liquor. It is probable that the product analysed is 3-nitro-6-methoxydiphenyl ether.

2-Nitro-4-phenoxyphenol (II).—3-Nitro-4-methoxydiphenyl ether (4 g.) was hydrolysed by a boiling solution of potassium hydroxide (30 g.) in water (200 c.c.) in a copper flask for 60 hours. The red solution with some red needles in suspension was acidified with hydrochloric acid and the yellow solid, which separated from an

emulsion, was collected, washed, and dried (1.0 g.). The substance crystallises from light petroleum in long, yellow needles, m. p. 51—52° (Found: C, 62.3; H, 4.0.  $C_{12}H_{10}O_4N$  requires C, 62.4; H, 3.9%). The substance gives a bright red potassium salt and when boiled in xylene with potassium carbonate and methyl sulphate yields 3-nitro-4-methoxydiphenyl ether, m. p. 73—74°. Since Borsche (*Ber.*, 1923, 56, [B], 1488) has shown that phenoxy groups in the *o*- or *p*-positions to nitro-groups are more reactive than similarly situated alkyloxy-groups, there can be no doubt in regard to the constitution of the product of nitration of *p*-methoxydiphenyl ether.

#### LIV.—*The Equilibrium between Methyl Formate and Methyl Alcohol, and Some Related Equilibria.*

By JENS ANTON CHRISTIANSEN.

THE announcement that the Badische Anilin- und Soda-Fabrik had succeeded in synthesising methyl alcohol from carbon monoxide and hydrogen attracted great interest. Patart (*J. Ind. Eng. Chem.*, 1925, 17, 430, 859) claimed priority in this invention; but without entering into this discussion it may be mentioned that the process

patented by the author in 1918, combined with the reaction

investigated by Stähler (*Ber.*, 1914, 47, 580), was the first which made it possible to prepare methyl alcohol from water gas, although any process by which the reaction

can be carried out without methyl formate as an intermediate product must be of the greatest value.

The author was able to measure the equilibrium constant of reaction (1) by the kind permission of Prof. E. Büllmann, Director of this Laboratory, to whom he wishes to express his thanks. Later, in connexion with a firm in Copenhagen, Mr. Arne Olsen and the author made some measurements of the equilibrium constant of reaction (2). The results of these researches are in this paper: the substance of them was described, with the permission of the firm, in a lecture to the Chemical Society of Copenhagen on October 14, 1924.

Earlier work had shown that when methyl alcohol vapour is passed over reduced copper at 200° it splits up according to the equation

and not, as stated by Sabatier, according to

Before this result was published, Mannich and Geillmann (*Ber.*, 1916, 49, 585) had drawn the same conclusion. As this reaction (—1) did not appear to be complete, a mixture of measured quantities of hydrogen and methyl formate was passed over reduced copper at about 180°, and a considerable decrease in volume observed, showing the occurrence of reaction (1).

To determine the equilibrium, a stream of electrolytic hydrogen, freed from oxygen by means of palladinised asbestos, and dried, was passed at a constant rate (by the use of a pressure regulator and capillary) through a saturator, containing methyl formate, in a thermostat. It then passed through a pipette containing reduced cuprous oxide on asbestos, which was heated in an electric oven, through two absorption tubes, and into a gas burette. The catalyst was reduced with hydrogen *in situ* before the experiment. The absorption tubes were filled with *N*/10-sodium hydroxide. In each experiment, the gas was allowed to escape before reaching the absorption tubes until the rate of flow and the temperatures of the saturator and the oven had been constant for some time. The escape was then stopped and the reaction products were collected. After a suitable time, the absorption tubes were removed and weighed (the hydrogen in them having been replaced by air free from carbon dioxide), and their contents titrated after addition of barium chloride (Winckler's method), so that both methyl alcohol and carbonic and formic acids were determined. The gas was analysed in an Orsat apparatus with platinum capillary. In this way, the amounts of methyl alcohol, methyl formate, hydrogen, carbon monoxide, and dioxide could be estimated. Allowance was made for water lost by evaporation from the absorption tubes, etc.

The equilibrium was also determined by starting with methyl alcohol. This was admitted directly to the catalyst in the oven from a burette through a capillary which was warmed above the b. p. of the alcohol. The results are in Table I, Nos. 1—10 being experiments on reaction (1), Nos. 11—17 on reaction (—1). The temperature of the oven was measured by a standardised thermometer placed outside the catalyst pipette; the error so produced was small, since the rate of flow was slow. The velocities in column 5 are in millimols. of methyl formate or pairs of millimols. of methyl

alcohol passing the catalyst per hour. Columns 12 and 13 give the initial ratio in molecules of ester to hydrogen, and are calculated (1) from the vapour pressure of the ester and the total pressure in the saturator, (2) from the analysis of the products; in the decomposition experiments the ratio should obviously be 0.500. These values give a check on the analyses, and show a satisfactory agreement. The values in the last column are those of the constant  $K_1 = C_{H_2}^2 C_{CH_3OCH} / C_{CH_3OH}^2$ .

The values of  $\log_{10} K_1$  (expts. 1—15) are plotted in Fig. 1 against  $1/T$ ; they show that the results of association and dissociation experiments lie on the same curve, proving that true equilibrium was reached. The values of  $K_2$  for the reaction  $CH_3 \cdot O \cdot OCH = CO + CH_3 \cdot OH$  were so discordant as to show that equilibrium had not

FIG. 1.

△ (dissociation) refers to experiments starting with  $CH_3 \cdot OH$  [reaction (-1)].  
 ○ (association) " " " " "  $H_2 + CH_3 \cdot O \cdot OCH$  [reaction (1)].

been reached. The values obtained from expt. 15 (Fig. 1) and expts. 16 and 17 (not plotted) lie well below the curve; evidently the catalyst, which was the same in all these experiments, had lost its activity, so that even the equilibrium ( $\pm 1$ ) was not now attained.

The values for  $CO_2$  and  $CH_4$  in the table suggest that the reaction

took place to a slight extent. If, however, a trace of water was present, carbon dioxide may have been formed by the reaction

(*J. Amer. Chem. Soc.*, 1921, 43, 1670); this would explain the excess of carbon dioxide found in some of the experiments.

The equilibrium constant of reaction (2) was determined in a

similar manner and in the same apparatus. The catalyst here was solid sodium methoxide. This absorbed some carbon monoxide, and hence the results are not very trustworthy. The same thing occurred, but to a much smaller extent (about 1 mol. of sodium methoxide disappearing for every 100 mols. of carbon monoxide converted into methyl formate), when the reaction was carried out in solution, and in this case the reaction causing the carbon monoxide to disappear was shown to be  $\text{CH}_3\cdot\text{O}\cdot\text{OCH} + \text{NaO}\cdot\text{CH}_3 = \text{CH}_3\cdot\text{O}\cdot\text{CH}_3 + \text{NaO}\cdot\text{OCH}$ . Hence the values of the equilibrium constant  $K_2$  are only to be regarded as preliminary, but those of the association and dissociation experiments agree fairly well, as the following table shows.

TABLE II.

Reaction.	Temp.	Log $K_2$ by exper.	Log $K_2$ calc.
(-2)	102°	1.82	1.81
(2)	74	1.53	1.40
(-2)	74	1.40	1.40
(-2)	70	1.29	1.34

$K_2 = C_{\text{CO}} \cdot C_{\text{CH}_3\cdot\text{OH}} / C_{\text{CH}_3\text{OOCCH}}$  is for the gas mixture leaving the catalyst. The values in column 4 are calculated by the equation  $\log_{10} K_2 = -1880/T + 4.82$ .

The effect of temperature on equilibrium should be accurately given over a fairly wide range by an expression of the form

$$\log_{10} K = -A/T + B,$$

where  $A$  = heat of reaction at constant volume divided by 4.571, and  $B$  is a constant (Scheffer, *Proc. K. Akad. Wetensch. Amsterdam*, 1917, 19, 636). Values calculated on this formula are in Table II and are represented by the straight line in Fig. 1. The values given in the literature for the heats of combustion of methyl alcohol and methyl formate are discordant, Stohmann's value for methyl alcohol being about 2 Cals. lower than that of Thomsen. I have preferred to use the latter, since, although Thomsen's "universal burner" is apt to give somewhat high values, the error may be expected to be small when the substances are volatile, whilst, on the other hand, Stohmann's values, according to Roth (*Z. Elektrochem.*, 1911, 17, 789), may be suspected to be low, especially in the case of volatile liquids.

The heat capacity of methyl alcohol has been calculated from the values in Landolt-Börnstein's tables for the ratio,  $k$ , between the two heat capacities. For methyl formate, no direct data seem to be available, but from the value for ethyl formate and those for methyl and ethyl alcohols the heat capacity of methyl formate (at constant volume) has been estimated at 10 cals. per degree.

The following table contains all the numerical values used in the calculation of the reaction heats at the temperatures in question.

Substance.	Heat of combustion at const. press.	Heat capacity at const. vol.
Methyl alcohol .....	182,230	7.8
Methyl formate .....	241,210	10.0
Carbon monoxide .....	67,960	5.0
Hydrogen .....	68,430	4.8

By means of this table the heat of reaction (1) at constant volume and about 200° is calculated to be 13,800 cal. and that of reaction (2) at about 100°, 8,600 cal. From these values and the above determinations of the equilibrium constants, the constants,  $B$ , of reactions (1) and (2) can be calculated as 3.61 and 4.82, respectively. These two numbers thus contain the results of the above investigation of the two reactions.

It is now possible to obtain from Fig. 1 and Table II a preliminary value of the equilibrium constant  $K_3 = C_{\text{CO}} \cdot C_{\text{H}_2}^2 / C_{\text{CH}_3\text{OH}}$  for the reaction (3). Calculation shows that

$$\log K_3 = -4896/T + 8.43 \quad . \quad . \quad . \quad (7)$$

From (7) it can be calculated that at about 200°  $K_3$  is about  $10^{-2}$ , so that at this temperature, if the hydrogen concentration is 1 mol. per litre, only 1% of the carbon monoxide will remain if the reaction  $2\text{H}_2 + \text{CO} = \text{CH}_3\text{OH}$  proceeds until equilibrium has been reached, whilst, on the other hand, if the hydrogen concentration is 0.01, only 1% of the carbon monoxide will be transformed into methyl alcohol.

The value of  $K_3$  can also be roughly predicted by means of one of the well-known approximate equations arrived at from Nernst's third law of thermodynamics, for instance, the one given by Nernst himself,

$$\log K_p = -Q_{18}/4.57T + 3.5 \log T + 2i_{\text{H}_2} + i_{\text{CO}} - i_{\text{CH}_3\text{OH}} \quad (8)$$

where the  $i$ 's are the so-called conventional chemical constants of the different molecular species.

As shown by Cederberg (*Dissert.*, Upsala, 1916), a close connexion seems to exist between the critical pressure of a substance and its chemical constant and therefore I have used the values  $i_{\text{H}_2} = 1.6$ ;  $i_{\text{CO}} = i_{\text{N}_2} = 2.6$ ;  $i_{\text{CH}_3\text{OH}} = i_{\text{SO}_2} = 3.3$  (see Pollitzer, *Ahrens's Sammlung* 17, 1912).

By means of  $K_p = (RT)^2 K_c$  and the data just mentioned we thus find

$$\log K_3 = -22700/4.57T + 1.5 \log T + 4.7 \quad . \quad . \quad (8, i)$$

As furthermore  $1.5 \log T$  at temperatures about 200° is very nearly equal to 4.0, the equation becomes

$$\log K_3 = -4966/T + 8.7 \quad . \quad . \quad . \quad (8, ii)$$

The agreement (see Fig. 2) between (8, ii) and (7) is as good as could be expected, considering the preliminary character of the investigation of reaction (2) and the approximations implied in the use of the Nernst equation (8).

By combining equation (7) with a similar relation derived from earlier experiments on the reaction

it is furthermore possible to calculate the equilibrium constant of the reaction (6). If we define  $K_9$  by means of the equation  $K_9 = C_{\text{H}_2\text{O}} \cdot C_{\text{CO}} / C_{\text{CO}_2} \cdot C_{\text{H}_2}$ , where the concentrations are those at equi-

FIG. 2.

librium, we get from Hahn's experiments (*Z. physikal. Chem.*, 1903, 44, 513; 1904, 48, 735; see Haber, "Thermodynamik technischer Gasreaktionen," Berlin, 1905)

$$\log_{10} K_9 = -1854/T + 1.66 \quad (10)$$

When this equation is subtracted from (8, ii) we obtain

$$\log_{10} K_6 = -3042/T + 6.77 \quad (11)$$

where  $K_6$  is the equilibrium value of  $C_{\text{CO}_2} \cdot C_{\text{H}_2}^2 / C_{\text{CH}_3\text{OH}} \cdot C_{\text{H}_2\text{O}}$ .

Finally it should be remarked that by means of existing data on the equilibria

and

and the equations given above, it should also be possible to calculate the value of the equilibrium constant for the reaction (5).

The first of these reactions has been investigated by Mayer and

Altmayer (*Ber.*, 1907, **40**, 2134), Coward and Wilson (*J.*, 1919, **115**, 1380), and Pring and Fairlie (*J.*, 1912, **101**, 91). The results of these authors may be represented with sufficient accuracy by means of the equation

$$\log K_p = \log \frac{p_{\text{CH}_4}}{p_{\text{H}_2}^2} = \frac{5450}{T} - 6.33 \quad . \quad . \quad (14)$$

If we wish to get  $K_c = C_{\text{CH}_4}/C_{\text{H}_2}^2$  with the concentrations expressed in mols. per litre, we must add  $\log RT = \log T - 1.09$  and consequently

$$\log K_c = 5450/T + \log T - 7.42 \quad . \quad . \quad (14, i)$$

For the reaction (14) a summary of the existing data is to be found in a paper by Jellinek and Diethelm (*Z. anorg. Chem.*, 1922, **124**, 220). From their table of the mean values of  $K_p$  found at different temperatures by different authors, the following expression may be calculated :

$$\log K_p = 8620/T - 8.80 \quad . \quad . \quad (15)$$

and transforming into  $K_c$ ,

$$\log K_c = \log \frac{C_{\text{CO}_2}}{C_{\text{CO}}^2} = \frac{8620}{T} + \log T - 9.89 \quad . \quad (15, i)$$

By adding these equations we get the equilibrium constant for the reaction  $2\text{H}_2 + 2\text{CO} = \text{CH}_4 + \text{CO}_2$ , viz.,

$$\log K_p = \log \frac{p_{\text{CH}_4} \cdot p_{\text{CO}_2}}{p_{\text{H}_2}^2 \cdot p_{\text{CO}}^2} = \frac{14070}{T} - 15.13 \quad . \quad . \quad (16)$$

$$\text{or} \quad \log K_c = \log \frac{C_{\text{CH}_4} \cdot C_{\text{CO}_2}}{C_{\text{H}_2}^2 \cdot C_{\text{CO}}^2} = \frac{14070}{T} + 2 \log T - 17.31 \quad (16, i)$$

Adding to this the equation (7), we get the logarithm of the equilibrium constant for the reaction  $\text{CH}_3\text{-OH} + \text{CO} = \text{CH}_4 + \text{CO}_2$ , viz.,

$$\log K_c = \log \frac{C_{\text{CH}_4} \cdot C_{\text{CO}_2}}{C_{\text{CH}_3\text{-OH}} \cdot C_{\text{CO}}} = \frac{9170}{T} + 2 \log T - 8.88 \quad . \quad (17)$$

from which it is evident that the formation of methyl alcohol from methane and carbon dioxide will take place only at temperatures at which methane is not at all stable, whilst it is possible, according to equations (11) and (7), to obtain reasonable amounts of methyl alcohol from hydrogen and either carbon monoxide or dioxide at not too high temperatures.

It is obvious that the equations given above all contain the uncertainty introduced by the use of the preliminary results for the equilibrium between carbon monoxide, methyl alcohol, and methyl formate.

*Summary.*

(1) The equilibrium constant of the reaction  $\text{CH}_3\cdot\text{O}\cdot\text{OCH} + 2\text{H}_2 = 2\text{CH}_3\cdot\text{OH}$  has been determined with fair accuracy at temperatures in the neighbourhood of  $200^\circ$ .

(2) Preliminary values for the equilibrium constant of the reaction  $\text{CH}_3\cdot\text{OH} + \text{CO} = \text{CH}_3\cdot\text{O}\cdot\text{OCH}$  at about  $100^\circ$  have been given.

(3) It is shown that by combination of the found values with existing data the equilibrium constants of the reactions  $\text{CO} + 2\text{H}_2 = \text{CH}_3\cdot\text{OH}$ ;  $\text{CO}_2 + 3\text{H}_2 = \text{CH}_3\cdot\text{OH} + \text{H}_2\text{O}$ ; and  $\text{CH}_4 + \text{CO}_2 = \text{CH}_3\cdot\text{OH} + \text{CO}$  may be calculated.

THE UNIVERSITY, COPENHAGEN.

[Received, September 21st, 1925.]

# LV.—*The Equilibria underlying the Soap-boiling Processes. The System Potassium Oleate–Potassium Chloride–Water.*

By JAMES WILLIAM MCBAIN and WILLIAM JOSEPH ELFORD.

THE study of soap solutions has shown that they exist in a number of forms, each with very striking characteristics. In pursuing the systematic study of the constitution of these liquids, jellies, liquid crystals, and curds, it is essential that the conditions under which each exists should be exactly delimited. Further, the processes of soap-boiling depend on the existence of this series of well-defined equilibria, which have, however, received very little systematic study.

We are now in a position to state that all soaps, pure, mixed commercial, whether potassium or sodium, are essentially of the same type. The differences are in degree and not in kind and the equilibria are so similar in the various cases that by means of numerical factors the effect of any electrolyte or mixture of electrolytes can be fairly closely predicted. Finally, to a large extent, the behaviour of a mixture of soaps can be inferred from that of its pure constituents taken separately. It is found also that the results from such small-scale laboratory experiments as are described in the present paper are in numerical agreement with similar results obtained on a full commercial scale.

Two previous contributions (McBain and Burnett, J., 1922, 121, 1320; McBain and Langdon, J., 1925, 127, 852) have dealt with the preliminary studies of sodium laurate and sodium palmitate in which the chief results were to show the various kinds of soap systems which exist, and to indicate some of the limits for the existence of ordinary isotropic soap solutions. The present instal-

ment is an account of a more thorough study of systems derived from potassium oleate,\* which possesses the advantage of being so soluble that all the possible systems can be observed at room temperature. Further, application of the new methods of optical investigation that were developed in a previous study of potassium laurate have enabled progress to be made with the delimitation of the two important anisotropic liquids, neat soap and middle soap.

All these phases exist equally well in the absence of salt and the simplest procedure is to begin with the two-component system oleate and water, in which most of the typical equilibria appear. Accordingly, this will be discussed first, together with observations made upon individual phases, followed by the data obtained with systems in which potassium oleate is the third component.

*Materials.*—Kahlbaum's ordinary potassium oleate was found to be unsuitable, as it was not homogeneous and contained excess of acid and not only did the concentrated solutions on warming become dark reddish-brown but they sometimes differed in physical state from those of purer potassium oleate. Our preparations were therefore made by neutralising oleic acid "Kahlbaum" with potassium ethoxide and when carefully dried remained as white powders. The oleic acid in each case had a nearly correct iodine value and a molecular weight (by titration) about 1% too high (compare Laing and McBain, J., 1920, 117, 1506). Potassium chloride "Kahlbaum" was used. Solutions were prepared in sealed thick-walled tubes of Duro glass by weighing in the requisite quantities and heating to whatever temperature was necessary to transform the contents into a single homogeneous liquid. Heating up to 170° was best carried out in a bath of glycerol, but for heating aqueous solutions to temperatures up to 400° an electric oven with mica windows was used and care was taken to heat and cool very slowly in order that adequate time should be allowed for the soap system to acquire the successive temperatures. Stirring was effected by slowly shaking the furnace as a whole, formation of air bubbles being avoided. In some cases a bath of the eutectic mixture of the nitrates of sodium and potassium was employed.

*Methods of Observation.*—In every soap system it is possible to observe a temperature,  $T_i$ , on heating to which it becomes a single homogeneous, isotropic liquid. For example, pure dry potassium oleate melts at 235–240° to form liquid crystal which, as will be shown, represents a point in the neat soap field, but on further

\* A preliminary study was carried out by F. T. Maggs, who determined a number of points on the boundaries of the region of isotropic soap solutions.

heating to  $300^{\circ}$  this melts sharply to form an ordinary clear isotropic liquid. This liquid is miscible with water in all proportions; the more water present, in general the lower the temperature  $T_i$ , and at room temperature potassium oleate solutions up to  $0.7N_w$  are clear and isotropic.

All subsequent experience has confirmed the observations of McBain and Burnett (*loc. cit.*) that no supersaturation occurs, with respect to formation of anisotropic liquid, upon cooling the isotropic solution, but supersaturation readily occurs with respect to formation of either true lamellar crystals or crystalline curd fibres or needles. The sudden change in viscosity which occurs when anisotropic liquid appears, and the even more sudden change accompanying the completion of its formation upon cooling sufficiently, serve as useful although very rough checks upon the optical observations.

We have found it essential to use polarised light both for macroscopic and for microscopic observation. It is possible to examine a number of systems at room temperature and up to  $80^{\circ}$ , using an ordinary object slide and cover glass and a Guttman heater (see MacLennan, *J. Soc. Chem. Ind.*, 1923, 42, 393T), but it is essential that a truly representative sample should be taken and that the whole of the sample be examined. It is necessary also to ensure that the conditions observed in the calibration of the temperature scale be maintained throughout. When a mixture of isotropic and anisotropic soap solutions is thinly spread out and thus examined between crossed Nicols, the dark isotropic patches are seen to be sharply differentiated from the illuminated anisotropic portions of the field.

For work at higher temperatures no suitable substance could be found for sealing the cover glass to the object slide, as in some cases the properties of the soap were much affected by it as well as by evaporation. Professor Kenrick of Toronto University kindly supplied a cell, made by fusing together two optically ground plates of pyrex glass, with narrow side tubes sealed in, and such a cell has been used up to  $120^{\circ}$ . Latterly we have used small flattened glass cells made from tubing, 2.5 mm. in diameter, blown into a small bulb which during the process of blowing is squeezed flat between two hot carbon blocks, leaving room for only a thin film therein. The cell could be filled with a representative sample by suction and then sealed off. Such cells were very readily annealed, any optical evidence of strain being thus removed. They could be employed in a small electric furnace on the stand of the microscope, and the temperatures there observed agree closely with those obtained by a macroscopic study of large tubes.

*Equilibria in the System Water-Potassium Oleate.*

Dilute aqueous potassium oleate is a homogeneous isotropic liquid which freezes with separation of ice, and at temperatures above  $300^{\circ}$  may without losing homogeneity be concentrated to 100% potassium oleate in the isotropic liquid condition. At all lower temperatures, potassium oleate is not miscible with water, but other intermediate phases are successively formed. Thus at  $20^{\circ}$  the highest concentration at which a homogeneous isotropic solution of potassium oleate can be prepared is  $0.70N_w$  (g.-mol. per 1000 g. of water). Above this concentration, an upper layer of higher concentration separates. This phase is a conic, anisotropic liquid and has been called in this laboratory "middle soap" (*Nature*, 1924, 113, 534; 114, 49; *Science*, 1925, 61, 613; McBain and Langdon, *loc. cit.*). Middle soap exists over a limited range of concentrations as a homogeneous phase which constitutes, like the isotropic solutions, a colloidal electrolyte. There is no great difference in molar conductivity between soap in the middle soap phase and soap in the isotropic phase. Middle soap up to  $1.25N_w$  shows no structure in the cardiod ultramicroscope, but above this concentration diffuse granular patches begin to show against the dark background.

Middle soap exists over only a limited range of concentrations, above which another distinct phase of still more concentrated solution appears. To this phase we have extended the term "neat soap." Neat soap resembles middle soap in being a conic anisotropic liquid and in being plastic; that is, devoid of noticeable elasticity. Each is rigid, the neat soap much less so with about the consistency of vaselin. Middle soap is darker than neat soap (due to presence of impurity). A moderately thin specimen of middle soap is clear and transparent, whereas neat soap is better described as semi-transparent and somewhat turbid. The heterogeneous mixture of these two is rigid and turbid, the turbidity being at a maximum between the normalities  $5N_w$  and  $6N_w$ . The exact range of concentrations for the existence of these phases has still to be determined, but for middle soap it lies between about  $0.9N_w$  and  $3.4N_w$  and for neat soap between  $7.5N_w$  and  $12N_w$ , within which limits a uniform field is obtained (see photograph I).

In many of the otherwise clear systems described above, small, white, star-like growths develop with time. Examination in the ultramicroscope shows them to consist of small rods plaited together to form branching structures. They probably consist of acid soaps produced by hydrolysis.

Photograph I, of  $9N_w$ -potassium oleate in polarised light, shows that neat soap, like middle soap, is a homogeneous, conic, anisotropic liquid soap with uniaxial interference figures. Further, on

III.— $25N_w$  Potassium oleate at room temperature. Showing crystalline flakes and anisotropic fluid. Crossed nicols.  $\times 60$ .

IV.— $13.3N_w$  Potassium oleate at room temperature. Crystals as seen under cardiod ultramicroscope.

cooling  $4N_w$ -potassium oleate below its critical temperature,  $T_c$  240°, the drops of neat soap which begin to appear separate in the form of the double cones which Lehmann (*Weid. Ann.*, 1895, 56, 771, etc.) gave as a classical illustration of liquid crystals in systems containing ammonium oleate. Ethyl azoxybenzoate likewise separates in the form of these double cones when cooled from the isotropic, amorphous liquid condition. Friedel (*Ann. Physique*, 1922, 18, 273) terms this structure "batomet" and regards it as proof that such systems are to be included in his so-called "smectic" group. Evidently both neat soap and middle soap are anisotropic liquids which would be included in the smectic group, and no soap systems are yet known which could be classified as "nematic." The fact that curd fibres have been shown by Mr. S. H. Piper to give radiograms with lines corresponding to spacings in three dimensions is a positive disproof of Friedel's contention that they were to be included in his "smectic" group, although he renamed the "liquides à conique" (conic anisotropic liquids) specially to include them.

At temperatures between 240° and 300° neat soap may be concentrated up to 100% anhydrous potassium oleate, but at lower temperatures there is an upper limit fixed by the separation of crystalline potassium oleate, usually in the form of extremely thin, hexagonal flakes. In the  $50N_w$ -solution there is still some neat soap left, showing that the hydration of the crystals cannot exceed 1 mol. of water per mol. of soap. It is not known whether these crystals of slightly hydrated potassium oleate can be dehydrated to anhydrous potassium oleate without any new phase separating. The excessively thin crystal plates are readily bent and are illustrated in photograph II.

The sharply outlined hexagonal lamellæ are sometimes thin enough to give interference colours in ordinary light, and under a polarising microscope exhibit polarisation colours and give sharp uniform extinction in four positions. A mass of the crystals has a wax-like consistency and presents a silvery appearance. Photographs III and IV show these crystals mixed with neat soap in the heterogeneous systems.

Thus in passing from one pure component, water, to the other pure component, potassium oleate, at 20°, at least four different phases are met with and the solutions are alternately homogeneous and heterogeneous. At temperatures above 180°, the very remarkable behaviour is met with that there is a region of homogeneous isotropic phase above the middle soap as well as below it, so that, for example, at 177°, on steadily concentrating an isotropic solution the anisotropic middle soap separates, and after its formation is completed and the solution is slightly more concentrated, isotropic

solution of still higher concentration begins to appear but exists over a narrow range, whereupon neat soap appears.

All these relations are shown in Fig. 1 and some of the numerical data from which the figure has been plotted are in Tables IA, B, C and D. The temperatures there recorded are  $T_i$ , the minimum temperature at which the system is a homogeneous isotropic liquid,

FIG. 1.

*Equilibrium diagram for the two-component system water-potassium oleate, showing the stable, homogeneous phases that occur at various temperatures. The boundary of the isotropic solution only is accurately known.*

determined visually or with the aid of optical apparatus;  $T_h$ , the temperature on heating to which anisotropic plastic liquid shows, by a marked fall in rigidity, that isotropic liquid is beginning to separate; and  $T_c$ , the temperature on heating to which crystals just disappear to form homogeneous neat soap. Concentrations are expressed in weight normality ( $N_w$ ), and also in "fractional proportions" of potassium oleate,  $N_w/(N_w + 1)$ , for use later in the triangular diagram of the three-component system.

TABLE IA.

*Appearance of aqueous potassium oleate at room temperature and phases present, together with temperatures,  $T_i$ , on heating to which the system becomes a clear homogeneous liquid.*

*Series a. Tubes partly evacuated before sealing.\**

System ( $N_w$ ).	Fractional proportion of K oleate.	Description of material at room temp.	$T_i$ (visual).

Homo. = homogeneous. Hetero. = heterogeneous. M. soap = "middle soap." N. soap = "neat soap."

\* The above systems were prepared from oleic acid of mol. wt. 285 and were all more deeply coloured than those prepared with 1924 (B) and 1925 soaps, possibly owing to a very slight amount of free oleic acid, which becomes oxidised at high temperatures. This would provide a possible explanation of the marked difference between 3.5 $N_w$ -solution prepared with this sample of soap and that prepared with succeeding samples.

† Minute droplets of a lemon-white phase in a brownish-red phase; system still rigid and plastic.

‡ Two immiscible plastic fluids, one lemon-coloured and tending to accumulate at the surface, the other deep reddish-brown and accumulating at the bottom of the tube.

*Effect of the Presence of Potassium Chloride in Isotropic Solutions  
of Potassium Oleate.*

Qualitative observations have been described by M. H. Fischer  
("Soaps and Proteins," New York, 1921) on the effect of adding

salts to ordinary soap solutions. Some of his experiments were repeated by Miss King (*J. Soc. Chem. Ind.*, 1922, 41, 147T). Fischer's observations were confined to fairly dilute soap solutions and were evidently influenced by the difficulties of ensuring adequate mixing and avoiding oxidation of soap, which greatly affect the results. The following observations were made by Miss King and F. T. Maggs as well as by ourselves.

The most important effect is that, whilst moderate additions of such salts as potassium chloride and potassium thiocyanate progressively increase the viscosity of the liquid, there is an ill-defined range of concentrations of salt for which the potassium oleate solutions set to a clear, transparent, elastic jelly like table jelly. For potassium chloride and potassium thiocyanate these concentrations are between about 0.4 and  $0.8N_w$ . This range is somewhat wider if sufficient time is given for gelatinisation; the whole system remaining homogeneous and clear if hydrolysis and oxidation are avoided.

Still further small additions of salt reduce the jelly to a more or less viscous, homogeneous liquid. In solutions of such soaps as do not gelatinise under the given conditions, for example, sodium palmitate at  $81^\circ$ , the viscosity rises to a maximum and then falls off very greatly before any salting-out takes place (compare Miss King's graph, *loc. cit.*). Similar behaviour is observed within the whole range of isotropic solutions.

Still higher concentrations of salt cause separation of the soap solution into two layers. The concentration of salt necessary to effect this depends, in a rather complicated way, on the concentration of the soap, as is seen in Figs. 2, etc., in which the boundaries of the isotropic field are accurately mapped. If the solutions are sufficiently dilute, say below  $0.6N_w$ -potassium oleate, the two liquid layers formed are both isotropic and are represented on the diagram within an indentation in the isotropic liquid boundary. The upper layer is "nigre" and contains most of the soap; the lower layer is "lye" containing a minute concentration of soap and a concentration of salt slightly higher than that in the nigre.

If the soap solution is more concentrated, say between  $0.75N_w$  and  $3N_w$ , the two phases separating out are neat soap and nigre. It will be noted that the presence of the salt greatly increases the possible concentration of soap in the isotropic solution; thus at  $20^\circ$  in the absence of salt the highest concentration at which potassium oleate forms a homogeneous isotropic liquid is  $0.70N_w$ , whereas in the presence of  $0.176N_w$ -potassium chloride the concentration of the soap may be increased to  $3N_w$ . As in the two-component system, so in the three-component system, increasing temperature extends the boundaries of the isotropic field.

*Equilibria in the System Water-Potassium Oleate-Potassium Chloride.*

Middle soap and neat soap, like isotropic solution, extend from the two-component system, aqueous potassium oleate, into the three-component system; thus not only is the two-component system the limiting boundary of the three-component system, but the same phases occur in each and no new ones appear through addition of salt. Discussion of the three-component system is thus reduced to delimiting the boundaries for the existence of the phases, the appearance and properties of which have previously been dealt with. In other words, a reference to the foregoing discussion of

FIG. 2.

Phase rule diagram at 20°. Potassium oleate-potassium chloride-water; concentrations being expressed in fractions of mols. of potassium oleate and potassium chloride, but in fractions of one kilogram of water. The shaded areas represent the approximate direction of the tie lines in the two-layer systems.

the two-component systems shows that solutions of pure soap spontaneously "salt out" in the absence of salt.

Most of the observations consisted in noting carefully the temperatures,  $T_i$ , at which heterogeneous systems just became isotropic, and it was found that these homogeneous isotropic solutions separated again at the same temperatures on cooling. It is only when the true crystalline lamellæ are due to appear that supersaturation has ever been observed.

Addition of salt to middle soap lowers the temperature,  $T_i$ , at which it becomes isotropic. Likewise, at higher temperatures, its field of existence progressively diminishes until at 189° it is reduced to a single point in the two-component system.

In most cases separation of the phases was so imperfect that they remained permanently in intimate mixture as a rigid, or extremely viscous mass, so that samples could not be separated for analysis. Indeed, the complete separation of neat soap from nigre, even in full-scale commercial work, is an art which calls for the highest skill on the part of the soap boiler, and middle soap has never been studied on the commercial scale. Apart from the extremely ready

FIG. 3.

separation of lye from nigre, it has been considered impossible to effect separations in small-scale experiments. However, recent experience indicates that at high temperatures certain of these separations may be possible which will then permit of direct analyses of the separated layers.

The data are in Table II and the isotherms deduced therefrom are shown in Figs. 2 to 5, which should be compared with the corresponding diagrams for sodium palmitate (McBain and

Langdon, *loc. cit.*), where also a fuller introduction to the subject is given.

The five tie-lines between nigre and lye shown in Figs. 2 and 3, which illustrate the general equilibria at 20°, were obtained by direct analyses of the two phases in equilibrium with each other. The cross in the middle of each line represents the total composition of each system which should, of course, lie upon the straight line connecting the compositions of the two phases in each case.

Fig. 2 represents the equilibria and the stable phases at 20°. It is the same equilateral triangle of unit height used in the previous papers, in which the respective corners represent 1 mol. of pure anhydrous potassium oleate, 1 mol. of potassium chloride, and 1 kilo. of water; and in which the co-ordinates are the fractions of these three quantities, the sum of which for each point on the diagram is unity. Although not so easily read as the rectangular diagram (Fig. 3), it is much more satisfactory for a complete survey of the field. In Fig. 3 technical units are employed for convenience of comparison with soap-boiling data.

Nearly half of each of Figs. 2 and 3 is occupied by the field of ordinary isotropic solutions. The general form of this extensive field resembles that for sodium palmitate (*loc. cit.*, Figs. 1 and 2), especially if the difference in temperature is taken into account. However, the greater solubility of potassium oleate is reflected in the distinctly larger amounts of salt which can be added without

destroying the homogeneity of the solution. The field of middle soap, though in both cases only approximately delimited, is much more prominent with potassium oleate, whereas the neat soap fields, as far as known, are fairly similar. The field representing crystalline soap is confined to a small part of the uppermost corner of the diagram on account of the low degree of hydration of crystals of potassium oleate. This field likewise requires further study.

In the previous communication (*loc. cit.*, p. 858) the possibility of the existence of a three-phase system, *viz.*, neat soap, nigre and

FIG. 4.

Solubility curves of potassium chloride and potassium oleate at 20°, 60°, 90°, 120°, 150°, 180°, and 210° showing the extreme limits of the field of homogeneous isotropic solutions capable of existing at these temperatures. The point M is the only concentration at which middle soap can exist up to 183°; above this temperature it is isotropic.

lye, is briefly discussed, and it is shown that it is confined to a negligibly narrow region. This is again the finding in the present case, but since a few instances have been met with where apparently these three phases stably co-exist over a very narrow range, corresponding provision has been made in Figs. 2 and 3 of the present paper by indicating the very narrow triangle connecting the compositions of these three phases immediately to the right of the projecting portion of the isotropic field. In Fig. 2 of the previous paper this triangle was represented by a single heavy tie-line, whereas, through inadvertence, in Fig. 1 it was omitted altogether.

For practical purposes, whether this region is a single line or such a very narrow triangle is of no importance.

M. C. Field attempted to test this question for us by preparing five solutions each of which was  $0.5N_w$ -potassium oleate and contained amounts of total potassium chloride ranging from  $1.70N_w$  to  $1.99N_w$ . All five exhibited three layers, the proportion of the middle layer being greatest in the first and progressively less in the others and the amount of upper layer changing accordingly. This would at first sight appear to establish the existence of the suggested

FIG. 5.

*Limits of existence, in technical units, of homogeneous isotropic solutions containing potassium chloride and potassium oleate at 20°, 60°, 90°, 120°, 180°, and 210°, showing the two regions in which solutions of pure soap form isotropic solutions at 210°.*

triangular field and give it a maximum width on the diagram extending from fractional proportion of potassium chloride = 0.53 to 0.57. However, the refractive index of the lye as well as of the middle layer changed progressively with the total composition of the system instead of each phase being identical in composition for all cases and varying only in amount. This is, then, direct proof that complete equilibrium was not attained and that the suggested triangle must be much narrower, having a width of only 1% or so of the total width of the diagram.

Figs. 4 and 5 present the isotherms which bound the field of

isotropic solutions at various temperatures from room temperature up to 210°. These have been much more carefully worked out than in the case of palmitate, and in addition to the actual experimental points indicated in the diagram the position of the isotherms was checked by a series of graphs representing cross sections of the triangular space model for various normalities of soap.

Whereas the maximum temperatures at which middle soap can exist are lowered by the addition of salt, sections 11 and 13 of Table II indicate that in neat soap they are not much affected.

*Summary.*

1. The equilibria between the various forms of a potassium soap are very similar to those for a sodium soap.

2. All the soap phases that exist in the three-component system, including salt, are found in the simpler system, soap and water, where also their separation is spontaneous; that is, they "salt out" in the absence of salt and may even be observed at room temperature.

3. The limits of the field of existence of isotropic liquid solutions of potassium oleate with and without potassium chloride have been accurately determined for temperatures up to 210°. This single phase includes wholly crystalloidal solutions and ranges at sufficiently high temperatures from pure water up to pure anhydrous liquid potassium oleate, the two being miscible in all proportions above 300°.

4. Improvements in the methods of optical investigation have enabled progress to be made with the delimitation of the two important anisotropic liquids, neat soap and middle soap. Both neat soap and middle soap are typical conic anisotropic liquids.

Our warm thanks are due to Messrs. Chris. Thomas and Bros., Ltd., who supported this work by awarding to one of us (W. J. E.) a Colston Research Fellowship.

LVI.—*Tetrahydroacridine, Octahydroacridine, and their Derivatives. Part II. Resolution of the Octahydroacridines (A) and (B).*

By WILLIAM HENRY PERKIN, jun., and WILLIAM GREENWELL SEDGWICK.

In Part I of this investigation (Perkin and Sedgwick, J., 1924, 125, 2437) it was shown that the reduction of tetrahydroacridine (I) with tin and hydrochloric acid leads at once to the formation of

two octahydroacridines (A, m. p.  $82^\circ$ , and B, m. p.  $72^\circ$ ), four atoms of hydrogen being absorbed. It is remarkable that, in spite of careful search, no intermediate product of reduction could be detected, because it was to be expected that the carbon-nitrogen conjugated system  $\cdot\text{C}:\text{C}:\text{C}:\text{N}\cdot$  would, in the first place, absorb two atoms of hydrogen to yield a hexahydroacridine (II) containing the grouping,  $\geq\text{C}:\text{C}:\text{C}:\text{N}\cdot$ .

Experiment showed that, if less reducing agent is employed than is necessary to convert the whole of the tetrahydroacridine into octahydroacridine, the product is a mixture of octahydroacridine and unchanged tetrahydroacridine. If, as may be assumed to be the case, hexahydroacridine (II) is the intermediate stage, it is probable that this substance is more readily reduced than tetrahydroacridine and is therefore at once converted into octahydroacridine, the corresponding amount of tetrahydroacridine remaining unchanged. It was pointed out in the previous communication (p. 2440) that remarkable as the observation seemed at first, the formation of two octahydroacridines by the addition of four atoms of hydrogen to tetrahydroacridine (I) is strictly in accordance with structural theory.

If the model (compare Sachse, *Ber.*, 1890, **23**, 1363; Mohr, *J. pr. Chem.*, 1918, **98**, 315) be set up and examined, it is at once evident that the pairs (III) and (IV) should result from the addition

of four hydrogen atoms to tetrahydroacridine and that both pairs should be resolvable into their *d*- and *l*-constituents. In order to prove that the configurations (III) and (IV) actually represent the two octahydroacridines (A) and (B), it was clearly necessary to demonstrate that both these substances can be resolved into active constituents. In our first experiments, resolution was attempted

with the aid of bromocamphorsulphonic acid, but without immediate success. It was then discovered that the salts of (A) and (B) with the *d*- and *l*-camphorsulphonic acids are sufficiently well characterised to allow of satisfactory fractional crystallisation, and in this way resolution was achieved in both cases. When the pure salts were decomposed by alkali, they at once yielded the *d*- and *l*-modifications of the octahydroacridines (A) and (B) in a pure state.

The stages in these resolutions will be clearly understood from the following tables :

(I) Resolution of *dl*-Octahydroacridine (A, m. p. 82°).

<i>d</i> -Camphorsulphonic acid	<i>l</i> -Camphorsulphonic acid
↓	↓
1-Octahydroacridine (A) <i>d</i> -camphorsulphonate (m. p. 183°)	<i>d</i> -Octahydroacridine (A) <i>l</i> -camphorsulphonate (m. p. 182°)
NaOH ↓	NaOH ↓
1-Octahydroacridine (A), m. p. 85°, $[\alpha]_D -32^\circ$ .	<i>d</i> -Octahydroacridine (A), m. p. 84.5°, $[\alpha]_D +34^\circ$ .
Mean rotation $[\alpha]_D \pm 33^\circ$ .	

(II) Resolution of *dl*-Octahydroacridine (B, m. p. 72°).

<i>d</i> -Camphorsulphonic acid	<i>l</i> -Camphorsulphonic acid
↓	↓
1-Octahydroacridine (B) <i>d</i> -camphorsulphonate (m. p. 172°)	<i>d</i> -Octahydroacridine (B) <i>l</i> -camphorsulphonate (m. p. 172°)
NaOH ↓	NaOH ↓
1-Octahydroacridine (B), m. p. 73°, $[\alpha]_D -24^\circ$ .	<i>d</i> -Octahydroacridine (B), m. p. 73°, $[\alpha]_D +22^\circ$ .
Mean rotation $[\alpha]_D \pm 23^\circ$ .	

When the corresponding *d*- and *l*-modifications are mixed, the inactive forms are at once produced, but loss of activity also occurs gradually when the *d*- or *l*-modifications are heated at or above their melting points and the change to the inactive form is complete on distillation under reduced pressure. It is curious, both in the case of (A) and of (B), that the inactive modification melts at a somewhat lower temperature than the active constituents, suggesting that the *dl*-modification may be a mixture and not a true racemic compound. It is interesting also that, on boiling with acetic anhydride, *l*-octahydroacridine (A) is converted into the acetyl derivative of *dl*-octahydroacridine (A) (m. p. 86°) described in the previous communication (p. 2449).

So far, sufficient evidence is not available to enable definite configurations to be assigned to the octahydroacridines (A) and (B),

but it is significant that, when tetrahydroacridone is reduced by sodium amalgam (*loc. cit.*, p. 2449), the product consists entirely of modification (A). The probability in this reduction is that the hydrogen atoms will add themselves on to the double linking in the direction indicated in (III) and we are for this reason inclined to assign the configuration (III) to octahydroacridine (A). In the earlier communication (p. 2450) it is shown that isatin condenses with *cyclohexanone* to yield tetrahydroacridinecarboxylic acid (compare Borsche, *Ber.*, 1908, 41, 2207) and that this acid yields, on reduction with sodium amalgam, a mixture of octahydroacridinecarboxylic acids (A) and (B), which, on distillation, decompose with elimination of carbon dioxide and formation of the octahydroacridines (A) and (B). These acids are doubtless also *dl*-modifications corresponding to (III) and (IV) and experiments on their resolution are in progress.

During the course of these resolution experiments, we thought it desirable to be able to confirm the results obtained with the octahydroacridines (A) and (B) by the investigation of another case of the same kind. We therefore condensed 1-methyl*cyclohexan-3-one* with (i) *o*-aminobenzaldehyde and (ii) isatin. In (i) we obtained a substance melting at 71° which may be either 6- or 8-methyltetrahydroacridine and in (ii) a 6(or 8)-methyltetrahydroacridinecarboxylic acid (m. p. 296°) which, on heating, yielded the same parent substance melting at 71°. When this substance is reduced with tin and hydrochloric acid, it is converted into a mixture of 6(or 8)-methyl-octahydroacridines (A, m. p. 92°) and (B, m. p. 80°), and again (compare above) only the modification (A) is produced when 6(or 8)-methyltetrahydroacridone (*loc. cit.*, p. 2442) is reduced with sodium amalgam. Of these modifications, the substance (A) has been resolved with the aid of the *d*- and *l*-camphorsulphonic acids and the active modifications have  $[\alpha]_D + 20^\circ$  and  $- 28^\circ$ , respectively, or a mean rotation of  $[\alpha] \pm 24^\circ$ .

#### EXPERIMENTAL.

The *l*-camphorsulphonic acid used in this research was prepared by sulphonating *l*-camphor with a mixture of sulphuric acid and acetic anhydride as described by Reychler (*Bull. Soc. chim.*, 1898, 111, 120). The *d*-acid was supplied by the British Drug Houses. Both gave physical constants in good agreement with those quoted in the literature, melting, in the anhydrous form, at 193° and showing, in solution as ammonium salts,  $[\alpha]_D \pm 19.9^\circ$ . The octahydroacridine (A) (m. p. 82°) used in the following experiments was obtained partly by the reduction of tetrahydroacridone with sodium amalgam, and both the (A) and (B) modifications were prepared

in quantity by the reduction of tetrahydroacridine and separated by the sulphuric acid method (compare Perkin and Sedgwick, *loc. cit.*, p. 2448).

*Resolution of dl-Octahydroacridine (A)* (m. p. 82°).—This *dl*-base (20 g.), dissolved in the minimum quantity of hot alcohol, was added to a concentrated solution of the equivalent quantity of *d*-camphorsulphonic acid (24.9 g.), and the mixture left over-night. The mother-liquor was then decanted from the crystalline mass of crude 1-octahydroacridine (A) *d*-camphorsulphonate, the crystals (24 g.) were quickly washed with a little alcohol, dissolved in the minimum quantity of boiling alcohol, and allowed to recrystallise. This operation was repeated four times, the final product, 1-octahydroacridine (A) *d*-camphorsulphonate (8 g.), separating in large, colourless prisms, m. p. 182° (Found: C, 65.4; H, 7.7.  $C_{13}H_{17}N, C_{10}H_{15}O \cdot SO_3H$  requires C, 65.9; H, 7.9%; 0.6084 required 14.55 c.c. of *N*/10-NaOH for neutralisation, whereas the theoretical amount is 14.5 c.c.).

In order to separate the free base, the salt was dissolved in alcohol, and the solution carefully neutralised with *N*/10-sodium hydroxide, phenolphthalein being used as indicator; the precipitation was then completed by the addition of water, and the base extracted three times with ether. The ethereal extract was dried over sodium sulphate and concentrated; 1-octahydroacridine (A) then separated slowly in well-defined plates, m. p. 85° (Found: C, 83.2; H, 9.1.  $C_{13}H_{17}N$  requires C, 83.4; H, 9.1%). 0.5 G. in 20 c.c. of alcohol ( $c = 2.5$ ) gave, in a 1-dm. tube,  $\alpha - 0.80^\circ$ , whence  $[\alpha]_D = -32^\circ$ .

*d*-Octahydroacridine (A) was isolated in the same manner by means of *l*-camphorsulphonic acid and melted at 84.5° (Found: C, 83.0; H, 9.0%).  $[\alpha]_D$  in alcohol,  $+34^\circ$  ( $c = 2.5$ ) and in acetone,  $+29^\circ$  ( $c = 2.0$ ). Both active modifications undergo racemisation on distillation and when equal quantities were mixed and the mixture was crystallised from ether, the *dl*-base (A) obtained melted at 82.5°. The melting point of a mixture of approximately equal quantities was 83°. The mother-liquor from the first crystallisation of 1-octahydroacridine (A) *d*-camphorsulphonate deposited, on further concentration, several crops of crystals of varying rotation. The last of these, on repeated recrystallisation, yielded ultimately a crop which was nearly pure *d*-octahydroacridine (A) *d*-camphorsulphonate (m. p. 180°), since the base, set free on neutralisation, had, in alcohol,  $[\alpha]_D + 25^\circ$ .

*Resolution of dl-Octahydroacridine (B)* (m. p. 72°).—This *dl*-base (10 g.) was slowly dissolved in a warm concentrated aqueous solution of *d*-camphorsulphonic acid (15 g.), the excess of acid over

that theoretically required to neutralise the base (12.4 g.) being necessary to effect complete solution. After 12 hours, the crystalline mass was collected, washed with alcohol, and dried between blotting paper, the filtrate (O) being preserved for subsequent treatment.

The crude *l*-octahydroacridine (B) *d*-camphorsulphonate crystallised from water with one molecule of the solvent, which was removed by drying in a desiccator over sulphuric acid or by heating in an air-oven.

The salt was then subjected to two crystallisations from alcohol; the ultimate yield of pure anhydrous *l*-octahydroacridine (B) *d*-camphorsulphonate was 4 g. and the salt melted at 172° with previous softening. 0.4693 G. of the salt required 11.1 c.c. of *N*/10-sodium hydroxide for neutralisation, whereas the theoretical amount is 11.2 c.c.

*l*-Octahydroacridine (B) was obtained from this salt by neutralisation with sodium hydroxide and separated from petroleum (b. p. 40—60°) in colourless plates, m. p. 73° (Found: C, 83.1; H, 9.5.  $C_{13}H_{17}N$  requires C, 83.4; H, 9.1%).  $[\alpha]_D$  in alcohol ( $c = 2.5$ ),  $-24^\circ$ ;  $[\alpha]_D$  in acetone ( $c = 1.0$ ),  $-19^\circ$ .

The filtrate (O), after removal of the crystals which had separated on further standing, was neutralised with sodium hydroxide, and the precipitated base extracted with ether. The ethereal extract was evaporated in a vacuum desiccator, and the crystalline residue (4 g.) showed a small dextrorotation in alcoholic solution.

This material was combined with *l*-camphorsulphonic acid under the conditions already described, the salt purified by repeated crystallisation, and the *d*-octahydroacridine (B) precipitated by neutralisation with sodium hydroxide. The base melted at 73° and had  $[\alpha]_D$  in alcohol ( $c = 2$ )  $+22^\circ$ .

The salts of octahydroacridine (B) with the camphorsulphonic acids are more soluble than those of the isomeride (A), particularly in anhydrous alcohol. This property may be utilised as a method for the separation of the two isomerides, in which case the mixture resulting from the reduction of tetrahydroacridine with tin and hydrochloric acid (*loc. cit.*, p. 2448) is dissolved in a warm concentrated alcoholic solution of the equivalent quantity of *d*-camphorsulphonic acid and allowed to crystallise. The first crop of crystals consists of almost pure octahydroacridine (A) *d*-camphorsulphonate and can be used directly for the resolution of the base.

6(or 8)-Methyltetrahydroacridine.—In preparing this substance, a mixture of *o*-aminobenzaldehyde (3 g.) with 1-methylcyclohexan-3-one (5 g.) was heated in an oil-bath at 100° for about an hour and then at 130° for 1½ hours. On distilling the product under

reduced pressure (15 mm.), water and unchanged methylcyclohexanone passed over below  $120^{\circ}$  and then *methyltetrahydroacridine* (3 g.) distilled at about  $150^{\circ}$  as a pale yellow oil which quickly solidified. The base crystallised from petroleum in colourless plates, m. p.  $70-71^{\circ}$  (Found: C, 85.0; H, 7.5.  $C_{14}H_{15}N$  requires C, 85.3; H, 7.6%). The *picrate*, prepared by mixing solutions of the base and picric acid in hot alcohol, crystallised on cooling in yellow prisms, m. p.  $182^{\circ}$  (darkening).

6(or 8)-*Methyltetrahydroacridinecarboxylic Acid*.—A solution of isatin (10 g.) in potassium hydroxide (42 c.c. of 30%) was mixed with alcohol (80 c.c.) and 1-methylcyclohexanone (20 g.) and refluxed for 12 hours. The alcohol was evaporated in an open basin, the viscid residue mixed with water, the semi-crystalline scum removed by filtration, and the *methyltetrahydroacridinecarboxylic acid* precipitated as a fine, yellow, crystalline powder by the addition of 50% acetic acid.

The dried product is pure enough for most purposes and is very sparingly soluble in the usual solvents. It separates from much alcohol in minute, yellow needles, m. p.  $296^{\circ}$  (decomp.) (Found: C, 74.8; H, 6.6.  $C_{15}H_{15}O_2N$  requires C, 74.7; H, 6.2%). The acid (10 g.) was heated in a distilling flask at its melting point until evolution of carbon dioxide had ceased and the dark liquid was then distilled under 15 mm. pressure; 6(or 8)-*methyltetrahydroacridine* passed over as a pale yellow oil which immediately crystallised. The recrystallised material melted at  $70-72^{\circ}$  and gave no depression of melting point when mixed with a specimen prepared by the *o*-aminobenzaldehyde process just described.

*The 6(or 8)-Methyloctahydroacridines*.—Methyltetrahydroacridine was reduced with tin and hydrochloric acid under the conditions described in the case of tetrahydroacridine (*loc. cit.*, p. 2448), and the resulting two methyloctahydroacridines (A) and (B) were separated in a manner similar to that employed in the separation of the octahydroacridines (A) and (B) (*loc. cit.*). *Methyloctahydroacridine* (A) was also obtained by the reduction of methyltetrahydroacridone and separated from ether or petroleum in colourless prisms, m. p.  $92^{\circ}$ . It was resolved with the aid of *d*- and *l*-camphorsulphonic acids exactly as described in the case of the octahydroacridines (A) and (B). The *d*- and *l*-isomerides melt at  $92^{\circ}$  (Found for the *d*-isomeride: C, 83.4; H, 9.4.  $C_{14}H_{19}N$  requires C, 83.6; H, 9.5%). 0.09 G. of the *d*-modification, dissolved in 15 c.c. of alcohol ( $c = 0.6$ ), gave in a 1-dcm. tube,  $\alpha = +0.12^{\circ}$ , whence  $[\alpha]_D + 20^{\circ}$ . 0.1 G. of the *l*-modification, dissolved in 20 c.c. of alcohol ( $c = 0.5$ ), gave in a 2-dcm. tube,  $\alpha - 0.28^{\circ}$ , whence  $[\alpha]_D - 28^{\circ}$ ; the mean rotation is therefore  $[\alpha]_D \pm 24^{\circ}$ .

The sulphate of *dl*-methyloctahydroacridine (B) is more readily soluble than the sulphate of the modification (A), and the base melts at  $80^\circ$ ; no attempt was made to resolve it into its active modifications.

One of us (W. G. S.) desires to express his thanks to the Salters' Institute of Industrial Chemistry for a Fellowship which has enabled him to engage in this investigation.

UNIVERSITY COLLEGE, LONDON.

[Received, December 28th, 1925.]

## LVII.—The Conversion of Berberine into $\beta$ -Homochelidonine (*α*-alloCryptopine).

By ROBERT DOWNS HAWORTH and WILLIAM HENRY PERKIN, jun.

DURING the course of the investigation of cryptopine and protopine (Perkin, J., 1916, 109, 815; 1918, 113, 493, 722; 1919, 115, 713) it was shown that these alkaloids contain a ten-membered ring, and that cryptopine and dihydrocryptopine are converted into quaternary chlorides, containing the berberine skeleton, when they are treated with phosphorus oxychloride :

Subsequently Gadamer (*Arch. Pharm.*, 1919, 257, 298; 1920, 258, 148) found that  $\beta$ -homochelidonine, one of the alkaloids occurring in *Sanguinaria canadensis* and *Chelidonium majus*, is converted into dihydroberberine methochloride, and dihydro- $\beta$ -homochelidonine into tetrahydroberberine methochloride under similar conditions. Gadamer therefore concluded that  $\beta$ -homochelidonine must, like cryptopine, contain a ten-membered ring and that the

change into dihydroberberine methochloride is to be represented thus:

It is in view of this close relationship that Gadamer (*loc. cit.*) suggested the name  $\alpha$ -allocryptopine for  $\beta$ -homochelidonine.

The synthesis of berberine recently achieved by Perkin, Ray, and Robinson (J., 1925, 127, 740; compare Späth, *Ber.*, 1925, 58, 2268) will, it is hoped, serve as a basis for the synthesis of other alkaloids of similar constitution and it now became important to devise a method which would enable synthetical alkaloids of the berberine type to be converted into alkaloids like cryptopine, protopine, and  $\beta$ -homochelidonine with which they are clearly closely allied. The present investigation is concerned with such a method, namely, with the conversion of berberine into  $\beta$ -homochelidonine. The development of the process to the synthesis of cryptopine and the allied alkaloids will, it is hoped, form the subject of future communications.

It has long been known (Voss and Gadamer, *Arch. Pharm.*, 1910, 248, 43; Freund, *Annalen*, 1913, 397, 1; Pyman, J., 1913, 103, 817; McDavid, Perkin, and Robinson, J., 1912, 101, 1220; Perkin, J., 1916, 109, 952) that tetrahydroberberine methohydroxide (I) loses water when its aqueous solution is evaporated in a vacuum and yields as chief product anhydrotetrahydromethylberberine (anhydromethylcanadine) (II), a remarkable change which results in the formation of a substance containing a ten-membered ring and in which the various groups occupy the same relative positions as in  $\beta$ -homochelidonine.

It is clearly only necessary to convert the group  $\cdot\text{CH}:\text{CH}\cdot$  in the latter formula into  $\cdot\text{CO}\cdot\text{CH}_2\cdot$  in order to achieve the synthesis of  $\beta$ -homochelidonine.

The realisation of this comparatively simple change proved to be a very difficult problem, mainly because the usual methods are not applicable to anhydrotetrahydromethylberberine. This substance exhibits a remarkable tendency, when treated with many of the usual reagents, and indeed merely on boiling with alcohol or chloroform, to revert to tetrahydroberberine methohydroxide or its salts with consequent loss of the ten-membered ring (compare Pyman, *loc. cit.*, p. 834). We observed the same change when an ice-cold solution of the base in chloroform was treated with bromine, since the crystalline perbromide which separated yielded tetrahydroberberine methobromide on decomposition with sulphurous acid. A series of experiments on the action of oxidising agents on anhydrotetrahydromethylberberine did not lead to the desired result, although interesting oxidation products were obtained, when this base was treated with silver hydroxide or hydrogen peroxide, which will be discussed in a future communication.

Some years since (*Ber.*, 1909, 42, 4811; 1910, 43, 959), Prileschajew carried out an important piece of work in the course of which he showed that ethylene derivatives,  $\cdot\text{CH}=\text{CH}\cdot$ , yield

ethylene oxides,  $\begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{CH}-\text{CH} \end{array}$ , on treatment with perbenzoic acid, and it seemed probable that, if this change could be brought about in the case of anhydrotetrahydromethylberberine, the resulting ethylene oxide grouping might be made to isomerise to  $\cdot\text{CO}\cdot\text{CH}_2\cdot$  and thus lead to the formation of  $\beta$ -homochelidonine (compare Weitz and Scheffer, *Ber.*, 1921, 54, 2344).

When an ice-cold solution of the base (II) in chloroform is added to an ice-cold solution of perbenzoic acid, the ethylene oxide derivative does not appear to be produced. Oxidation takes place rapidly, however, and a base,  $\text{C}_{21}\text{H}_{23}\text{O}_5\text{N}$ , isomeric but not identical with  $\beta$ -homochelidonine, is obtained in good yield. This curious substance crystallises from water, decomposes at  $135^\circ$ , and yields a hydrochloride,  $\text{C}_{21}\text{H}_{23}\text{O}_5\text{N}\cdot\text{HCl}$ , which is sparingly soluble in water. These and other properties seem to indicate that it is an amine oxide containing the group

In connexion with the formation and properties of this substance, it is interesting to note that Meisenheimer (*Ber.*, 1919, 52, 1667) has observed that perbenzoic acid converts methylallylaniline into the amine oxide,  $\text{CH}_2\text{:CH}\cdot\text{CH}_2\cdot\text{NMePh}\cdot\text{O}$ , without affecting the

ethylenic linking of the allyl group. He shows that this amine oxide undergoes a curious isomeric change to phenylmethylallyl-hydroxylamine,  $\text{CH}_2\text{:CH}\cdot\text{CH}_2\text{-O}\cdot\text{NMePh}$ , when heated with alkalis, and Bamberger and Leyden (*Ber.*, 1901, 34, 12) state that dimethyl-aniline oxide is converted into a mixture of *o*- and *p*-dimethyl-aminophenol by contact with sulphuric acid.

These curious isomeric changes encouraged us to examine in detail the action of various reagents on anhydrotetrahydromethylberberine oxide (III) and it was ultimately observed that in the presence of glacial acetic acid and hydrochloric acid, this amine oxide isomerises to a basic substance which crystallises from ethyl acetate in colourless prisms, m. p. 160—161°, and is identical with  $\beta$ -homochelidonine. The synthetic alkaloid gave no depression in m. p. when mixed with a specimen of  $\beta$ -homochelidonine, for which we are indebted to Professor Gadamer; the hydrochloride was readily soluble in water and crystallised from alcohol-ether in colourless needles which were identical in appearance and behaviour with the hydrochloride of the naturally occurring alkaloid. The garnet-red aurichloride, m. p. 190—192° (decomp.), had all the properties of the double salt prepared from the natural product, whilst the colour reactions of the synthetic and the natural alkaloid with concentrated sulphuric acid, Fröhde's, and Erdmann's reagents were indistinguishable. We propose to investigate the mechanism of the above synthesis, more particularly in regard to the action of other reagents on the amine oxide, and details of this work as well as of the extension of the method to the synthesis of cryptopine, protopine, and allied alkaloids are reserved for a later communication.

#### EXPERIMENTAL.

Anhydrotetrahydromethylberberine was prepared as recommended by Pyman (*loc. cit.*, p. 833), but we found it advisable to use as little excess of silver hydroxide as possible in the preparation of tetrahydroberberine methohydroxide. Tetrahydroberberine methiodide, dissolved in boiling water, is agitated for  $\frac{1}{2}$  hour with the calculated amount of silver hydroxide, and the solution is filtered hot and tested for unchanged methiodide with silver nitrate. If iodide is still present, a further small quantity of silver hydroxide is added and the process repeated if necessary. The whole is then filtered and the solution evaporated exactly as described by Pyman. The perbenzoic acid used in these experiments was prepared by the method of Baeyer and Villiger (*Ber.*, 1900, 33, 1575). It was extracted with ether and the content of the ethereal solution

estimated, immediately before use, by titration with potassium iodide and *N*/10-sodium thiosulphate.

*Anhydrotetrahydromethylberberine Oxide*.—Anhydrotetrahydromethylberberine (2 g.), dissolved in dry chloroform, was gradually added to a solution of perbenzoic acid (estimated as 1.8 g.) in ether (100 c.c.), maintained below 5° by immersion in ice. An oil gradually separated which sometimes crystallised on standing. After remaining over-night, the mixture was shaken with 10% sodium hydroxide; the amine oxide then solidified as a white solid (1.5 g.) and was collected after several hours. A second crop may be obtained from the filtrate by the careful addition of strong sodium hydroxide.

*Anhydrotetrahydromethylberberine oxide* crystallises from water in colourless, slender prisms, m. p. 135° (decomp.) (Found: C, 68.1; H, 6.5.  $C_{21}H_{23}O_5N$  requires C, 68.3; H, 6.2%). It is soluble in chloroform or acetic acid, moderately easily soluble in ethyl acetate, and almost insoluble in ether or petroleum. It dissolves in hot water, but is less soluble in sodium hydroxide solution. On cooling the solution of the base in hot dilute hydrochloric acid, the *hydrochloride* separates in colourless nodules, m. p. 203° (decomp.) with previous darkening. It is more soluble in water than in dilute hydrochloric acid (Found: C, 62.2; H, 6.0.  $C_{21}H_{23}O_5N \cdot HCl$  requires C, 62.1; H, 5.9%).

*$\beta$ -Homochelidonine*.—The amine oxide (1.5 g.), dissolved in glacial acetic acid (10 c.c.) and concentrated hydrochloric acid (5 c.c.), was heated in rapidly boiling water for an hour, the pale yellow solution diluted with water, made alkaline with potassium hydroxide,\* and the cream-coloured solid collected. This was dissolved in methyl alcohol (20 c.c.), mixed with ether (200 c.c.), the ethereal solution washed with water until free from methyl alcohol, rapidly dried over potassium carbonate, and concentrated to a small bulk. On standing,  $\beta$ -homochelidonine separated; it crystallised from ethyl acetate in brilliant, colourless, monoclinic prisms, m. p. 160–161° (Found: C, 68.3; H, 6.5. Calc. for  $C_{21}H_{23}O_5N$ : C, 68.3; H, 6.2%). The crystals were exactly like those of a specimen of  $\beta$ -homochelidonine which Professor Gadamer very kindly sent us and there was no change in melting point when the two specimens were mixed.

Synthetic  $\beta$ -homochelidonine dissolves in concentrated sulphuric

\* The base is not completely precipitated from its salts by the addition of ammonia, and this property of  $\beta$ -homochelidonine is made use of in the isolation of the alkaloid from the plant (Schmidt and Selle, *Arch. Pharm.*, 1890, 228, 441).

acid to a yellow solution which rapidly becomes violet and slowly changes to bright red. With Fröhde's reagent, a yellow solution is obtained which soon becomes violet and then passes through brilliant blue to bluish-green. The base dissolves in Erdmann's reagent to a yellow solution which rapidly becomes violet and then dirty violet. These colour reactions are indistinguishable from those exhibited by the specimen of naturally occurring  $\beta$ -homochelidonine under similar conditions. The hydrochloride was obtained by dissolving the base in dilute hydrochloric acid and evaporating to dryness. The residue dissolved readily in alcohol and, on addition of ether, the hydrochloride slowly separated in slender, colourless, silky needles which turn yellow and shrink at about  $170^{\circ}$  and decompose at about  $190^{\circ}$ . The hydrochloride of the natural alkaloid possessed identical properties. The aurichloride separated on addition of gold chloride to the solution of the base in dilute hydrochloric acid, and crystallised from alcohol in warts of garnet-red crystals, m. p.  $190-192^{\circ}$  (decomp.). No alteration in m. p. was observed when this sample was mixed with the garnet-red aurichloride prepared in the same way from natural  $\beta$ -homochelidonine.

One of us (R. D. H.) desires to thank the Commissioners of the 1851 Exhibition for a studentship, and the Government Grant Committee of the Royal Society and the Research Fund Committee of the Chemical Society for grants towards the expense of this investigation.

[Received, December 28th, 1925.]

LVIII.—10-Chloro-5:10-dihydrophenarsazine and its Derivatives. Part I. The Synthesis, Preparation, and Some Properties of 10-Chloro-5:10-dihydrophenarsazine.

By HAROLD BURTON and CHARLES STANLEY GIBSON.

THE reaction between arsenious halides and secondary aromatic amines was the subject of a patent of F. Bayer & Co. (D.R.-P. 281049, Friedländer, "Fortschritte," 1914, XII, 843), and Wieland and Rheinheimer (*Annalen*, 1921, 423, 1) made a comprehensive study of the derivatives of the compound obtained by condensing arsenious chloride and diphenylamine. To this compound, Wie-

land and Rheinheimer gave the name "phenarsazine chloride" and ascribed to it the constitution

which is the same as that ascribed to it by the patentees.\*

\* Wieland and Rheinheimer (*loc. cit.*) prepared the compound phenarsazine, which undoubtedly has the structure

The product of the reaction between diphenylamine and arsenious chloride is derived from phenarsazine by the addition of hydrogen chloride. This compound has hitherto been variously known as "diphenylamine arsenious chloride" (Contardi, *Giorn. Chim. Ind. Appl.*, 1920, i, 11; ii, 100), "phenarsazine chloride" (Wieland and Rheinheimer, *loc. cit.*), and "6-chlorophenarsazine" (Lee Lewis and Hamilton, *J. Amer. Chem. Soc.*, 1921, 43, 2218; Lee Lewis, Lowry, and Bergeim, *ibid.*, p. 891). In systematically describing this class of compounds, the name phenarsazine is retained for the parent substance and the atoms are numbered as indicated. The product of the reaction between diphenylamine and arsenious chloride and its simple derivatives are regarded as substitution products of 5:10-dihydrophenarsazine, at present unknown. "Phenarsazinic acid," which is already in use for the oxidation product of these derivatives, still applies.

Although the patent referred to was taken out in 1913 and issued in the German Empire in December, 1914, the specification was not available in this country until September, 1920. Our knowledge of this type of heterocyclic compound up to 1918 was limited to that contained in a brief abstract of the patent, which referred only to the general reaction between arsenious chloride and diarylamines without mentioning any specific compound (*J. Soc. Chem. Ind.*, 1915, 34, 636). It ought to be pointed out that Dr. W. C. Ball independently prepared the compound early in 1918 (unpublished report of the Anti-gas Department) by the action of arsenious chloride on diphenylamine and examined a number of its simpler derivatives. Professor G. T. Morgan in 1918 (unpublished report) also studied the reaction and prepared certain analogues of 10-chloro-5:10-dihydrophenarsazine. In preparing his "diphenylamine arsenious chloride," Contardi (*loc. cit.*) heated diphenylamine hydrochloride and arsenious oxide together in the proportions for the following reaction to take place:

The reaction as described by Contardi does take place, but we have not been able to obtain the high yield recorded, probably because the product of the reaction is decomposed rapidly by water at the temperature employed.

The compound so easily obtained in almost quantitative yield by heating

The work now described was in progress before the paper by Wieland and Rheinheimer (*loc. cit.*) was available, and it seems desirable to describe our results, which supplement those of these two workers.

The constitution ascribed to 10-chloro-5 : 10-dihydrophenarsazine has been proved to be correct by the following synthesis, which may be represented diagrammatically :

The first stage consisted in diazotising *o*-nitroaniline and coupling the diazo-compound with *o*-bromophenylarsenious oxide (I). The resulting compound, 2-bromo-6'-nitrodiphenylarsinic acid, is reduced to the corresponding amino-compound (III) by means of ferrous hydroxide. By heating in amyl alcohol with potassium carbonate and a small quantity of copper powder, the amino-compound is readily converted into phenarsazinic acid (IV), and this, when reduced in hydrochloric acid-alcohol solution by sulphur dioxide, is readily converted into 10-chloro-5:10-dihydrophenarsazine identical with the substance prepared by the action of arsenious chloride on diphenylamine according to the equation

The preparation by Burton and Gibson (J., 1924, **125**, 2277) of the *N*-acetyl, *N*-propionyl, and *N*-benzoyl derivatives is confirmatory evidence of the presence of the :NH group in 10-chloro-5 : 10-dihydrophenarsazine.\* Wieland and Rheinheimer (*loc. cit.*) also have described the preparation of the *N*-methyl derivative from

together arsenious chloride and diphenylamine under the conditions described by previous workers is systematically described as 10-chloro-5:10-dihydro-phenarsazine.

\* Whilst 10:10'-oxy-5:10-dihydrophenarsazine reacts with acetyl chloride to give 10-chloro-5-acetyl-5:10-dihydrophenarsazine, benzoyl chloride and the oxy-compound react quantitatively as follows:

arsenious chloride and *N*-methyldiphenylamine. In connexion with our work on the phenarsazinic acids of this group of compounds, it was important to prepare the corresponding acid (Burton and Gibson, *loc. cit.*) with a view to investigate its trypanocidal properties. The only substance we have obtained by condensing arsenious chloride with *N*-methyldiphenylamine and working up the product under the conditions described by Wieland and Rheinheimer is 10-chloro-5 : 10-dihydrophenarsazine and not 10-chloro-5-methyl-5 : 10-dihydrophenarsazine (the *N*-methyl derivative). The melting point of the material we isolated from this reaction (about 10% of the theoretical quantity) was unaffected on admixture with an authentic specimen of 10-chloro-5 : 10-dihydrophenarsazine. Whilst the melting point, quoted by Wieland and Rheinheimer, of the supposed *N*-methyl derivative is 203° (some 8—10° higher than that of 10-chloro-5 : 10-dihydrophenarsazine), its further characterisation is somewhat inconclusive.\* Like Wieland and Rheinheimer, we have failed to obtain the *N*-methyl derivative by attempting to methylate 10-chloro-5 : 10-dihydrophenarsazine and we therefore attempted to synthesise the compound according to the following scheme based on the method for obtaining the parent substance :

Whether the compound (VII) is actually formed we are unable to say, but when the product obtained by heating 2-bromo-6'-methylaminodiphenylarsinic acid (VI) in amyl alcohol with potassium carbonate and copper powder is reduced in hydrochloric acid-alcohol solution with sulphur dioxide 10-chloro-5:10-dihydrophenarsazine, *o*-bromophenylarsenious chloride and methylaniline are obtained (see p. 459). While the *N*-acyl derivatives of 10-chloro-5 : 10-dihydrophenarsazine are prepared quite readily, the fact that we have been unable to prepare the *N*-methyl derivative either directly or by synthesis is not easily explained.

The most convenient way for preparing 10-chloro-5 : 10-dihydrophenarsazine in the laboratory is by heating one molecular proportion of diphenylamine with rather more than one molecular proportion of freshly distilled arsenious chloride in dichlorobenzene. The

\* The micro-analysis quoted by the above authors showed a nitrogen content of 5.0%, the calculated values for  $\text{NH}(\text{C}_6\text{H}_4)_2\text{AsCl}$  and  $\text{NMe}(\text{C}_6\text{H}_4)_2\text{AsCl}$  being 5.05 and 4.95% of nitrogen, respectively.

product crystallises from the solution on cooling and is rapidly purified by extraction with carbon tetrachloride. The fact that the reaction between arsenious chloride and diphenylamine takes place slowly at the ordinary temperature \* (actually a yield of 10% of the theoretical was obtained after 16 months) has enabled us to study the reaction somewhat closely. When the two reacting substances are mixed in the presence of a solvent, a white, crystalline substance having the composition  $\text{HCl} \cdot \text{NH}(\text{C}_6\text{H}_5)_2 \cdot \text{AsCl}_3$ , is slowly deposited. In a sealed apparatus no development of pressure was recorded, but the solution became dark green and crystals of 10-chloro-5:10-dihydrophenarsazine were slowly deposited. The same white crystalline substance was formed immediately on mixing diphenylamine hydrochloride and arsenious chloride, but no further reaction took place. On heating a mixture of arsenious chloride and diphenylamine or its hydrochloride in high-boiling solvents, the additive compound dissolves, a copious evolution of hydrogen chloride takes place, and 10-chloro-5:10-dihydrophenarsazine is rapidly formed. From these results, it appears that at the ordinary temperature diphenylamine and arsenious chloride react to liberate hydrogen chloride which combines with unchanged diphenylamine, forming its hydrochloride which then crystallises as the additive compound with arsenious chloride. The substitution product is soluble and has not been isolated, but it is clear that this soluble compound is intermediate in the formation of the final product. If the mixture is not heated and no escape for the hydrogen chloride is provided, it is obvious that the reaction cannot go to completion. In view of the results of the large number of investigations on the action of arsenious chloride on aniline (summarised by Schmidt, *J. Amer. Chem. Soc.*, 1921, 43, 2449) it is quite probable that the soluble intermediate compound may have the composition  $(\text{C}_6\text{H}_5)_2\text{N} \cdot \text{AsCl}_2$ . The ease of formation of 10-chloro-5:10-dihydrophenarsazine is very striking in view of the fact that usually para-substitution takes place when arsenic is introduced into the nucleus of aromatic amines. This is the case, not only in the formation of arsanilic acid, but also when arsenious chloride reacts with dialkylanilines (Michaelis and Rabinerson, *Annalen*, 1892, 270, 139; Michaelis, *Ber.*, 1908, 41, 1514); with monoalkylanilines and arylglycines (Poulenc Frères and Oechsli, French Patents 450214, 462276, and 473704). The following scheme of reactions was therefore studied with a view to the preparation of *p*-phenylaminophenylarsenious chloride (diphenylamine-*p*-arsenious chloride), which obviously

\* The investigation of the reaction between diphenylamine and arsenious chloride at the ordinary temperature was carried out by the late Mr. D. C. Vining and one of us (C. S. G.).

cannot be prepared directly from arsenious chloride and diphenylamine :

The reduction of the arsenic acid (XII) in the usual manner causes the elimination of the arsenic, and diphenylamine is the main product of the reaction. Consequently it has not been possible to prepare *p*-phenylaminophenylarsenious chloride (XIII), although its *N*-acetyl derivative (XI) is easily obtainable. In view of the ease with which 10-chloro-5:10-dihydrophenarsazine is obtained, this result is not unexpected.

In studying the action of arsenious chloride on aniline, Schmidt (*loc. cit.*) isolated trianilinoarsine hydrochloride,  $(\text{C}_6\text{H}_5\cdot\text{NH}_2\cdot\text{HCl})_3\text{As}$ , which was first described by Schiff (*Compt. rend.*, 1863, 56, 268, 1095). By heating this compound for a long time, either alone or in the presence of an excess of aniline, Schmidt claimed to have obtained 10-chloro-5:10-dihydrophenarsazine, which he identified as the corresponding oxy-compound.\* Schmidt states that the reaction which takes place may be expressed as follows :

Since we have been able to isolate diphenylamine from the product obtained by heating the trianilinoarsine hydrochloride with an excess of aniline, it is possible that the formation of 10-chloro-5:10-dihydrophenarsazine may be due to the action of arsenious chloride on diphenylamine which is formed under these conditions. This possibility is supported by the fact that when arsenious chloride and  $\beta$ -naphthylamine are heated together in *o*-dichlorobenzene solution 14-chloro-14:7-dihydrodibenzophenarsazine (XIV)

\* Schmidt states that the oxy-compound is crystallised from acetic acid. It has been known for some time (Wieland and Rheinheimer, *loc. cit.*) that under such conditions the oxy-compound is converted into the 10-acetyl-5:10-dihydrophenarsazine.

is readily obtained with elimination of ammonium chloride, and is identical with the product obtained by heating di- $\beta$ -naphthylamine with arsenious chloride under identical conditions (D.R.-P., *loc. cit.*).  $\alpha$ -Naphthylamine and arsenious chloride do not react to give a compound analogous to 10-chloro-5:10-dihydrophenarsazine; the compound 7-chloro-7:14-dihydrodibenzophenarsazine (XV) is, however, readily obtained from di- $\alpha$ -naphthylamine (D.R.-P., *loc. cit.*).

The ease of the *oo'*-substitution in diphenylamine is also well illustrated by the preparation in good yield of 10:10'-oxy-5:10-dihydrophenarsazine from diphenylamine and arsenious oxide according to the equation:

The reaction takes place readily at temperatures above  $130^\circ$  in the presence of phosphorus pentoxide.

Regarding 10-chloro-5:10-dihydrophenarsazine, one of its most striking properties is its power of forming molecular compounds. Molecular compounds with acetic acid, *s*-tetrachloroethane, chlorobenzene, *o*-dichlorobenzene, acetone, carbon tetrachloride, and arsenious chloride have been isolated.

The chlorine atom in 10-chloro-5:10-dihydrophenarsazine can be easily replaced by other atoms or groups. Some of these derivatives have been described by Wieland and Rheinheimer (*loc. cit.*). The most convenient way of preparing the corresponding bromo- and iodo-compounds—we have not succeeded in preparing the latter compound directly from diphenylamine and arsenious iodide—is by adding the corresponding concentrated halogen acid to the solution of the oxy-compound in acetic acid. The bromo- and iodo-compounds are formed almost quantitatively in a state of purity. The iodo-compound resembles the chloro-compound in showing a similar tendency to form molecular compounds with, for example, benzene and acetic acid. Wieland and Rheinheimer noticed the solubility of the oxy-compound in methyl alcohol and isolated the colourless 10-methoxy-5:10-dihydrophenarsazine. The analogous *n*-butoxy- and benzyloxy-compounds described in the present paper are also colourless and being more soluble than the methoxy-derivative are more useful in preparing other derivatives, for example, the sulpho-compound.

#### EXPERIMENTAL.

*o*-Bromophenylarsinic Acid,  $\text{C}_6\text{H}_4\text{Br}\cdot\text{AsO}(\text{OH})_2$ .—*o*-Aminophenylarsinic acid (36 g.) dissolved in hydrobromic acid (126 c.c.; *d* 1.265) and water (63 c.c.) was diazotised at  $0^\circ$  with sodium nitrite (12.6 g.)

in water (25 c.c.). The cold diazo-solution was added gradually, with stirring, to a solution of cuprous bromide at 30–40°. (The cuprous bromide solution was made by boiling 16.5 g. of copper carbonate, 165 c.c. of hydrobromic acid, and copper until the solution was clear.) The solid matter was filtered off, and extracted with hot alcohol. The alcoholic extract was evaporated to dryness, boiled with sodium carbonate solution and filtered. On acidifying with concentrated hydrochloric acid, *o*-bromophenylarsinic acid (27 g.) separated in nearly colourless crystals, m. p. 201° (decomp.). The acid crystallises from aqueous alcohol in colourless prisms, m. p. unchanged (Found: As, 26.4. Calc., As, 26.7%).

*o*-Bromophenylarsenious Oxide (I).—*o*-Bromophenylarsinic acid (14 g.) was dissolved in alcohol (14 c.c.) and concentrated hydrochloric acid (14 c.c.) containing a trace of iodine. Sulphur dioxide was passed into the boiling mixture for 30 minutes; the chloroarsine then separated as a heavy oil. After evaporation of the alcohol, the oil was extracted with benzene. The benzene solution was shaken with ammonia (14 c.c.;  $d$  0.880) and, after the mixture had cooled, the solid matter was filtered off. This was washed with water until free from ammonium chloride and dried. The benzene filtrate on evaporation gave a small quantity of the oxide. The yield was 92.5% of the theoretical. *o*-Bromophenylarsenious oxide is insoluble in most neutral solvents and melts at 234–238° (Found: As, 30.25.  $C_6H_4OBrAs$  requires As, 30.4%).

2-Bromo-6'-nitrodiphenylarsinic Acid (II).—A suspension of *o*-nitroaniline (13.8 g.) in concentrated hydrochloric acid (80 c.c.) and water (250 c.c.) was cooled to 0° and diazotised with a solution of sodium nitrite (7.6 g.) in water. The filtered solution was added with stirring to a solution, at 20°, of *o*-bromophenylarsenious oxide (27.2 g.) in 5*N*-sodium hydroxide solution (174 c.c.) diluted to 500 c.c. with water, and containing 10 c.c. of 10% aqueous copper sulphate solution to which ammonia had been added to form the soluble complex. The mixture was stirred for 2 hours, made faintly acid to litmus, and filtered. On adding concentrated hydrochloric acid to the filtrate, until Congo-paper turned blue, 2-bromo-6'-nitrodiphenylarsinic acid (19.6 g.) was precipitated. It crystallised from dilute alcohol in pale yellow prisms, m. p. 254–255° (decomp.) (Found: Br, 20.9; As, 19.2.  $C_{12}H_9O_4NBrAs$  requires As, 19.4; Br, 20.7%).

2-Bromo-6'-aminodiphenylarsinic Acid (III).—Ferrous hydroxide was precipitated from a hot solution of ferrous sulphate (50 g.) in water (150 c.c.) by adding an excess of 25% sodium hydroxide solution. To the boiling suspension a solution of 2-bromo-6'-nitrodiphenylarsinic acid (11.5 g.) in dilute sodium hydroxide was added

slowly with stirring. The mixture was then boiled for 15 minutes. After filtration from the ferric hydroxide, the colourless solution was acidified with concentrated hydrochloric acid (Congo-paper), and the precipitated amino-acid (9.8 g.) filtered. It crystallised from dilute alcohol in colourless prisms, m. p. 213—214° (decomp.) (Found: As, 20.7; Br, 22.3.  $C_{12}H_{11}O_2NBrAs$  requires As, 21.1; Br, 22.45%).

*2-Bromo-6'-methylaminodiphenylarsinic Acid (VI).*—2-Bromo-6'-aminodiphenylarsinic acid (21.4 g.) was suspended in water (150 c.c.) and mixed with 7.6 g. of methyl sulphate. After thorough mixing, a solution of sodium hydroxide (5 g.) in water (20 c.c.) was added in five portions at intervals of 30 minutes. The mixture was well shaken after each addition. The solution was then acidified with hydrochloric acid, and the crude acid filtered. This was dissolved in the minimum quantity of hot alcohol and allowed to cool; a crop of unchanged material (6.0 g.) was then obtained. The alcoholic solution was evaporated and a fraction (10.8 g.), m. p. 192—193°, obtained. This fraction on recrystallisation from alcohol melted at 193—194° (decomp.) (Found: C, 42.3; H, 3.7; Br, 21.6.  $C_{13}H_{13}O_2NBrAs$  requires C, 42.2; H, 3.5; Br, 21.6%).

*2-Bromo-6'-dimethylaminodiphenylarsinic Acid.*—A mixture of 2-bromo-6'-aminodiphenylarsinic acid (4.3 g.) and methyl sulphate (10 c.c.) was heated on the steam-bath for 3 hours. After decomposition of the resulting solution with sodium carbonate solution, the acid was precipitated by hydrochloric acid. It crystallised from aqueous alcohol in clusters of colourless needles, m. p. 220—221° (decomp.) (Found: C, 43.8; H, 4.2; Br, 21.0.  $C_{14}H_{15}O_2NBrAs$  requires C, 43.75; H, 3.9; Br, 20.8%).

*The Formation of Phenarsazinic Acid (IV) from 2-Bromo-6'-aminodiphenylarsinic Acid. Isolation of 10-Chloro-5:10-dihydrophenarsazine (V).*—A mixture of 2-bromo-6'-aminodiphenylarsinic acid (10.8 g.), dry potassium carbonate (4.4 g.), amyl alcohol (80 c.c.), and a trace of copper powder was boiled under reflux for 12 hours. The amyl alcohol was removed with steam, and the aqueous residue filtered from the copper. The solution was acidified with hydrochloric acid, and the precipitated acid (8.9 g.) filtered off, well washed with water, and dissolved in a mixture of alcohol (20 c.c.) and concentrated hydrochloric acid (20 c.c.) containing a trace of iodine. Sulphur dioxide was passed into the boiling solution for 10 minutes; yellow solid matter then began to separate. After cooling, the crude 10-chloro-5:10-dihydrophenarsazine (8.6 g.) was filtered off and extracted with carbon tetrachloride. This solution, on cooling, deposited yellow needles, melting at 191—192° alone or mixed with an authentic sample of 10-chloro-5:10-dihydrophenarsazine.

*Reduction of 2-Bromo-6'-aminodiphenylarsinic Acid. Isolation of o-Bromophenylarsenious Chloride.*—A hot solution of 2-bromo-6'-aminodiphenylarsinic acid (5 g.) in alcohol (5 c.c.), concentrated hydrochloric acid (5 c.c.), and a trace of iodine was treated with sulphur dioxide for 45 minutes. On cooling, a gummy solid separated which slowly solidified. It was filtered off, and found to be *o*-bromophenylarsenious chloride, m. p. 65–66°, the melting point being unchanged by admixture with an authentic sample. 2-Bromo-6'-methylaminodiphenylarsinic acid and 2-bromo-6'-dimethylaminodiphenylarsinic acid under similar conditions yield methylaniline and dimethylaniline, identified as acetomethylanilide and *p*-nitroso-dimethylaniline, respectively, together with *o*-bromophenylarsenious chloride.

*Attempted Preparation of N-Methylphenarsazinic Acid (VII).*—A mixture of 2-bromo-6'-methylaminodiphenylarsinic acid (11.1 g.), dry potassium carbonate (4.2 g.), amyl alcohol (80 c.c.), and a trace of copper powder was boiled under reflux for 12 hours. After steam distillation of the volatile products the aqueous residue was acidified and the crude acid (6.5 g.) filtered off. This was dissolved in alcoholic hydrochloric acid, and the boiling solution, to which a trace of iodine had been added, was saturated with sulphur dioxide for 20 minutes. A tarry precipitate was obtained which on extraction with carbon tetrachloride gave a crop of yellow needles, m. p. 191°. This substance was 10-chloro-5:10-dihydrophenarsazine, identified by comparison with an authentic sample.

The mother-liquors from the alcoholic hydrochloric acid treatment were evaporated, made alkaline with ammonia, and extracted with ether. This ethereal extract on evaporation gave a small quantity of an oil, smelling of methylaniline. On acetylation a small amount of acetomethylanilide, m. p. 101°, was obtained.

*Action of Arsenious Chloride on Methyl-diphenylamine.*—(a) Attempts to prepare 10-chloro-5-methyl-5:10-dihydrophenarsazine from methyl-diphenylamine and arsenious chloride in the presence of dichlorobenzene resulted in decomposition of the reacting substances and no crystalline matter could be isolated.

(b) Methyl-diphenylamine (36.6 g.) and arsenious chloride (36.2 g.) were heated under reflux at 200° for 2 hours. The coloured residue was cooled, extracted with light petroleum, and the solid residue (46.2 g.) worked up, following as closely as possible the details described by Wieland and Rheinheimer (*loc. cit.*). The only compound isolated (yield 10%) was 10-chloro-5:10-dihydrophenarsazine, m. p. 187–190°, identical in every respect with an authentic specimen.

*10-Chloro-5:10-dihydrophenarsazine.*—A mixture of diphenyl-

amine (17 g.), arsenious chloride (20 g.), and *o*-dichlorobenzene (40 c.c.) was boiled under reflux for 5 hours, hydrogen chloride escaping steadily. On cooling, the dark green solution deposited a mass of crystals which were filtered off, washed with petrol, dried, and crystallised from carbon tetrachloride. 10-Chloro-5:10-dihydrophenarsazine prepared in this way melts at 191—192° and is bright yellow (yield almost theoretical).

*The Reaction between Diphenylamine and Arsenious Chloride at the Ordinary Temperature.*—Arsenious chloride (8.3 g.) was dissolved in dry benzene (10 c.c.) and treated with diphenylamine (7.8 g.). Solution resulted, and after 1 hour crystallisation commenced. After 24 hours the crystalline matter was filtered off rapidly in the absence of air, washed with dry benzene, and dried on porous tile in a vacuum (Found: Cl, 35.9.  $C_{12}H_{12}NCl_4As$  requires Cl, 36.7%).

The crystals formed above, on filtration in the ordinary manner, become opaque and then consist for the most part of diphenylamine hydrochloride. The same compound is produced when diphenylamine hydrochloride and arsenious chloride are mixed in the presence of a solvent.

In an experiment using arsenious chloride (20 g.), diphenylamine (17 g.) and *s*-tetrachloroethane (40 c.c.), the mixture was kept for 16 months. No change of pressure in the flask was observed. After making alkaline with sodium carbonate solution, the volatile products were distilled in steam. The residue (3.0 g.) was converted into 10-chloro-5:10-dihydrophenarsazine by treating it in hot acetic acid solution with dry hydrogen chloride. On cooling, the chloroarsine separated in greenish-yellow needles, m. p. 189—190°.

*p*-Phenylacetylaminophenylarsinic Acid (*N*-Acetyldiphenylamine-*p*-arsinic acid) (X).—A solution of *N*-acetyl-*p*-aminodiphenylamine (22.6 g.) in dilute hydrochloric acid (25 c.c. of concentrated acid and 150 c.c. of water) was cooled to 0° and diazotised with sodium nitrite (7.4 g.) in water (20 c.c.). The diazo-solution was added gradually, with vigorous stirring, to a solution of sodium arsenite made by dissolving arsenious oxide (15 g.) in sodium carbonate solution (24 g. of anhydrous sodium carbonate in 105 c.c. of water) containing a small amount of copper sulphate. The arsenite solution was maintained at 30—35° and kept alkaline by addition of sodium hydroxide solution. After the evolution of nitrogen had ceased, the solution was filtered from tarry matter and made slightly acid to litmus. This procedure caused a further quantity of dark-coloured, tarry matter to be precipitated. After filtration, and evaporation to small bulk, the crude acid (16.5 g.), m. p. 121°, was obtained by making the solution strongly acid. The pure acid, m. p. 126° (decomp.), crystallises from water in almost colour-

less prisms containing  $1\text{H}_2\text{O}$  (Found:  $\text{H}_2\text{O}$ , 4.7; As, 21.2.  $\text{C}_{14}\text{H}_{16}\text{O}_5\text{NAs}$  requires  $\text{H}_2\text{O}$ , 5.1; As, 21.2%).

*p*-Phenylaminophenylarsinic Acid (*Diphenylamine-p-arsinic acid*) (XII).—The crude acetyl-arsinic acid (15 g.) was boiled for one hour with a mixture of concentrated hydrochloric acid (30 c.c.) and alcohol (30 c.c.). The solution turned green and the required arsenic acid was precipitated by water. The crude acid (13 g.) contained some green matter very difficult to separate. Purification was conveniently accomplished by treating a concentrated solution of the ammonium salt with magnesium sulphate solution, when the sparingly soluble magnesium salt was precipitated. Extraction of the magnesium salt with successive quantities of hot water and treatment of the solution with dilute sulphuric acid resulted in the formation of almost colourless, hair-like crystals of the arsenic acid, m. p.  $265^\circ$  (decomp.) (Found: As, 25.5.  $\text{C}_{12}\text{H}_{12}\text{O}_3\text{NAs}$  requires As, 25.6%).

*p*-Phenylacetylaminophenylarsenious Chloride (*N-Acetyldiphenylamine-p-arsenious chloride*) (XI).—A hot solution of the acetyl-arsinic acid (9 g.) in alcohol (30 c.c.) and concentrated hydrochloric acid (9 c.c.) containing a trace of iodine was saturated with sulphur dioxide. On cooling, solid matter separated, and the mother-liquors on evaporation yielded a further crop of crystals. The *arsenious chloride*, after filtration and drying, crystallised from benzene-ligroin in colourless needles, m. p.  $141^\circ$  (Found: Cl, 20.0.  $\text{C}_{14}\text{H}_{12}\text{ONCl}_2\text{As}$  requires Cl, 20.0%).

Considerable difficulty has been met with in trying to prepare the arsenious chloride from *p*-phenylaminophenylarsinic acid. Attempts at reduction analogous to those of the corresponding acetyl derivative using the crude acid were unsuccessful owing to the persistence of the green matter. An attempt at reduction in the absence of hydrochloric acid to produce the oxide, caused elimination of the arsenic and diphenylamine was obtained, identified by its melting point and the melting point of its hydrochloride. The pure acid on reduction in the presence of hydrochloric acid gave a crystalline product which was mainly diphenylamine hydrochloride. The crystals did contain a small amount of a substance containing arsenic, but not in sufficient quantity for identification.

*Action of Arsenious Chloride on Aniline.*—Aniline (51 g.) was added carefully to arsenious chloride (18 g.), and the mixture boiled gently for 72 hours. During the heating a sublimate of aniline hydrochloride and ammonium chloride formed. The product was made alkaline with sodium hydroxide solution and steam-distilled until the distillate was free from aniline and ammonia. By continued steam distillation, diphenylamine, identified by its melting point and the melting point of its hydrochloride, was obtained.

The insoluble residue in the flask was filtered, washed with water, dried at 100°, and weighed (39% of theory). The crude oxy-compound was converted into 10-chloro-5:10-dihydrophenarsazine by hydrochloric acid and acetone, and subsequent evaporation of the solution to dryness. The crude chloro-compound on crystallisation from carbon tetrachloride melted at 186—187°.

*Action of Arsenious Chloride on  $\beta$ -Naphthylamine.*—A mixture of  $\beta$ -naphthylamine (21.5 g.), arsenious chloride (30 g.), and *o*-dichlorobenzene (60 c.c.) was boiled under reflux for 18 hours. On mixing, a colourless, crystalline compound separated, which on warming dissolved. Hydrogen chloride was evolved and a white solid (ammonium chloride) collected in the condenser. The solution, on cooling, deposited a dark orange, crystalline mass. This was purified by three crystallisations from nitrobenzene and was thus obtained in yellow needles, m. p. 355° (decomp.) (Found: As, 19.3; N, 3.9.  $C_{20}H_{13}NClAs$  requires As, 19.85; N, 3.7%).

*14-Chloro-14:7-dihydrodibenzophenarsazine (XIV).*—Di- $\beta$ -naphthylamine (13.5 g.), arsenious chloride (10 g.), and *s*-tetrachloroethane (70 c.c.) were boiled under reflux for 90 minutes. After the first 30 minutes the yellow product began to separate from the boiling solution. The compound was filtered off and crystallised from nitrobenzene, separating in yellow needles, m. p. 355° (decomp.). The yield was 55% of the theoretical (Found: As, 19.6; N, 3.9.  $C_{20}H_{13}NClAs$  requires As, 19.85; N, 3.7%).

*7-Chloro-7:14-dihydrodibenzophenarsazine (XV).*—Di- $\alpha$ -naphthylamine (13.5 g.; 1 mol.) and 10 g. of arsenious chloride (1.1 mols.) were boiled in 20 c.c. of *s*-tetrachloroethane for 7 hours. Hydrogen chloride escaped rather more slowly than in the previous preparations. The product separated, on cooling, as a brown powder (11.4 g., or 60.3%).

*7-Chloro-7:14-dihydrodibenzophenarsazine* crystallises from hot nitrobenzene in minute, yellowish-brown needles, m. p. 278—279° (decomp.) (Found: As, 19.6.  $C_{20}H_{13}NClAs$  requires As, 19.85%).

*10:10'-Oxy-5:10-dihydrophenarsazine.*—A mixture of diphenylamine (15 g.), arsenious oxide (2.9 g.), and phosphorus pentoxide (3.2 g.) is heated with vigorous mechanical stirring at 160—170° for 1 hour. On cooling, a hard, black cake is obtained which is treated with sodium carbonate solution, and steam-distilled, diphenylamine (10.7 g.) passing over. The remaining oxy-compound (5 g.) is filtered off, and converted into 10-chloro-5:10-dihydrophenarsazine by dissolving it in acetone by addition of sufficient hydrochloric acid and evaporating the resulting solution to dryness. Crystallisation from carbon tetrachloride gives the pure product.

A mixture of 10:10'-oxy-5:10-dihydrophenarsazine (10 g.),

acetyl chloride (3.2 g.) and dry benzene (100 c.c.) is boiled under reflux for 6 hours, solution occurring after a few minutes' heating; on cooling, crystalline matter separates. This is filtered off and on washing with cold acetone yields crude 10-chloro-5-acetyl-5:10-dihydrophenarsazine (3.5 g.), m. p. 221–224°. By crystallisation from benzene, the pure product is readily obtained (compare Burton and Gibson, *loc. cit.*).

If 10:10'-oxy-5:10-dihydrophenarsazine (19.1 g.) is treated with benzoyl chloride (10.7 g.; 2 mols.) under similar conditions, no 10-chloro-5-benzoyl-5:10-dihydrophenarsazine is produced, but 10-chloro-5:10-dihydrophenarsazine (20.5 g.; theory, 21.2 g.), m. p. 190–191°, and benzoic anhydride (7.9 g.; theory, 8.6 g.), m. p. 41°, are obtained.

*Molecular Compounds of 10-Chloro-5:10-dihydrophenarsazine.*—When 10-chloro-5:10-dihydrophenarsazine is crystallised from the following solvents, crystals are obtained containing solvent of crystallisation. These crystals effloresce slowly in air, but heating at 110° causes rapid dissociation, leaving pure 10-chloro-5:10-dihydrophenarsazine in each case.

(a) Acetic acid	A, C <sub>2</sub> H <sub>4</sub> O <sub>2</sub>	(Loss, 18.5; calc., 17.8%)
(b) <i>s</i> -Tetrachloroethane	2A, C <sub>2</sub> H <sub>2</sub> Cl <sub>4</sub>	{ „ 23.7; „ 23.2 }
(c) Chlorobenzene	2A, C <sub>6</sub> H <sub>5</sub> Cl	{ „ 17.0; „ 16.8 }
(d) <i>o</i> -Dichlorobenzene	2A, C <sub>6</sub> H <sub>4</sub> Cl <sub>2</sub>	{ „ 21.0; „ 20.9 }
(e) Acetone	2A, C <sub>3</sub> H <sub>6</sub> O	{ „ 9.3; „ 9.5 }
(f) Carbon tetrachloride	A, CCl <sub>4</sub>	{ „ 35.6; „ 35.7 }

(A denotes NH<C<sub>6</sub>H<sub>4</sub>>AsCl).

10-Chloro-5:10-dihydrophenarsazine is extremely soluble in arsenious chloride, giving a dark green solution. A hot, concentrated solution, on cooling, deposits magnificent, scarlet scales of the compound A, AsCl<sub>3</sub> (loss, 39.3; calc., 39.7%). This is sufficiently stable to allow of filtration, but on exposure to air or washing with solvents yields the original chloro-compound.

10-Bromo-5:10-dihydrophenarsazine.—(a) A mixture of diphenylamine (8.5 g.), arsenious bromide (17.3 g.), and *o*-dichlorobenzene (20 c.c.) is boiled under reflux for 18 hours. Hydrogen bromide is liberated steadily. The crude bromo-compound (9.6 g.) that separates on cooling crystallises from toluene in greenish-yellow prisms, m. p. 217–218°.

(b) 10-Acetyl-5:10-dihydrophenarsazine (15 g.) dissolved in boiling glacial acetic acid (200 c.c.) is treated with hydrobromic acid (10 c.c.; 30%) in glacial acetic acid (25 c.c.). On cooling, 10-bromo-5:10-dihydrophenarsazine (13.3 g.) separates (Found: As, 23.3; Br, 24.8%).

10-Iodo-5:10-dihydrophenarsazine.—On treating a hot solution

of 10-acetyl-5:10-dihydrophenarsazine (4.5 g.) in glacial acetic acid (70 c.c.) with hydriodic acid (2.5 c.c.; 50%) diluted with acetic acid (10 c.c.) the pure iodo-compound (5.6 g.) separates in brownish-orange needles, m. p. 217—221° (decomp.) (Found: As, 20.1%).

10-*n*-Butoxy-5:10-dihydrophenarsazine,  $\text{NH}(\text{C}_6\text{H}_4)_2\text{As}\cdot\text{O}\cdot\text{C}_4\text{H}_9$ .—A solution of 10:10'-oxy-5:10-dihydrophenarsazine (5 g.) in *n*-butyl alcohol (50 c.c.), on cooling deposited a mass of pale yellow needles, m. p. 158—160° (Found: As, 23.7.  $\text{C}_{16}\text{H}_{18}\text{ONAs}$  requires As, 23.8%).

A boiling solution of 10:10'-oxy-5:10-dihydrophenarsazine (15 g.) in *n*-butyl alcohol (180 c.c.) is saturated with dry hydrogen sulphide for 2 hours. The compound crystallises during the reaction and after collection is recrystallised from toluene. 10:10'-Sulpho-5:10-dihydrophenarsazine crystallises in yellow needles, m. p. 256—264° (decomp.). Yield 67% of theory (Found: As, 29.1%).

10-Benzoyloxy-5:10-dihydrophenarsazine,

prepared in an analogous manner to the corresponding *n*-butyl compound, crystallises in colourless needles, m. p. 173—175° (Found: As, 21.1.  $\text{C}_{19}\text{H}_{16}\text{ONAs}$  requires As, 21.5%).

## LIX.—10-Chloro-5:10-dihydrophenarsazine and its Derivatives. Part II. The Action of Primary Chloroarsines on Diphenylamine and its Homologues.

By HAROLD BURTON and CHARLES STANLEY GIBSON.

It has been shown (preceding paper) that the reaction between arsenious chloride and diphenylamine and its homologues goes very readily either when the two substances are heated alone, or more conveniently, in the presence of a suitable solvent, dihydrophenarsazine derivatives being formed. The reaction taking place may be generally expressed ( $\text{R}_1 = \text{R} - \text{H}$ ;  $\text{R}'_1 = \text{R}' - \text{H}$ ):

It seemed desirable to investigate the application of the reaction to the case of dichloroarsines with a view to obtain dihydrophenarsazine derivatives of the type  $\text{XAs} \begin{smallmatrix} \text{R}_1 \\ \text{R}'_1 \end{smallmatrix} \text{NH}$  [ $\text{X}$  = univalent hydrocarbon or substituted hydrocarbon radical]. The most

convenient dichloroarsine was phenyldichloroarsine, easily prepared by reducing phenylarsinic acid, which in turn is readily obtainable by the Bart reaction on aniline.

When the reaction between phenyldichloroarsine and diphenylamine was carried out under the conditions employed for preparing 10-chloro-5 : 10-dihydrophenarsazine, *viz.*, with equimolecular quantities heated in the presence of *o*-dichlorobenzene, the product was not 10-phenyl-5 : 10-dihydrophenarsazine, but 10-chloro-5 : 10-dihydrophenarsazine, the substance obtained by the condensation of arsenious chloride and diphenylamine. It appeared that the reaction to produce 10-chloro-5 : 10-dihydrophenarsazine might be either (a) or (b).

It was also recognised that reaction (a) might be the final result of the following two reactions.

In a preliminary experiment two molecules of the chloroarsine and one molecule of diphenylamine were heated together in *o*-dichlorobenzene solution. A theoretical yield of 10-chloro-5 : 10-dihydrophenarsazine calculated on the quantity of diphenylamine taken was obtained, and instead of the easily recognisable diphenylchloroarsine, only phenyldichloroarsine was obtained on examining the filtrate from the solid product. Experiments using molecular proportions of the reacting substances, heated for a longer time, also gave theoretical amounts of 10-chloro-5 : 10-dihydrophenarsazine, but it was not until the reaction was carried out in the absence of solvent that we were able to collect a volatile substance, which was identified as benzene.

In view of these results, the publication of a paper by Lewis and Stiegler (*J. Amer. Chem. Soc.*, 1925, 47, 2551) containing experiments on the condensation of  $\beta$ -chlorovinylchloroarsine with diphenylamine and phenyl- $\alpha$ -naphthylamine, and the description of the condensation products "6- $\beta$ -chlorovinylphenarsazine," and "7- $\beta$ -chlorovinyl-7 : 12-dihydro- $\gamma$ -benzophenarsazine," seemed somewhat anomalous to us, especially as the melting points of the two compounds quoted (186—187° and 213°, respectively) were so near to those of 10-chloro-5 : 10-dihydrophenarsazine and 7-chloro-

7:12-dihydrobenzophenarsazine (191—192° and 219—220°, respectively), and therefore we decided to repeat our work; extend it to other diarylamines; and finally repeat Lewis and Stiegler's experiments.

We have done this and find that our initial observations are correct. The extension of the work consisted in studying the action of phenyldichloroarsine on phenyl-*p*-tolylamine, *pp'*-ditolylamine, and phenyl- $\alpha$ -naphthylamine. In each case, the reaction proceeded as with diphenylamine and instead of the *As*-phenyl derivatives we obtained the chlorodihydrophenarsazine derivative.

The compound isolated from phenyl-*p*-tolylamine, namely, 10-chloro-2-methyl-5:10-dihydrophenarsazine,\* has been synthesised from the former substance and arsenious chloride. The *N*-acetyl derivative of this compound has been prepared, and also the corresponding *phenarsazinic acids*, using the method of Burton and Gibson (J., 1924, 125, 2276). The compound obtained from *pp'*-ditolylamine is referred to in the German Patent (D.R.-P. 281049, Friedländer, "Fortschritte," 1914, XII, 843), but so far as we can discover, this substance, 10-chloro-2:8-dimethyl-5:10-dihydrophenarsazine, has not yet been described in the literature. We have prepared it from *pp'*-ditolylamine and arsenious chloride, and also obtained its *N*-acetyl derivative.

A repetition of Lewis and Stiegler's work, adhering as far as possible to their quantities and conditions, showed that the reaction between diphenylamine and  $\beta$ -chlorovinyl-dichloroarsine proceeded in a similar manner to that using phenyldichloroarsine. In the presence of *o*-dichlorobenzene a quantitative yield of 10-chloro-5:10-dihydrophenarsazine was obtained, which after crystallisation from carbon tetrachloride melted at 186—187° and did not depress the melting point of a pure specimen. Further crystallisation from the same solvent gave a pure product, m. p. 190—191°, identical with an authentic specimen. From phenyl- $\alpha$ -naphthylamine in boiling *o*-dichlorobenzene solution we isolated 7-chloro-7:12-dihydrobenzophenarsazine, also in quantitative yield. In the absence of solvent, the yields were not so good, but the products obtained were identical with those from the experiments done in *o*-dichlorobenzene. It was found necessary to crystallise the crude 10-chloro-5:10-dihydrophenarsazine twice from carbon tetrachloride before it would melt at 190—191°, and although the product from phenyl- $\alpha$ -naphthylamine was crystallised from xylene, following Lewis and Stiegler's directions, it melted three degrees low, and had to be further crystallised from toluene before it was pure. We were able

\* The nomenclature of these compounds is described in the preceding paper.

to prove the formation of vinyl chloride in these experiments by passing the hydrogen chloride and vinyl chloride evolved through a solution of bromine in carbon tetrachloride, when the colour of the bromine was discharged. That this decoloration was not due to acetylene produced by decomposition of the  $\beta$ -chlorovinyl-dichloroarsine was further demonstrated by washing the carbon tetrachloride solution with dilute sodium carbonate solution, and after subsequent drying and removal of the carbon tetrachloride, determining the boiling point of the residue. This was  $160\text{--}162^\circ$ , which is in good agreement with the b. p.,  $162.5\text{--}163^\circ$ , recorded by Biltz (*Ber.*, 1902, 35, 3526) for  $\alpha$ -bromo- $\beta$ -chlorobromoethane.\* During these experiments we were unable to isolate any compound of the type  $\text{XAs} \begin{smallmatrix} \text{R}_1 \\ \text{R}_1 \end{smallmatrix} \text{NH}$ .

#### EXPERIMENTAL.

Freshly-made phenyldichloroarsine, b. p.  $247\text{--}250^\circ/752\text{ mm.}$ , and  $\beta$ -chlorovinyl-dichloroarsine, b. p.  $93\text{--}94^\circ/24\text{ mm.}$ , were used in the following experiments. The diphenylamine and *o*-dichlorobenzene also were freshly distilled.

*Condensations of Phenyldichloroarsine with Diphenylamine and Related Compounds.*—(a) *In the presence of solvent.* In the preliminary experiments a mixture of diphenylamine (8.45 g.), phenyldichloroarsine (22.3 g.), and *o*-dichlorobenzene (20 c.c.) was heated under reflux for 8 hours. Hydrogen chloride had then ceased to be evolved. The green solution was cooled, mixed with petrol (20 c.c.), and the solid filtered off. This, after being washed with petrol (30 c.c.) and dried to constant weight at  $100^\circ$ , crystallised from benzene in yellow needles, m. p.  $189\text{--}190^\circ$ , and was identical in all respects with an authentic sample of 10-chloro-5:10-dihydrophenarsazine prepared from diphenylamine and arsenious chloride. The yield was almost theoretical.

Similar experiments using (a) phenyl-*p*-tolylamine, (b) di-*p*-tolylamine, and (c) phenyl- $\alpha$ -naphthylamine gave (a) 10-chloro-2-methyl-5:10-dihydrophenarsazine, m. p.  $199\text{--}200^\circ$  (decomp.), (b) 10-chloro-2:8-dimethyl-5:10-dihydrophenarsazine, m. p.  $261\text{--}262^\circ$ , after

\* Lewis and Stiegler, in calculating the value for the percentage of chlorine in the supposed 10- $\beta$ -chlorovinyl-5:10-dihydrophenarsazine, arrived at too high a value, the actual figure being 11.69% instead of 12.00%. Their low analytical data for a sample of pure 10-chloro-5:10-dihydrophenarsazine together with its low melting point explain, in all probability, the reason they have assigned the wrong constitution to this compound. The obvious impurity of their 7-chloro-7:12-dihydrobenzophenarsazine, the m. p. of which was  $6^\circ$  below that of a pure specimen, is, no doubt, the cause of their low analytical data.

previous decomposition, and (c) 7-chloro-7:12-dihydrobenzophenarsazine, m. p. 218—219°.

In the second series of experiments, half the quantity of phenyldichloroarsine was used and the mixture was boiled for 16 hours. The product was treated in the same manner, and a yield of 93% of the theoretical quantity of 10-chloro-5:10-dihydrophenarsazine was obtained. (The yields of the other chlorodihydrophenarsazines varied from 90—95%.)

(b) *In the absence of solvent.* These experiments consisted in heating mixtures of diphenylamine and phenyldichloroarsine, in the molecular ratio of 1:1 and 1:2, in a metal-bath, the temperature of which was raised to 230° during 30 minutes and maintained for 45 minutes. The volatile product, after being washed with dilute sodium carbonate solution and dried, boiled at 80°; it was benzene. The residue in the flask, after crystallising from boiling *o*-dichlorobenzene, was 10-chloro-5:10-dihydrophenarsazine.

10-Chloro-2-methyl-5:10-dihydrophenarsazine,

—A mixture of phenyl-*p*-tolylamine (36.6 g.), arsenious chloride (40 g.), and *o*-dichlorobenzene (80 c.c.) was boiled under reflux for 4 hours. On cooling, the chloro-compound (51 g.) separated as a mass of green crystals. On crystallisation from benzene, the substance was obtained in yellow needles, m. p. 199—200° (decomp.) (Found: Cl, 12.3.  $\text{C}_{13}\text{H}_{11}\text{NClAs}$  requires Cl, 12.2%).

10-Chloro-2:8-dimethyl-5:10-dihydrophenarsazine,

was prepared by heating together for 4 hours a mixture of di-*p*-tolylamine (32.7 g.), arsenious chloride (33.2 g.), and *o*-dichlorobenzene (133 c.c.). The crude chloro-compound (44.7 g.) crystallised from nitrobenzene in orange prisms, m. p. 261—262° with previous decomposition (compare D.R.-P., *loc. cit.*) (Found: As, 24.2.  $\text{C}_{14}\text{H}_{13}\text{NClAs}$  requires As, 24.5%).

10-Chloro-5-acetyl-2-methyl-5:10-dihydrophenarsazine was prepared by boiling a mixture of the corresponding phenarsazine (30 g.) with acetic anhydride (60 c.c.) for 3½ hours. On cooling, the *acetyl* derivative (25 g.) separated in almost colourless crystals. It separated from benzene-light petroleum in clusters of almost colourless needles, m. p. 154—155° (Found: Cl, 10.7.  $\text{C}_{15}\text{H}_{13}\text{ONClAs}$  requires Cl, 10.6%).

10-Chloro-5-acetyl-2:8-dimethyl-5:10-dihydrophenarsazine.—A suspension of the chloroarsine (10 g.) in acetic anhydride (50 c.c.) was boiled for 2 hours, when solution was complete and the colour of

the original compound had almost disappeared. After removal of half the acetic anhydride by distillation the crude acetyl compound separated in nearly colourless needles. It separated from benzene-light petroleum in colourless needles, m. p. 164—165° (Found: As, 21.4.  $C_{16}H_{15}ONClAs$  requires As, 21.6%).

*2-Methylphenarsazinic acid*,  $NH\langle\begin{smallmatrix} C_6H_3Me \\ C_6H_4 \end{smallmatrix}\rangle AsO.OH$ , separated in good yield when a mixture of the chloroarsine and chloramine-T had stood for 12 hours. It crystallised from aqueous acetic acid in colourless, fine needles which did not melt when heated but decomposed above 300° (Found: As, 25.6.  $C_{13}H_{12}O_2NAs$  requires As, 25.9%). The *sodium* salt crystallises from water in colourless, hair-like needles. The *hydrochloride* was obtained by treating a suspension of the acid in boiling alcohol with concentrated hydrochloric acid until crystalline matter began to separate. On cooling, the hydrochloride separated in colourless, small prisms, m. p. 209—211° (decomp.) (Found: Cl, 10.9.  $C_{13}H_{12}O_2NAs.HCl$  requires Cl, 10.9%).

*2:8-Dimethylphenarsazinic acid* was prepared by boiling a suspension of the chloroarsine (10 g.) in acetone (200 c.c.) with a solution of chloramine-T (18.5 g. in 185 c.c. of water) for 30 minutes. The orange colour of the original substance disappeared and colourless, crystalline matter was produced. The *acid* (6.3 g.) separated from aqueous acetic acid in colourless, glistening plates, which decomposed without melting at a high temperature (Found: As, 24.5.  $C_{14}H_{14}O_2NAs$  requires As, 24.7%). The *sodium* salt crystallises from water in colourless needles, and the *hydrochloride*, prepared as above, was obtained in colourless needles, m. p. 216° (decomp.) after previous softening (Found: As, 21.7.  $C_{14}H_{14}O_2NAs.HCl$  requires As, 22.1%).

*N-Acetyl-2:8-dimethylphenarsazinic acid*, prepared in the usual manner, separated from dilute acetic acid in colourless prisms, m. p. 240° (decomp.) (Found: As, 21.65.  $C_{15}H_{16}O_3NAs$  requires As, 21.7%).

*Condensation of  $\beta$ -Chlorovinylchloroarsine with Diphenylamine and Phenyl- $\alpha$ -naphthylamine.*—(a) *In the presence of solvent.* The mixture of diphenylamine (10.6 g.),  $\beta$ -chlorovinylchloroarsine (13.0 g.), and *o*-dichlorobenzene (25 c.c.) was boiled under reflux for 12 hours. Owing to the formation of a certain amount of tarry matter, the crude compound, isolated as in the phenylchloroarsine experiments, was extracted in a Soxhlet with carbon tetrachloride. The 10-chloro-5:10-dihydrophenarsazine obtained melted at 187° without further crystallisation, and a sample of it did not depress

the melting point of an authentic specimen. The yield was quantitative. Further crystallisation from the same solvent gave pure 10-chloro-5:10-dihydrophenarsazine, m. p. 190—191°. A similar experiment using phenyl- $\alpha$ -naphthylamine gave 7-chloro-7:12-dihydrobenzophenarsazine, m. p. 218—219°.

(b) *In the absence of solvent.* The quantities and conditions used in these experiments were the same as those described by Lewis and Stiegler. The only difference in procedure after the initial reaction was that the crude mass from the diphenylamine was extracted with carbon tetrachloride in a Soxhlet apparatus and finally crystallised from carbon tetrachloride. In this way, we obtained a specimen of pure 10-chloro-5:10-dihydrophenarsazine, m. p. 190—191° (Found: Cl, 12.8; As, 26.8%). From the phenyl- $\alpha$ -naphthylamine experiment pure 7-chloro-7:12-dihydrobenzophenarsazine was obtained, m. p. 219—220° (compare Lewis and Hamilton, *J. Amer. Chem. Soc.*, 1921, **43**, 2218) after a further crystallisation from toluene (Found: Cl, 10.9%).

# LX.—*The Molecular Configurations of Polynuclear Aromatic Compounds. Part V. The Identity of the Nitration Products derived from 2:7- and 4:5-Dinitrophenanthraquinones.*

By GEORGE HALLATT CHRISTIE and JAMES KENNER.

THE conversion of 2:7-dinitrophenanthraquinone successively into 2:4:7-trinitrophenanthraquinone and 4:6:4'-trinitrodiphenic acid,

has been already described (Christie and Kenner, *J.*, 1923, **123**, 779). At the same time, it was intimated that a similar set of reactions had been carried out in the case of the dinitro-quinone which is produced with the 2:7-isomeride by nitration of phenanthraquinone and which Schmidt and Kämpf (*Ber.*, 1903, **36**, 3745) concluded to be a 4:5-derivative (I). The new trinitro-quinone was therefore thought to be a 2:4:5-derivative (II), and so different from the above-mentioned 2:4:7-isomeride, when it was oxidised to a diphenic acid (III) from which 4:6:4':6'-tetra-nitrodiphenic acid was obtained by further nitration:

It was therefore remarkable that when the acid (III) was resolved into optically active forms by fractional crystallisation of the quinidine or, better, of the quinine salts, a very close correspondence was revealed between the physical constants of the various salts and of those derived from the 4 : 6 : 4'-trinitro-acid. This will be apparent from the following table :

	4 : 6 : 4'-Acid. 289—290°	New acid. 291°
Melting point.		
Quinine <i>d</i> -salt.	M. p. 222°; $[\alpha]_D -156.4^\circ$	M. p. 222°; $[\alpha]_D -156.1^\circ$
„ <i>l</i> -salt.	M. p. 175°; $[\alpha]_D -69.1^\circ$	M. p. 176°; $[\alpha]_D -77.5^\circ$

This agreement also extends to the original trinitro-quinones, each of which crystallises from benzene in yellow, hexagonal prisms, which melt at 209° and contain one molecular proportion of benzene of crystallisation.

In spite, therefore, of the apparently conclusive nature of the evidence in favour of the constitutional formulæ assigned to these various compounds, the possibility suggested itself that the two series might in reality be identical. This was confirmed when it was found that the melting point of the two acids was not depressed by mixing them, and that the same applied to the *quinoxaline* derivative, m. p. 307°, prepared by condensing each of the trinitro-quinones with *o*-phenylenediamine. It followed either that the orientation of the two dinitro-quinones, from which the same trinitro-quinone had been obtained, was in some respect faulty or that, in the course of nitration of these dinitro-compounds, migration of a nitro-group had occurred in one case. Whichever of these be correct, it seemed advisable if possible to determine the orientation of the trinitro-compound by an independent method.

It had previously been shown (Kenner and Stubbings, J., 1921, 119, 593) that  $\gamma$ -6 : 6'-dinitrodiphenic acid was converted by reduction into a phenanthridone derivative (IV), and it was now found that 4 : 6 : 4' : 6'-tetranitrodiphenic acid is similarly convertible

into the corresponding diamino-compound (V), of which both neutral and basic sulphates were isolated.

The trinitrodiphenic acid, however, under similar conditions yielded an amino-acid soluble both in alkali and in excess of mineral acid. Clearly this result indicates that the trinitro-acid is a 4:6:4'-derivative, derived from a 2:4:7-trinitrophenanthraquinone:

It has been pointed out (J., 1923, **123**, 780) that a 2:4:5:7-tetra-nitrophenanthraquinone could not be obtained from the trinitro-compound under very vigorous conditions of nitration. Hence it was just conceivable that the production of the same trinitro-compound from the two dinitrophenanthraquinones was due to the formation of the tetranitro-derivative in the first place, followed by elimination of a nitro-group under the conditions of experiment:

Although this would be a novel reaction, and is not observed in the case of the compound 4:6:4':6'-tetranitrodiphenic acid, it was deemed advisable to examine the behaviour of the closely related compound, 3:3'-dinitrobenzil (VI), on nitration. No difficulty was experienced in converting this into the corresponding

3:5:3':5'-tetranitrobenzil, the constitution of which was proved by its oxidation to 3:5-dinitrobenzoic acid:

### EXPERIMENTAL.

*2:4:7-Trinitrophenanthraquinone from 4:5-Dinitrophenanthraquinone.*—When the procedure described in the case of 2:7-dinitrophenanthraquinone (Christie and Kenner, *loc. cit.*, p. 783) was applied to the 4:5-isomeride, the trinitro-derivative was obtained, after crystallisation from benzene, in stout, yellow prisms, m. p. 209° (Found: loss of weight at 120°, 18.6.  $C_{14}H_5O_8N_3 \cdot C_6H_6$  requires loss, 18.5%. Found for material previously heated at 120°. N, 12.3.  $C_{14}H_5O_8N_3$  requires N, 12.25%). Solutions of the quinone (0.75 g.) and *o*-phenylenediamine (0.38 g.) in glacial acetic acid reacted at once when mixed. The precipitated quinoxaline derivative separated from benzene in clusters of colourless needles, m. p. 307° (Found: N, 16.75.  $C_{20}H_9O_8N_5$  requires N, 16.9%). An identical product was obtained from the quinone derived from 2:7-dinitrophenanthraquinone.

*4:6:4'-Trinitrodiphenic Acid from 4:5-Dinitrophenanthraquinone.*—The acid prepared from the above trinitroquinone by the usual process of oxidation with potassium dichromate and sulphuric acid was obtained first as an oil and then as a solid, m. p. 292° [Found: equiv., 188.3.  $C_{12}H_5O_6N_3(CO_2H)_2$  requires equiv., 188.5]. Solutions of the acid (4.6 g.) in alcohol (100 c.c.) and of quinine hydrate (9.2 g.) in alcohol (70 c.c.) were mixed and boiled; a salt (5.8 g.) separated on cooling. On evaporating the alcoholic liquor, an oil remained from which a second salt (5.8 g.) was obtained by treatment with dry ether.

*Quinine d-4:6:4'-trinitrodiphenate*, the less soluble of the two salts so obtained, forms colourless, octahedral prisms, m. p. 222.5° (decomp.) and free from alcohol. For a 1.25% solution in 10*N*-acetic acid,  $[\alpha]_D^{25} = -156.1^\circ$  (Found: N, 9.6.  $C_{34}H_{55}O_{14}N_7$  requires N, 9.6%).

*Quinine l-4:6:4'-trinitrodiphenate* melts at 176° (decomp.) after repeated purification by solution in alcohol and precipitation by

ether. For a 0.5% solution in chloroform,  $[\alpha]_D^{20} = -77.5^\circ$  (Found: N, 9.7.  $C_{54}H_{55}O_{14}N_7$  requires N, 9.6%).

Quinidine salts, m. p.  $228^\circ$  and  $178^\circ$ , agreeing in crystalline form with those previously described (Christie and Kenner, *loc. cit.*) were also obtained. For 0.7% solutions in chloroform, the respective observed values for  $[\alpha]_D$  were  $-189.2^\circ$  and  $+109.9^\circ$ . The poor agreement between the latter value and that previously recorded is to be attributed partly to a clerical error, which led to the value  $56.04^\circ$  being quoted in place of the correct value of  $85.55^\circ$ , and partly to the lower melting point of the salt employed on the previous occasion.

*d*-4 : 6 : 4'-Trinitrodiphenic acid, prepared from the quinine salt in the manner described in the earlier papers, was an oil which very slowly solidified to colourless prisms, m. p.  $281-282^\circ$  (decomp.). For a 3.11% solution in ether,  $[\alpha]_D = +23.47^\circ$ , and on conversion into a 1.48% solution of the sodium salt,  $[\alpha]_D = -149.0^\circ$ . For a 0.84% solution of sodium salt prepared without investigating the rotatory power of the acid,  $[\alpha]_D = -151.1^\circ$ . For a 1.36% solution of the sodium salt from the quinidine salt, m. p.  $178^\circ$ ,  $[\alpha]_D = -146.1^\circ$ , and the acid melted at  $281-282^\circ$  (decomp.).

*l*-4 : 6 : 4'-Trinitrodiphenic acid, from the quinine salt, melted and decomposed at  $280-282^\circ$ , and showed  $[\alpha]_D = -15.14^\circ$  for a 2.80% solution in ether. For a 1.05% solution of the sodium salt subsequently prepared,  $[\alpha]_D = +136.6^\circ$ . The changes in sign of rotatory power thus observed in passing from the acid to the sodium salt show that the prefixes *d*- and *l*- as used in the previous paper require to be interchanged.

Quinine salts prepared from the acid derived from 2 : 7-dinitrophenanthraquinone melted at  $222^\circ$  and  $175^\circ$ , respectively, and exhibited specific rotatory powers of  $-156.4^\circ$  (1.28% solution in 10*N*-acetic acid) and  $-69.11^\circ$  (0.63% solution in chloroform).

*Reduction of 4 : 6 : 4' : 6'-Tetranitrodiphenic Acid.*—When a solution of stannous chloride (33 g.) in hydrochloric acid (30 c.c.) was slowly added to a solution of the acid (3 g.) in glacial acetic acid (30 c.c.) and hydrochloric acid (24 c.c.), heat was evolved, a red colour was produced which slowly disappeared, and a precipitate formed. This was collected after the mixture had been boiled for an hour, and after being washed with hydrochloric acid it was dissolved in concentrated sulphuric acid. By cautious dilution with water, yellow plates were obtained which turned green when exposed to the air and light, and left no residue on ignition. They blackened, but did not melt, when heated to  $300^\circ$  (Found: N, 15.2.  $C_{14}H_{10}O_2N_4 \cdot H_2SO_4$  requires N, 15.4%). The aqueous extract obtained by warming the material with sodium carbonate

solution was shown in the usual manner to contain sulphate ions.

When a solution of the material in sulphuric acid was added to sodium acetate solution, a green precipitate was obtained which still contained sulphur after being thoroughly washed and was apparently a basic sulphate (Found: N, 17.7.  $C_{14}H_{10}O_2N_4 \cdot \frac{1}{2}H_2SO_4$  requires N, 17.8%).

*Reduction of 4:6:4'-Trinitrodiphenic Acid.*—The result of applying the procedure described above to 4:6:4'-trinitrodiphenic acid was less satisfactory than that of heating a suspension of the finely ground acid in hydrochloric acid at 100° with an amount of tin about 50% in excess of that theoretically necessary for complete reduction. By collecting the almost colourless solid portion of the product, washing it with hydrochloric acid, and cautious precipitation with water of its solution in sulphuric acid, a yellow material was obtained which turned green on exposure to air and exhibited the properties of an amino-acid [Found: N, 11.3; equiv., 120.6.  $C_{13}H_{10}ON_3(CO_2H) \cdot H_2SO_4$  requires N, 11.45%; equiv., 122.3].

*3:5:3':5'-Tetranitrobenzil.*—Dinitrobenzil (30 g.) reacted vigorously with nitric acid (150 g.;  $d$  1.5) and sulphuric acid (180 g.) when heated at 100° for 10 minutes, so that it was necessary to cool the liquid. Finally, the mixture was heated for 20 hours at 100° and then poured on to ice. The solid product consisted of 3:5-dinitrobenzoic acid (m. p. 205°, equiv. 213.1) and a neutral substance insoluble in cold sodium carbonate solution. By crystallisation from benzene, yellow needles of a tetranitrobenzil, m. p. 168°, were obtained (Found: N, 14.35.  $C_{14}H_6O_{10}N_4$  requires N, 14.35%). Its orientation was demonstrated by adding excess of hydrogen peroxide to a solution of the compound in dilute aqueous sodium hydroxide. Heat was evolved and after about  $\frac{1}{2}$  hour the dark coloration first produced had given place to a pale yellow. An excellent yield of 3:5-dinitrobenzoic acid was obtained on acidification. Tetranitrobenzil was, however, unchanged by prolonged heating with the above nitration mixture, so that it was not an intermediate product in the formation of dinitrobenzoic acid from dinitrobenzil.

The *quinoxaline* derivative of tetranitrobenzil, prepared in the usual manner by condensation in glacial acetic acid solution, formed colourless needles, m. p. 274° (Found: N, 18.4.  $C_{20}H_{10}O_8N_6$  requires N, 18.2%).

One of us (G. H. C.) wishes to make grateful acknowledgment of a grant from the Department of Scientific and Industrial Research

which enabled him to participate in this work. We are also indebted to the Research Fund Committee of the Chemical Society for a grant towards the purchase of materials.

THE UNIVERSITY, SHEFFIELD.

## LXI.—Orientation Effects in the Diphenyl Series. Part I.

By HENRY GEORGE DENNETT and EUSTACE EBENEZER TURNER.

SINCE the nitration of 4 : 4'-dihydroxydiphenyl (Kunze, *Ber.*, 1888, 21, 3331; Schultz, *ibid.*, 3530; Hirsch, *ibid.*, 1889, 22, 336) and of its diethyl ether (Hirsch, *loc. cit.*; Brady and McHugh, *J.*, 1923, 123, 2047) affords symmetrical (3 : 5'-)dinitro-derivatives, it might be supposed that 4 : 4'-dibromodiphenyl would nitrate to give 4 : 4'-dibromo-3 : 5'(or 3 : 3')-dinitrodiphenyl. Unsymmetrical nitration, however, actually occurs, with the almost quantitative formation of the 2 : 3'(2 : 5'?)-dinitro-compound. This is the first example of unsymmetrical substitution in the diphenyl series.

Whilst the nitration of *p*-tolyl ethyl ether apparently affords only the 3-nitro-derivative (Staedel, *Annalen*, 1883, 217, 162), *p*-chlorotoluene yields a mixture of approximately equal quantities of the 2- and 3-nitro-compounds (Holleman, *Proc. K. Akad. Wetensch. Amsterdam*, 1908, 11, 257).

The nitration of 4 : 4'-dibromodiphenyl was described by Fittig (*Annalen*, 1864, 132, 206) and Schultz (*ibid.*, 1874, 174, 218) as giving a dinitro-derivative, m. p. 148°, regarded by Beilstein (*Handbuch*, 4th Edn., v, 585) as probably being identical with the 2 : 2'-dinitro-compound, m. p. 138°, previously synthesised by Ullmann and Bielecki (*Ber.*, 1901, 34, 2177). The work of Fittig and Schultz has been repeated and confirmed. Reduction of their dinitro-compound afforded the diamine, m. p. 89°, described by Schultz (*loc. cit.*), but this diamine could not be caused to undergo condensations of the type to be expected of a symmetrical diamine. This appeared to show that unsymmetrical nitration had occurred. Moreover, the dinitro-derivative depressed the m. p. of the 2 : 2'-dinitro-compound obtained from 2 : 5-dibromonitrobenzene (Ullmann and Bielecki, *loc. cit.*).

4 : 4'-Dibromo-2-nitrodiphenyl, prepared from 2-nitrobenzidine, was identical with the mononitro-derivative, m. p. 124°, prepared by Lellmann's method (*Ber.*, 1882, 15, 2837) and apparently is the first product of nitration of dibromodiphenyl. When nitrated, it was converted into the dinitro-compound, m. p. 148°, which there-

fore has one nitro-group in position 2. It was then found that one bromine atom in the dinitro-compound possessed much greater reactivity than the other.

Hot, concentrated potassium hydroxide had no action on the dinitro-compound, which, however, reacted vigorously with piperidine to give a bromopiperidinodinitrodiphenyl. 4:4'-Dibromo-2-nitrodiphenyl and 4:4'-dibromo-2:2'-dinitrodiphenyl were not affected by piperidine, and it is therefore clear that the above piperidino-derivative is 4-bromo-4'-piperidino-2:3'-dinitrodiphenyl, and that the original dinitro-compound is the 2:3'-derivative.\*

In the entrance of a nitro-group into the B nucleus of dibromodiphenyl (I), the bromophenyl group A apparently has greater directive influence than the bromine atom in B, the nitro-group

entering position 2, whilst in the nitration of the mononitro-compound (II), conditions are favourable, according to the ordinary theories of substitution, for 3'-nitration in A.

It has similarly been found that the dinitro-derivative of 4:4'-dichlorodiphenyl described by Schmidt and Schultz (*Annalen*, 1881, 207, 340) is 4:4'-dichloro-2:3'-dinitrodiphenyl. It reacts with piperidine even more readily than does the corresponding dibromocompound, giving 4-chloro-4'-piperidino-2:3'-dinitrodiphenyl. The relative activation, by a nitro-group, of a chlorine and a bromine atom is a subject it is hoped to investigate later on.

The diamine referred to above is therefore 4:4'-dibromo-2:3'-diaminodiphenyl. Schultz (*loc. cit.*), by oxidising this substance, obtained what he called a bromaminobenzoic acid, m. p. 155°. This was probably a mixture of 4-bromo-2-amino- and 4-bromo-3-amino-benzoic acids, which melt respectively at 225° and 222°. Further, Strasser and Schultz (*Annalen*, 1881, 210, 194), by reducing, and thus debrominating, the diamine, obtained a base which they called  $\gamma$ -benzidine. This is evidently 2:3'-diaminodiphenyl.

A preliminary investigation has shown that the nitration of 4:4'-ditolyl affords, first, a mononitro-compound, m. p. 91–92°,

\* It might be objected that in the nitration of dibromodiphenyl, both nitro-groups could enter the same nucleus. Against this objection, however, are at least three facts: (1) the difficulty of introducing a third substituent into one nucleus of diphenyl compounds other than hydroxy- and amino-derivatives, (2) the reactivity of one bromine atom in the dinitro-compound, which, if nitration occurred twice in the same nucleus, would almost certainly be 4:4'-dibromo-2:6-dinitrodiphenyl, i.e., a compound containing no reactive bromine atom, and (3) the quantitative nature of the nitration.

and then a dinitro-compound, m. p.  $119^{\circ}$ . The latter we regard as the 2:3'-dinitro-compound. Ullmann and Frentzel (*Ber.*, 1905, 38, 726) have described the 3:3'(3:5'?)-derivative, which for present purposes has been prepared by heating 4-iodo-2-nitrotoluene with copper bronze.

The preparation of compounds containing amino-groups in the 3:3'- or 3:5'-positions in the diphenyl molecule is a matter of considerable difficulty. According to Ullmann and Frentzel (*loc. cit.*), when *m*-nitrobenzenediazonium sulphate is added, under certain conditions, to cuprous chloride and hydrochloric acid, the chief product is 3:3'(3:5'?)-dinitrodiphenyl. We have found, on the contrary, that excellent yields of *m*-chloronitrobenzene are invariably obtained (compare Emde, *Apoth. Ztg.*, 1915, 30, 293). The dinitro-compound may be obtained from *m*-iodonitrobenzene as stated by Ullmann and Bielecki (*loc. cit.*). The latter substance is only obtainable in small yields by the method of Jacobson, Fertsch, and Heubach (*Annalen*, 1898, 303, 338), but this difficulty has now been overcome.

During some experiments on the condensation of aldehydes with benzidine, we prepared from *p*-nitrobenzaldehyde a compound to which Barzilowski (*J. Russ. Phys. Chem. Soc.*, 1891, 23, 69) had assigned formula (III). We have found that this compound readily condenses with a second molecule of a keto-compound, and is therefore (IV).

#### EXPERIMENTAL.

*Nitration of 4:4'-Dibromodiphenyl.*—Nitration in glacial acetic acid by Lellmann's method (*loc. cit.*) gave a mononitro-compound, m. p.  $124^{\circ}$ . Nitration using excess of nitric acid (*d* 1.5) gave a crude dinitro-compound, m. p.  $130\text{--}135^{\circ}$ , which, after being once crystallised from benzene, melted at  $148^{\circ}$ . A small quantity of the mononitro-compound was obtained from the mother-liquors.

The dinitro-compound was not affected when boiled with very concentrated aqueous potassium hydroxide, whilst alcoholic alkali led to a black product which will be investigated in due course.

*Preparation of 4:4'-Dibromo-2-nitrodiphenyl.*—2-Nitrobenzidine sulphate was ground into a fine paste with a little water and diazotised at  $5^{\circ}$ . The solution was poured with vigorous shaking into a cold suspension of cuprous bromide in hydrobromic acid-sodium

bromide. The vigorous reaction over, the whole was heated at 100° for a short time and the gummy solid was collected and warmed with sodium hydroxide to remove phenolic substances. The yellow residue, containing considerable quantities of benzerythrene derivatives, after several crystallisations from alcohol and benzene, melted at 124°. The m. p. was not affected by admixture with the first-named nitro-compound (Found: Br, 4.5.  $C_{12}H_7O_2NBr_2$  requires Br, 4.5%).

*Nitration of 4:4'-Dibromo-2-nitrodiphenyl.*—This substance was dissolved in two parts of warm nitric acid ( $d$  1.5). On cooling, pale yellow needles separated, which, after crystallisation from benzene, melted at 148° and did not depress the m. p. of the above dinitro-compound having the same m. p.

*4-Bromo-4'-piperidino-2:3'-dinitrodiphenyl.*—The dinitro-compound, m. p. 148°, was gently warmed with a little piperidine for about a minute. An orange colour at once developed, and, on cooling, the whole set to a crystalline paste owing to the separation of piperidine hydrobromide. It was treated with water, and the orange-red solid so obtained once crystallised from alcohol; the *piperidino*-compound was then obtained in orange-red needles, m. p. 136—137° (Found: Br, 19.3.  $C_{17}H_{16}O_4N_3Br$  requires Br, 19.7%). The *piperidino*-compound was unaffected by further heating with piperidine.

4:4'-Dibromo-2-nitro- and 4:4'-dibromo-2:2'-dinitro-diphenyl were also heated for several minutes with piperidine. In both cases the compounds were recovered unchanged.

*Preparation of 4:4'-Dibromo-2:3'-diaminodiphenyl.*—The corresponding dinitro-compound was reduced with iron, water, and ferric chloride (Roberts and Turner, J., 1925, 127, 2004). The properties of the diamine agreed with those recorded in the literature. It condensed with salicylaldehyde, but not with carbon disulphide, under conditions similar to those under which benzidine readily condenses with this substance.

*Disalicylidene-4:4'-dibromo-2:3'-diaminodiphenyl* separates from benzene as a yellow, crystalline powder, m. p. 195° (Found: N, 5.1.  $C_{28}H_{18}O_2N_2Br_2$  requires N, 5.1%).

*Nitration of 4:4'-Dichlorodiphenyl.*—The dichloro-compound readily dissolved in warm nitric acid ( $d$  1.5), and, on cooling, the dinitro-compound crystallised out. After washing and drying, it was once crystallised from alcohol and then had m. p. 140°.

*4-Chloro-4'-piperidino-2:3'-dinitrodiphenyl.*—The dichloro-compound was warmed for a few seconds with piperidine, the mixture diluted, and the product filtered off, washed with water, and crystallised from alcohol; the *piperidino*-compound was then obtained in

orange needles, m. p.  $132^{\circ}$  (Found: Cl, 10.0.  $C_{17}H_{16}O_4N_3Cl$  requires Cl, 9.8%). The piperidino-compound was not affected by further heating with piperidine, which also had no effect on 4:4'-dichloro-2:2'-dinitrodiphenyl prepared from 2:5-dichloronitrobenzene by the method of Ullmann and Bielecki (*loc. cit.*).

*Preparation of Mononitro-4:4'-ditolyl.*—A solution of ditolyl in glacial acetic acid containing one equivalent of nitric acid ( $d$  1.4) was evaporated until, on cooling, yellow prisms separated. These, after crystallisation from alcohol, melted at  $91$ – $92^{\circ}$  (Found: N, 6.2.  $C_{14}H_{13}O_2N$  requires N, 6.1%). The nitro-compound is readily soluble in alcohol, acetic acid, or benzene. Ditolyl is unaffected when dissolved in cold acetic-nitric acid mixtures.

*Preparation of Dinitro-4:4'-ditolyl.*—Sufficient nitric acid ( $d$  1.5) was added to the hydrocarbon to form a clear solution, without cooling. On leaving, slender, yellow needles separated. These, after being collected, washed with water, and crystallised from alcohol, and then from glacial acetic acid, melted at  $119^{\circ}$  (Found: N, 10.6.  $C_{14}H_{12}O_4N_2$  requires N, 10.3%).

*Preparation of 3:3' (3:5')-Dinitro-4:4'-ditolyl.*—4-Iodo-2-nitrotoluene was prepared from 2-nitro-*p*-toluidine as follows: the base (30 g.) was diazotised in dilute sulphuric acid, and the product added to a cold and well-shaken solution of 45 g. of potassium iodide in 1 l. of saturated sodium acetate solution. The brown tar which separated rapidly solidified, and was crystallised from alcohol in presence of charcoal. The yield of pure 4-iodo-2-nitrotoluene was 85% of the theoretical quantity. The iodo-compound reacted normally with copper bronze. After 20 minutes' heating at  $240^{\circ}$ , the whole was heated at  $260^{\circ}$  for a few minutes, and the cooled product extracted with benzene in presence of charcoal. The benzene was evaporated, and the residue crystallised from alcohol. The dinitroditolyl thus obtained melted at  $175$ – $176^{\circ}$  and its properties agreed with those described by Ullmann and Frentzel (*loc. cit.*).

*Preparation of 3:5'-Dinitrodiphenyl.*—(a) *By the method of Ullmann and Frentzel (loc. cit.).* The exact instructions of these authors were carried out on some dozen occasions. In one or two cases, small quantities of impure dinitrodiphenyl were isolated, but in most of the experiments *m*-chloronitrobenzene was obtained in about 85% of the theoretical yield. (b) *From m-iodonitrobenzene.* The iodo-compound was prepared by the following modification of the usual method (Jacobson, Fertsch, and Heubach, *loc. cit.*). *m*-Nitroaniline (60 g.) was ground with 56 c.c. of concentrated sulphuric acid, 200 c.c. of water were added, and the whole was well ground. The suspension was diazotised at  $5^{\circ}$  with 30.6 g. of sodium nitrite in 150 c.c. of water; addition of the nitrite solution in three

portions, below the surface of the suspension, diminished the formation of the diazoamino-compound. The filtered diazo-solution was poured in small quantities into a well-shaken, boiling solution of 110 g. of potassium iodide and 230 g. of hydrated sodium acetate in 1.5 l. of water. The mixture was then cooled, extracted with carbon tetrachloride, the extract washed with sodium thiosulphate, dried, evaporated, and the residue distilled under diminished pressure. The yield of *m*-iodonitrobenzene (m. p. 38°, b. p. 145—155°/15 mm.) was 70% of the theoretical. When the iodo-compound was heated with copper bronze as described by Ullmann and Bielecki (*loc. cit.*), an average conversion into dinitrodiphenyl of 40% of the theoretical was obtained.

*Reduction of 3:5'-Dinitrodiphenyl.*—The method previously employed by Emde (*loc. cit.*) was found to be unsatisfactory; reduction with iron, water, and ferric chloride also led to small yields of diamine. This readily forms the *disalicylidene* derivative, which separates from benzene in canary-yellow leaflets, m. p. 176—177° (Found: N, 7.3.  $C_{26}H_{20}O_2N_2$  requires N, 7.1%).

*p*-Nitrobenzylidenesalicylidenebenzidine.—The product (m. p. 221—222°, Barzilowski, *loc. cit.*) of interaction of *p*-nitrobenzaldehyde (1 mol.) and benzidine (1 mol.) in hot alcoholic solution was heated under reflux with an alcoholic solution of salicylaldehyde (excess). The red colour of the suspended solid rapidly changed to yellow, and after 30 minutes' boiling the precipitate was collected and crystallised from benzene; yellow prisms, m. p. 210°, were then obtained (Found: N, 10.1.  $C_{26}H_{19}O_3N_3$  requires N, 10.0%).

*p*-Nitrobenzylideneacetylisopropylidenebenzidine.—*p*-Nitrobenzylidenebenzidine was warmed with acetylacetone, and the solution obtained was diluted with alcohol and allowed to cool; brownish-yellow, warty prisms, m. p. 185°, then separated (Found: N, 10.6.  $C_{28}H_{21}O_3N_3$  requires N, 10.9%).

The authors desire to thank the Research Fund Committee of the Chemical Society for a grant in aid of this investigation, and Mr. W. Gordon Adam, of The Gas Light and Coke Company, for a gift of benzene.

## LXII.—*The Complex Salts of $\beta\beta'\beta''$ -Triaminotriethylamine with Nickel and Palladium.*

By FREDERICK GEORGE MANN and WILLIAM JACKSON POPE.

WE have already shown (*Proc. Roy. Soc.*, 1925, **A**, 109, 444) that  $\beta\beta'\beta''$ -triaminotriethylamine may act as a tetra-acidic or a triacidic base, according as the tertiary nitrogen atom exerts or does not exert its basicity. The compound thus gives a tri- and a tetra-hydrochloride, and also two platinichlorides,

and  $2\text{N}(\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}_2)_3, 8\text{HCl}, 4\text{PtCl}_4, 20\text{H}_2\text{O}$  (II), two aurichlorides and two rhodichlorides. When, however, the base co-ordinates with metals, it acts solely as a tetramine, and two new types of complex salts were described: thus bivalent platinum of co-ordination number 4 furnishes triaminotriethylamineplatinous iodide,  $[\text{Pt tren}] \text{I}_2$  (III), whilst quadrivalent platinum of co-ordination number 6 gives dichlorotriaminotriethylamineplatonic chloride,  $[\text{Pt tren Cl}_2] \text{Cl}_2$  (IV). In these formulæ, the symbol "tren" denotes one molecule of the base.

The complex compounds which the base furnishes with nickel have now been prepared, and fall into two distinct classes. It is known that bivalent nickel may show a co-ordination number of 4 or 6, furnishing, for example, tetramminonickel sulphate (V) and hexamminonickel iodide (VI).

Triaminotriethylamine similarly gives triaminotriethylaminenickelous sulphate (VII) and tris-triaminotriethylaminebisnickelous tetraiodide (VIII): these two compounds are of the same general type as (V) and (VI) in that the metal shows a co-ordination number of 4 and 6 respectively, although in the latter class three molecules of the tetramine distributed between two atoms of nickel are required if the metal is to show a co-ordination number of 6.

Each of these two classes of complex nickel compounds possesses distinct points of interest. We have pointed out (*loc. cit.*, p. 446) that in compounds of the type of triaminotriethylamineplatinous iodide (III), it might be expected that less strain on the amine molecule would result if two molecules of the base shared two atoms of the metal, thus giving a compound of the type  $[\text{Pt}_2 \text{tren}_2] \text{I}_4$ . The same applies to triaminotriethylaminenickelous sulphate (VII), a compound which by virtue of its high solubility in water lends itself to further investigation. Molecular weight determinations

show, however, that the sulphate has the normal composition denoted by formula (VII), and that one molecule of the base can actually satisfy one atom of the metal; conductivity measurements point to the same conclusion.

With regard to the compound of co-ordination number 6, tris-triaminotriethylaminebisnickelous tetraiodide (VIII), it is difficult to see how this complex, composed of three molecules of the base arranged around the two nickel octahedra, can be other than dissymmetric; all attempts to resolve the tetraiodide, however, proved fruitless, possibly owing to the rapid racemisation of the active complex.

The base has also been co-ordinated with bivalent palladium to give triaminotriethylaminepalladious iodide, a compound precisely similar to the platinous iodide (III).

Triaminotriethylamine thus furnishes three distinct types of complex compound, one with bivalent metals of co-ordination number 4, *e.g.*, compounds (III) and (VII), and two with metals of co-ordination number 6, *e.g.*, compounds (IV) and (VIII). These are the first complex compounds to have been prepared with a tetramine; they are, moreover, the first compounds to be described in which an aliphatic tertiary nitrogen atom occupies a co-ordination position.

#### EXPERIMENTAL.

*Preparation of Triaminotriethylaminenickelous Thiocyanate and Tris-triaminotriethylaminebisnickelous Tetraiodide.*—Nickel succinimide,  $[\text{Ni}(\text{N}:\text{C}_2\text{O}_2:\text{C}_2\text{H}_4)_2\cdot 2\text{H}_2\text{O}]\cdot 6\text{H}_2\text{O}$  (Tschugaeff, *Ber.*, 1906, 39, 3197) forms an excellent starting point for the preparation of the co-ordinated derivatives of the metal, since the succinimide residues are easily replaced by aliphatic amines. A mixture of triaminotriethylamine trihydrochloride (32.5 g.) and 33% aqueous caustic soda solution (40.0 c.c.) is therefore warmed on the water-bath until sodium chloride alone remains undissolved. The mixture is poured into a hot solution of nickel succinimide (25.0 g.) in alcohol (750 c.c.). The green solution changes rapidly to blue and is boiled gently for 30 minutes. It is cooled, the precipitated sodium chloride filtered off, and the solution then evaporated gently on the water-bath with the occasional addition of water until it is free from alcohol and of about 60 c.c. in volume. The solution, now of a deep blue, contains a mixture of the two complex ions  $[\text{Ni tren}]^{++}$  and  $[\text{Ni}_2\text{tren}_2]^{++++}$ ; these can be isolated readily as the thiocyanate and tetraiodide, respectively. If the solution is poured into a warm strong solution of potassium thiocyanate, the thiocyanate separates as a pale blue powder or deep blue crystals according to the concentration of the nickel solution; if the original solution is poured into hot strong

potassium iodide, the tetraiodide separates as a reddish-violet powder or deep violet crystals. These two compounds and their derivatives will be described in turn.

*Triaminotriethylaminenickelous thiocyanate*,  $[\text{Ni tren}](\text{SCN})_2$ . The thiocyanate crystallises with great facility from hot aqueous solution in long, very beautiful, deep blue prisms, and two such recrystallisations of the crude product obtained by precipitation with potassium thiocyanate furnish the pure thiocyanate. The latter darkens in colour at  $260^\circ$  and melts with decomposition at  $285^\circ$ ; it is soluble in hot, but almost insoluble in cold water [Found : C, 30.1; H, 5.6; N, 26.3; ionised (SCN), 35.95.  $\text{C}_8\text{H}_{18}\text{N}_6\text{S}_2\text{Ni}$  requires C, 29.9; H, 5.65; N, 26.2; 2(SCN), 36.2%]. Very rarely the thiocyanate

crystallises in long, narrow, and very thin plates: this form is of the same colour as the prismatic variety, and differs from it apparently only in crystalline habit.

Mr. J. W. Notman of Clare College, working under the direction of Mr. A. Hutchinson, F.R.S., has furnished the following report:

"*Triaminotriethylaminenickelous thiocyanate*. System, orthorhombic. Class, bipyramidal.  $a : b : c = 0.736 : 1 : 1.167$ . The substance occurs in fairly well-developed crystals, of elongated prismatic habit, of which four were measured.

Forms present:  $B \{010\}$ ,  $m \{110\}$ ,  $l \{120\}$  observed on one crystal only,  $e \{011\}$ ,  $f \{012\}$ .

Angles	$mm_s$		Meas.	Calc.
	$110 : 1\bar{1}0$	=	$72^\circ 42'$	—
	$Bm$	$010 : 110$	= $53 \ 33$	$53^\circ 39'$
	$Bc$	$010 : 011$	= $40 \ 35$	—
	$ef$	$011 : 012$	= $19 \ 9$	$19 \ 9$
	$ff'$	$012 : 012$	= $60 \ 52$	$60 \ 32$

The crystals were deep blue in colour and, being very opaque, did not lend themselves to optical examination. Some exceedingly thin plates obtained in the case of one preparation enabled straight extinction to be determined."

Both the nickel complexes recorded in this paper are very sensitive to acids, and the addition of hydrochloric acid immediately converts the deep blue of the complex into the pale green of the normal nickel salt. If a warm solution of the thiocyanate is treated with chloroplatinic acid solution, the normal platinichloride (II) of the base is therefore precipitated: if, however, a solution of sodium platinichloride is used, *triaminotriethylaminenickelous platinic tetra-thiocyanate*,  $[\text{Ni tren}]\text{PtCl}_4(\text{SCN})_2$ , is precipitated as a russet-brown powder, insoluble in water: it shrinks at  $211\text{--}213^\circ$ ,

but does not melt below 280° (Found: C, 14.9; H, 2.8; N, 12.8.  $C_8H_{18}N_6Cl_4S_2NiPt$  requires C, 14.6; H, 2.8; N, 12.8%).

*Triaminotriethylaminenickelous Sulphate*,  $[Ni\ tren]SO_4 \cdot 7H_2O$ .—Hot aqueous solutions of the thiocyanate (6.0 g.) and silver sulphate (5.82 g.) were mixed, and the product, after gently boiling for 15 minutes, was filtered and evaporated down to small bulk on the water-bath. The concentrated solution on cooling deposited deep blue crystals; these were recrystallised from a little hot water, filtered, and dried in air. This sulphate, like normal nickel sulphate, gives a series of hydrates. The product obtained as above is the *heptahydrate* (Found:  $SO_4$ , 22.7;  $H_2O$ , 29.4.  $C_8H_{32}O_{11}N_4SNi$  requires  $SO_4$ , 22.5;  $7H_2O$ , 29.5%). The heptahydrate when placed over calcium chloride for 24 hours gives the *dihydrate* as a fine red-dish-blue powder (Found: C, 21.3; H, 6.6;  $SO_4$ , 28.4.  $C_8H_{22}O_6N_4SNi$  requires C, 21.4; H, 6.55;  $SO_4$ , 28.5%). The dihydrate on prolonged exposure to calcium chloride, or when heated in a vacuum at 100°, gives the *anhydrous sulphate* as a pale-blue powder, which does not melt below 300° (Found:  $SO_4$ , 32.25.  $C_8H_{18}O_4N_4SNi$  requires  $SO_4$ , 31.9%).

If the anhydrous sulphate has the formula  $[Ni\ tren]SO_4$ , the molecular weight is 300.9, and the "apparent" molecular weight in dilute aqueous solution (if ionisation is complete) is 150.4. If, however, it has the formula  $[Ni_2tren_2](SO_4)_2$ , the molecular weight is 601.8, and the "apparent" molecular weight 200.6. The results actually obtained by the cryoscopic method are as follows, *c* being the concentration of the anhydrous sulphate expressed as g. in 100 g. of water:

<i>c</i> .....	0.422	1.32	1.70	3.23
"Apparent" mol. wt. ....	160 (157*)	173	180	218

\* Calculated value, correct to only two significant figures.

These results furnish strong evidence that the sulphate has the simple formula  $[Ni\ tren]SO_4$ , and that the "apparent" molecular weight approaches to 150 at great dilution, and increases with increasing concentration as the degree of ionisation falls. If the compound possessed the double formula, it could not show an apparent molecular weight of less than 200. This conclusion is confirmed by the close correspondence between the equivalent conductivities of normal nickelous sulphate and triaminotriethylaminenickelous sulphate at 25°.

Vol. (litres) containing 1 g. equiv. of sulphate .....	128	256	512	1024
Equiv. cond. { $NiSO_4$ .....	88.2	98.9	109.3	117.4
{ $[Ni\ tren]SO_4$ .....	85.9	96.7	106.0	119.2

The values for nickel sulphate are those given by Franke (*Z. physikal. Chem.*, 1895, **16**, 472), those for the tetramine derivative have been determined by Mr. A. F. H. Ward of J  sus College and Mr. L. F. S. Ward of Trinity College, to whom the authors' thanks are due.

*Tristriaminotriethylaminebisnickelous Tetraiodide,*

—The crude reddish-violet iodide obtained by precipitation with potassium iodide in the original preparation is recrystallised three times from hot water, and so obtained in heavy, deep violet crystals : if the hot aqueous solution is too concentrated or is chilled too rapidly, the tetraiodide separates as an oil which subsequently solidifies (Found : C, 18.9; H, 5.4; I, 45.1, 45.1, 45.2; Ni, 10.4, 10.3;  $\text{H}_2\text{O}$ , 5.5.  $\text{C}_{36}\text{H}_{122}\text{O}_7\text{N}_{24}\text{I}_8\text{Ni}_4$  requires C, 19.2; H, 5.5; I, 45.1; Ni, 10.4;  $\text{H}_2\text{O}$ , 5.6%). On one occasion when a small quantity of the iodide was rapidly recrystallised from a little hot water, the *dihydrate* separated (Found : C,\* 19.5, 19.6; H, 5.2, 5.2; N, 15.15; I, 46.2, 46.0.  $\text{C}_{18}\text{H}_{58}\text{O}_2\text{N}_{12}\text{I}_4\text{Ni}_2$  requires C, 19.6; H, 5.3; N, 15.3; I, 46.2%). The anhydrous tetraiodide, obtained by heating either of the above hydrates in a vacuum at  $110^\circ$ , is a pale violet powder, m. p.  $307\text{--}309^\circ$  (decomp.) (Found : I, 47.4.  $\text{C}_{18}\text{H}_{54}\text{N}_{12}\text{I}_4\text{Ni}_2$  requires I, 47.6%).

If, after the crude tetraiodide has been precipitated in the original preparation, the filtrate is treated with saturated potassium thiocyanate solution, triaminotriethylaminebisnickelous thiocyanate separates in fair yield and after two recrystallisations is pure; both complexes can thus be isolated from the same preparation.

The *tetrabromide*,  $[\text{Ni}_2\text{tren}_3]\text{Br}_4$ , can be obtained in small yield by treating the final solution in the original preparation with strong sodium bromide solution, or in better yield by treating a saturated solution of the tetracamphorsulphonate described later with sodium bromide. It is obtained on recrystallisation as a pale reddish-blue, anhydrous powder, which does not melt below  $290^\circ$  (Found : H, 6.1; Br, 36.4, 36.7; Ni, 13.6.  $\text{C}_{18}\text{H}_{54}\text{N}_{12}\text{Br}_4\text{Ni}_2$  requires H, 6.2; Br, 36.5; Ni, 13.4%).

*Attempted Resolution of the Tristriaminotriethylaminebisnickelous Complex,  $[\text{Ni}_2\text{tren}_3]^{++++}$ .*—The *tetra-d-  -bromocamphor-  -sulphonate*,  $[\text{Ni}_2\text{tren}_3](\text{C}_{10}\text{H}_{14}\text{O}_4\text{BrS})_4$ . Solutions of 16.0 g. of the tetraiodide ( $3\frac{1}{2}\text{H}_2\text{O}$ ) and 23.56 g. of silver *d-  -bromocamphor-  -sulphonate*, each in 75 c.c. of hot water, were mixed and the product, after gentle

\* Throughout this paper, repeated analytical results refer to analyses of different preparations of the compound, and not merely to repeated analyses of the same preparation : the figures given for this dihydrate are the only exception.

boiling, was filtered and evaporated until crystals appeared on the surface. The solution was now cooled and filtered, and the crystalline residue three times recrystallised from water. The anhydrous *tetra-d-bromocamphorsulphonate* was thus obtained as a pale violet, crystalline powder, which shrinks at  $180^\circ$  and melts with decomposition at  $183\text{--}185^\circ$  (Found: H, \* 6.2; Br, 17.8; S, 7.05; Ni, 6.5.  $\text{C}_{58}\text{H}_{110}\text{O}_{16}\text{N}_{12}\text{Br}_4\text{S}_4\text{Ni}_2$  requires H, 6.2; Br, 17.8; S, 7.1; Ni, 6.5%).

The tetrabromocamphorsulphonate is so slightly soluble in water that it could not be reconverted by double decomposition into the bromide or iodide. The hot aqueous solution was therefore added carefully to a hot dilute solution of sodium picrate, and the *tetrapicrate*,  $[\text{Ni}_2\text{tren}_3](\text{C}_6\text{H}_2\text{O}_7\text{N}_3)_4 \cdot 3\text{H}_2\text{O}$ , precipitated as a fine, dark yellow powder, which when filtered, washed with water and alcohol, and air-dried melted with decomposition at  $205\text{--}206^\circ$  (Found: C, 33.25; H, 4.5; N, 22.2.  $\text{C}_{42}\text{H}_{68}\text{O}_{31}\text{N}_{24}\text{Ni}_2$  requires C, 33.1; H, 4.5; N, 22.1%).

This tetrapicrate was found to be identical in composition and melting point with that obtained directly from the tetraiodide; it is only very slightly soluble in boiling water and insoluble in all ordinary organic solvents except formamide. No rotation could be detected in a 0.5% solution of the picrate in formamide in a 2-dcm. tube: stronger solutions could not be used owing to the high absorption of light.

The *tetra-d-camphor- $\beta$ -sulphonate*,  $[\text{Ni}_2\text{tren}_3](\text{C}_{10}\text{H}_{15}\text{O}_4\text{S})_4$ . Solutions of the tetraiodide (19.0 g.) and silver *d*-camphor- $\beta$ -sulphonate (22.8 g.), each in warm water (80 c.c.), were mixed, and the product after gentle boiling was filtered and then evaporated until crystals appeared in the solution. The latter was cooled and filtered, and the crystallised product three times recrystallised from warm water. The *tetra-d-camphorsulphonate* was thus obtained as a reddish-violet, crystalline powder, which shrinks at  $230^\circ$  and melts at  $233\text{--}235^\circ$ : it is appreciably more soluble in water than the corresponding bromocamphorsulphonate (Found: H, 7.8; S, 8.9; Ni, 7.95.  $\text{C}_{58}\text{H}_{114}\text{O}_{16}\text{N}_{12}\text{S}_4\text{Ni}_2$  requires H, 7.8; S, 8.7; Ni, 7.9%). A warm solution of the camphorsulphonate was mixed with that of potassium iodide, and the crystals which separated on cooling were rapidly recrystallised from a little hot water, the pure tetraiodide being thus obtained (Found: I, 45.1%). A 2% aqueous solution of this tetraiodide in a 4-dcm. tube gave no perceptible rotation.

Attempts to prepare a crystalline tartrate of the complex failed, only syrupy solutions being obtained.

\* All the camphor derivatives (and certain others) recorded in this paper gave low and irregular values for carbon, but satisfactory values for hydrogen.

*Triaminotriethylaminenickelous d-bromocamphorsulphonate,*

Attempts were also made to prepare the above tetra-*d*-bromocamphor- $\pi$ -sulphonate by double decomposition of the tetraiodide with ammonium *d*-bromocamphorsulphonate. It was found, however, that when solutions of the tetraiodide (4 g.) and an excess of the ammonium sulphonate (6 g.), each in warm water (20 c.c.), were mixed, and the product warmed on the water-bath, ammonia was evolved, and crystals soon appeared on the surface. This product was twice recrystallised from warm water, and finally obtained as beautiful, bluish-violet, crystalline plates. These on analysis proved to be *triaminotriethylaminenickelous d-bromocamphorsulphonate* (Found: Br, 18.6; S, 7.5; Ni, 6.65;  $\text{H}_2\text{O}$ , 4.2.  $\text{C}_{26}\text{H}_{50}\text{O}_{10}\text{N}_4\text{Br}_2\text{S}_2\text{Ni}$  requires Br, 18.55; S, 7.4; Ni, 6.8;  $2\text{H}_2\text{O}$ , 4.2%). Heating in a vacuum at  $110^\circ$  gives the pale blue, anhydrous product, m. p.  $263\text{--}266^\circ$  (decomp.). The identity of this compound was further confirmed by treating its warm aqueous solution with potassium thiocyanate solution, when triaminotriethylaminenickelous thiocyanate separated, and when once recrystallised was pure (Found: N, 25.85%). This degradation of the nickel complex of co-ordination number 6 to that of co-ordination number 4 by the action of an ammonium salt was found to be general, and to follow presumably the equation  $[\text{Ni}_2\text{tren}_3]\text{X}_4 + 4\text{NH}_4\text{X}' = 2[\text{Ni tren}]\text{X}_2 + \text{tren } 4\text{HX}' + 4\text{NH}_3$ . It is noteworthy that the third molecule of the tetramine in the higher complex is evicted but not replaced by the ammonia under these conditions, and all attempts made to prepare compounds having the complex  $[\text{Ni tren}(\text{NH}_3)_2]^{++}$  failed. In the particular case of the *d*-bromocamphorsulphonate described above, the colours of the dihydrate (bluish-violet) and the anhydrous product (pale blue) are characteristic of nickel complexes having co-ordination numbers of 6 and 4 respectively, and therefore the dihydrate has probably the composition

*Triaminotriethylaminepalladious Iodide*,  $[\text{Pd tren}]\text{I}_2$ .—A warm solution of triaminotriethylamine trihydrochloride (5.4 g.) in 33% aqueous caustic soda solution (7.4 c.c.) is added to a solution of palladium dichloride (3.0 g.) in hot water (70 c.c.). An amorphous, yellow precipitate at once appears, but redissolves when the solution is heated on the water-bath. After heating for 2 hours, the solution is evaporated to small bulk, filtered, and mixed with warm strong potassium iodide solution. The cream-coloured precipitate is filtered off, and recrystallised from much hot water, in which the iodide is only moderately soluble. The *triaminotriethylaminenickelous iodide* is thus obtained as a fine, cream-coloured powder,

which after drying over sulphuric acid darkens in colour at  $220^{\circ}$  and melts at  $224-226^{\circ}$  (decomp.) (Found: C, 14.1; H, 3.9; I, 49.6; Pd, 20.9.  $C_6H_{18}N_4I_2Pd$  requires C, 14.2; H, 3.6; I, 50.1; Pd, 21.1%).

If instead of adding potassium iodide to the above solution, the latter is chilled, made just acid with hydrochloric acid, and treated with an excess of dilute palladium dichloride solution, a fine dark brown precipitate separates. The latter redissolves if the solution is warmed, and on filtering and cooling, long, chocolate-coloured needles separate. These crystals decompose largely if an attempt is made to recrystallise them from boiling water, and their identity is therefore uncertain; they would appear to be *triaminotriethylamine-palladious palladiochloride*,  $[Pd\ tren]PdCl_6 \cdot H_2O$ , and owe their formation presumably to partial atmospheric oxidation of the palladious chloride solution (Found: C, 12.3; H, 3.8; Cl, 35.3; Pd, 35.7.  $C_6H_{20}ON_4Cl_6Pd_2$  requires C, 12.2; H, 3.4; Cl, 36.0; Pd, 36.15%).

CAMBRIDGE.

[Received, December 16th, 1925.]

### LXIII.— $\gamma\gamma'\gamma''$ -Triaminotripropylamine and its Complex Compounds with Nickel.

By FREDERICK GEORGE MANN and WILLIAM JACKSON POPE.

THE preparation of  $\gamma\gamma'\gamma''$ -triaminotripropylamine is similar to that of  $\beta\beta'\beta''$ -triaminotriethylamine, for molten phthal- $\gamma$ -bromopropylimide on treatment with gaseous ammonia gives  $\gamma\gamma'\gamma''$ -triphthalimidotripropylamine hydrobromide, which on hydrolysis furnishes the required base. Whereas, however, the tertiary nitrogen atom in triaminotriethylamine is so feebly basic that the amine may act as a tri- or a tetra-acidic base, that in triaminotripropylamine, by virtue of its greater distance from the primary amine groups, is strongly basic, and the amine therefore always acts as a tetra-acidic base. The strongly basic character of the tertiary amine group in triaminotripropylamine causes the synthesis to follow a rather different course from that of the corresponding ethyl base. Ammonia reacts with phthal- $\beta$ -bromoethylimide to give triphthalimidotriethylamine, mixed with about 12% of the hydrobromide of this base: phthal- $\gamma$ -bromopropylimide, however, gives solely triphthalimidotripropylamine hydrobromide, and none of the free base. The hydrobromide, moreover, is largely contaminated with various amorphous by-products, and the yield of the triphthalimido-compound is therefore low.

It has been shown (preceding paper) that nickel succinimide on treatment with triaminotriethylamine gives a mixture of two com-

plex ions, the bivalent triaminotriethylaminenickelous ion,  $[\text{Ni tren}]^{++}$ , in which the metal shows a co-ordination number of 4, and the quadrivalent tristriaminotriethylaminebisnickelous ion,  $[\text{Ni}_2 \text{tren}_3]^{++++}$ , in which the metal has a co-ordination number of 6. Nickel succinimide on treatment with triaminotripropylamine gives, however, one complex of the first type only, and the triaminotripropylamine-nickelous ion,  $[\text{Ni trpn}]^{++}$ , in which the metal shows a co-ordination number of 4, can be precipitated as the thiocyanate. The symbol "trpn" is here used to denote one molecule of the tetramine. This complex ion is less stable and less strongly electropositive than the corresponding ethyl complex ion; the thiocyanate undergoes slight decomposition even on recrystallisation from hot water, whilst precipitation with potassium iodide in the original preparation furnishes the hydroxy-iodide of the above complex. The normal iodide is prepared by the double decomposition of some far more stable salt such as the nitrate.

No complex compound of triaminotripropylamine with nickel or with platinum in which the metal showed a co-ordination number of 6 could be isolated. It would seem, therefore, that the very well defined dichlorotriaminotriethylamineplatinic chloride,

has no stable propyl homologue.

#### EXPERIMENTAL.

##### *Triphthalimidotripropylamine Hydrobromide,*

—A stream of dry ammonia gas is passed through molten phthal- $\gamma$ -bromopropylimide at  $150^\circ$  until the product becomes too viscous to allow further passage of the gas, the reaction being about twice as rapid as that with phthal- $\beta$ -bromoethylimide under like conditions. The cold pale-yellow product (with containing tube) is pulverised, and twice extracted with boiling alcohol: the residue is washed with water, and then recrystallised from hot acetic acid. The solution, when filtered and cooled, deposits  $\gamma\gamma'\gamma''$ -triphthalimidotripropylamine hydrobromide with one molecule of acetic acid of crystallisation. This product, when washed with acetic acid and ether and dried in the air, is pure; on heating, it liberates acetic acid at  $100$ – $105^\circ$ , and finally melts at  $243$ – $244^\circ$ , i.e., at the melting point of the hydrobromide itself (Found: C, 58.5; H, 5.0; Br, 11.4.  $\text{C}_{35}\text{H}_{35}\text{O}_8\text{N}_4\text{Br}$  requires C, 58.4; H, 4.9; Br, 11.1%). The hydrobromide itself can be obtained by heating the above product in a vacuum at  $100^\circ$ , or by crystallisation from a large volume of very dilute hydrobromic acid, from which the

hydrobromide separates in colourless needles, m. p. 243—245° (Found : Br, 12.1.  $C_{33}H_{31}O_6N_4Br$  requires Br, 12.1%).

*Triphthalimidotripropylamine*,  $(C_6H_4 \cdot C_2O_2 \cdot N \cdot C_3H_7)_3N$ .—The hydrobromide with acetic acid of crystallisation (2 g.) is dissolved in boiling water (450 c.c.), and to the clear solution is added a slight excess of *N*-sodium hydroxide (6.0 c.c.). A white precipitate of *triphthalimidotripropylamine* immediately separates, and when filtered, washed with boiling water, and twice recrystallised from alcohol, is obtained in fine needles, m. p. 150—151° (Found : C, 68.8; H, 5.2.  $C_{33}H_{30}O_6N_4$  requires C, 68.5; H, 5.2%).

*γ'γ''-Triaminotripropylamine Tetrahydrochloride*,

—Triphthalimidotripropylamine hydrobromide with acetic acid of crystallisation (10 g.) and hydrochloric acid (300 c.c., 1:1 by volume) are boiled under reflux. The solution becomes clear in about 4 hours, and after 7 hours is chilled, the phthalic acid separated, and the filtrate evaporated to small bulk. The tetrahydrochloride is so soluble in water that it cannot be crystallised, and prolonged evaporation of its solution merely gives a syrup: the concentrated solution is therefore poured into alcohol, and the heavy syrup which separates, solidifies on standing and stirring to a crystalline mass of the tetrahydrochloride, which is filtered off and washed with alcohol. The *tetrahydrochloride* is thus obtained as slightly deliquescent, white crystals which melt with foaming at 227—229°; the water of crystallisation is not liberated on heating in a vacuum at 100° (Found : C, 31.1; H, 8.2; Cl, 41.3, 41.7.  $C_{18}H_{58}ON_8Cl_8$  requires C, 31.5; H, 8.45; Cl, 41.3%).

*Triaminotripropylamine platinichloride*,

is prepared in the usual way, and when recrystallised from a little water separates in orange-coloured needles (Found : C, 10.3; H, 3.2; Pt, 36.7;  $H_2O$ , 4.9.  $C_9H_{34}O_3N_4Cl_{12}Pt_2$  requires C, 10.2; H, 3.2; Pt, 36.8;  $3H_2O$ , 5.1%). The anhydrous material darkens at 250° and melts with decomposition at 257—258°.

*Triaminotripropylamine aurichloride*,

separates when concentrated solutions of the tetrahydrochloride and of potassium aurichloride are mixed. It is filtered, washed with water, and dried without recrystallisation; the orange-yellow needles, m. p. 191—192° (decomp.), are even more soluble in alcohol and acetone than in water (Found : C, 6.9; H, 2.0; Au, 49.4, 49.5.  $C_9H_{34}O_3N_4Cl_{12}Au_4$  requires C, 6.75; H, 2.1; Au, 49.2%).

*Triaminotripropylamine picrate*,  $N(C_3H_7 \cdot NH_2)_3, 4C_6H_4O_7N_3 \cdot H_2O$ , is almost insoluble in the usual liquids, but can be recrystallised

from boiling water, one litre of which dissolves about 1 g. of the picrate. The latter separates in pale yellow needles which soften at 190° and melt with decomposition at 222° (Found: C, 35.2; H, 3.5.  $C_{33}H_{38}O_{26}N_{16}$  requires C, 35.3; H, 3.4%).

*Tribenzoyltriaminotripropylamine*,  $N(C_6H_5NHCO\cdot C_6H_5)_3$ , prepared in the usual way, is obtained after three recrystallisations from anhydrous acetone as fine, white crystals, m. p. 129—131° (Found: C, 72.1; H, 7.2.  $C_{30}H_{36}O_3N_4$  requires C, 71.9; H, 7.25%).

*The Co-ordination Derivatives of Triaminotripropylamine.*

*Triaminotripropylaminenickelous thiocyanate*,  $[Ni\ trpn](SCN)_2$ .—The tetrahydrochloride of the base (12.0 g.) is warmed with 33% aqueous caustic soda solution (16.0 c.c.) until sodium chloride alone remains undissolved: the mixture is then added to a hot solution of nickel succinimide (8.5 g.) in alcohol (250 c.c.). The colour of the solution changes rapidly from pale green to blue. The solution is now treated precisely as in the preparation of the corresponding ethyl derivative (p. 483), and the concentrated aqueous solution is filtered directly into a cold strong solution of potassium thiocyanate. The fine precipitate is filtered off and twice recrystallised from hot water, from which the *triaminotripropylaminenickelous thiocyanate* separates on rapid cooling in pale lilac-blue, crystalline leaflets, and on slow cooling in long needles of the same colour. The difference between these two forms, as in the case of the corresponding ethyl derivative, is apparently solely one of crystalline habit (Found: C, 36.6; H, 6.55; Ni, 16.2.  $C_{11}H_{24}N_6S_2Ni$  requires C, 36.4; H, 6.7; Ni, 16.2%). The thiocyanate melts at 260—261° with decomposition; it is far less stable than the corresponding ethyl compound, and when recrystallised from hot water always leaves behind on the filter a small quantity of an amorphous green product, presumably nickel hydroxide.

*Triaminotripropylaminenickelous Iodide*,  $[Ni\ trpn]I_2\cdot 1\frac{1}{2}H_2O$ .—The thiocyanate in hot aqueous solution is treated with a solution of the calculated quantity of silver nitrate, and the product, after filtering, evaporated to small bulk. The cold concentrated solution is added to a cold saturated potassium iodide solution, and the crystalline precipitate filtered off and washed with a little water, alcohol, and ether. The *iodide* is thus obtained as a fine, apple-green, crystalline powder (Found: I, 48.05; Ni, 11.0.  $C_{13}H_{54}O_3N_8I_4Ni_2$  requires I, 48.1; Ni, 11.1%).

*Triaminotripropylaminenickelous Hydroxyiodide*,

—If the warm concentrated aqueous solution obtained by treating nickel succinimide with the amine is mixed with about twice its

volume of hot strong potassium iodide solution, fine, sea-green, crystalline leaflets rapidly appear. These crystals consist of the above *hydroxyiodide* combined with potassium iodide, and have the composition  $2[\text{Ni trpn}]\text{I}(\text{OH})\cdot\text{KI}\cdot 2\text{H}_2\text{O}$ . This compound is decomposed, however, even by cold water, and the preparation of the pure material is therefore almost impossible: slight dissociation occurs when the crystals are washed even with a little alcohol to free them from mother-liquor, and various preparations always give in consequence a low iodine and high carbon value (Found: C, 22.7; H, 5.3; N, 11.0; I, 37.7; Ni, 11.5.  $\text{C}_{18}\text{H}_{54}\text{O}_4\text{N}_8\text{I}_3\text{NiK}$  requires C, 22.0; H, 5.5; N, 11.4; I, 38.7; Ni, 11.9%).

If the mother-liquor after the separation of these crystals is treated further with potassium thiocyanate solution, a small precipitate of triaminotripropylaminenickelous thiocyanate is obtained.

When the green crystals of the potassium iodide addition product are dissolved in warm water, a deep blue solution is at once obtained, and, on cooling, deep blue crystals of *triaminotripropylaminenickelous hydroxyiodide*,  $[\text{Ni trpn}]\text{I}(\text{OH})\cdot 2\text{H}_2\text{O}$ , separate. The hydroxyiodide is quite stable in the presence of water, and can be recrystallised repeatedly from boiling water without apparent change (Found: C, 25.5; H, 6.3; N, 13.0; I, 29.5; Ni, 13.5.  $\text{C}_9\text{H}_{25}\text{O}_3\text{N}_4\text{INi}$  requires C, 25.3; H, 6.85; N, 13.1; I, 29.7; Ni, 13.75%). This compound when heated in a vacuum at  $100^\circ$  readily loses its water of crystallisation, but at the same time undergoes slight further hydrolysis, and the anhydrous product is therefore never quite pure. When the hydroxyiodide in strong aqueous solution is treated with strong potassium iodide solution, the sea-green crystals of the above potassium iodide addition product once again separate, and when recrystallised from water again furnish the pure deep blue hydroxyiodide. Moreover, when the hydroxyiodide in aqueous solution is treated with potassium thiocyanate solution, a rapid precipitation of triaminotripropylaminenickelous thiocyanate occurs, and the latter when once recrystallised from hot water is pure (Found: N, 23.2.  $\text{C}_{11}\text{H}_{24}\text{N}_6\text{S}_2\text{Ni}$  requires N, 23.2%). Aqueous solutions of the hydroxyiodide are distinctly alkaline, and on exposure to air absorb carbon dioxide.

In view of the ready formation and great stability of dichlorotriaminotriethylamineplatinic chloride,  $[\text{Cl}_2\text{Pt tren}]\text{Cl}_2$  (p. 482) many experiments were made to prepare the corresponding propyl derivative. No definite evidence of the formation of such a compound could be obtained, however, and the attempt was finally abandoned.

# LXIV.—The Resolution of *dl*-Alanine and the Formation of *trans*-2:5-Dimethylpiperazine.

By FREDERIC BARRY KIPPING and WILLIAM JACKSON POPE.

THE  $\alpha$ -2:5-dimethylpiperazine of Stoehr (*J. pr. Chem.*, 1893, 47, 494; 1897, 55, 49) was identified by Pope and Read (*J.*, 1912, 101, 2327; 1914, 105, 219) as the *trans*-isomeride; the same compound was obtained by Hoyer (*Z. physiol. Chem.*, 1902, 34, 347) by the reduction of lactimide,  $\text{NH} \begin{smallmatrix} \text{CO} \cdot \text{CHMe} \\ \text{CHMe} \cdot \text{CO} \end{smallmatrix} \text{NH}$ . The latter compound would therefore appear to be internally compensated or *trans*-3:6-diketo-2:5-dimethylpiperazine produced by anhydride formation from a molecule each of *d*- and *l*-alanine; this conclusion, as will be shown later, is not necessarily correct. The two optically active alanines, on the other hand, yield optically active anhydrides (E. Fischer, *Ber.*, 1906, 39, 453) which are necessarily the *d*- and *l*-*cis*-3:6-diketo-2:5-dimethylpiperazines. It might be expected that on reduction the latter substances would yield the *d*- and *l*-*cis*-2:5-dimethylpiperazines; the racemic compound of these two isomerides should be represented by the  $\beta$ -2:5-dimethylpiperazine of Stoehr (*loc. cit.*), but Pope and Read were unable to separate such a compound from the material which they examined.

It thus seemed desirable to reduce the anhydride of one of the optically active alanine anhydrides or *cis*-3:6-diketo-2:5-dimethylpiperazines for the purpose of isolating and further characterising the *d*- and *l*-*cis*-2:5-dimethylpiperazines which were presumably associated in Stoehr's  $\beta$ -compound. A certain quantity of *d*-alanine was prepared by the hydrolysis of silk as described by Fischer (*Ber.*, 1906, 39, 462), but the process, although satisfactory, is tedious. The preparation was hastened by preparing *dl*-alanine from acetaldehyde, potassium cyanide and ammonium chloride by the method of Zelinsky and Stadnikov (*Ber.*, 1908, 41, 2061) and resolving this into its optically active components.

Fischer (*Ber.*, 1899, 32, 2459) resolved benzoyl-*dl*-alanine by crystallisation with cinchonine, and Gibson and Pope (*J.*, 1912, 101, 939) improved this method by the alternate use of strychnine and brucine; the hydrolysis to *d*- and *l*-alanine proceeds, however, only with difficulty. Gibson and Simonsen (*J.*, 1915, 107, 798) resolved *dl*-*p*-toluenesulphonylalanine by crystallisation with strychnine and brucine, and Colombano and Sanna (*Atti R. Accad. Lincei*, 1913, 22, 292) resolved *dl*-alanine by crystallising its ethyl ester with bromocamphorsulphonic acid.

None of these methods proved satisfactory for preparing the

optically active alanines in quantity and we therefore devised a new one. It was found that *d*-hydroxymethylenecamphor and *d*-chloromethylenecamphor do not condense with *dl*-alanine, but that condensation occurs readily with the ethyl ester of alanine; the method of resolution by means of *d*-hydroxymethylenecamphor described by Pope and Read (J., 1914, 105, 219) is therefore applicable and the condensation products can be hydrolysed by concentrated hydrochloric acid, yielding the optically active alanines. This method of resolving *dl*-alanine seems to be the most convenient yet described; by its aid *l*-alanine has been separated in quantity from the racemic compound.

Several methods for converting the *d*- and *l*-alanines into the *d*- and *l*-*cis*-3 : 6-diketo-2 : 5-dimethylpyperazines, or the optically active lactimides, were studied. Hoyer's method of heating alanine in dry hydrogen chloride at 180–200°, boiling the product with lead hydroxide, and removing the metal by hydrogen sulphide gave poor yields. One method described by Fischer (*Ber.*, 1906, 39, 467), in which the ethyl ester of alanylalanine, prepared from alanine ethyl ester and alanyl chloride, is treated with gaseous ammonia, also gives poor yields. Fischer's second method (*Ber.*, 1906, 39, 543), in which the ethyl ester of alanine is preserved for several weeks, is satisfactory and gives a yield of about 70%.

When the optically active lactimides, which have necessarily the *cis*-configuration, were reduced with sodium and alcohol, the chief product, and indeed the only one which could be isolated, was the potentially optically inactive *trans*-2 : 5-dimethylpyperazine identified by Pope and Read. It thus seems clear that the lactimide undergoes enolisation during reduction in accordance with the scheme

and that the original *cis*-compound thus becomes converted into the *trans*-2 : 5-dimethylpyperazine accompanied by little, if any, of the *cis*-isomeride. No evidence is thus obtainable as to whether inactive lactimide is the racemic or *cis*-compound or the internally compensated or *trans*-compound.

#### EXPERIMENTAL.

*dl*-Alanine, prepared by Zelinsky and Stadinov's method, was converted into its ethyl ester, which was then heated for 2 hours on the water-bath with an equimolecular quantity of *d*-hydroxymethylenecamphor. On pouring into water, extracting with light

petroleum, and evaporating the petroleum solution after drying with potassium carbonate, an oil was obtained which readily crystallised; the crystalline product was repeatedly crystallised from light petroleum until its melting point became constant at 108–109°. The substance thus obtained in long, white needles is the *d*-methylene-camphor-*l*-alanine ethyl ester,  $C_8H_{14} \begin{smallmatrix} \diagup C:CH-NH \cdot CHMe \cdot CO_2Et \\ \diagdown CO \end{smallmatrix}$

(Found: C, 68.9; H, 8.9.  $C_{16}H_{25}O_3N$  requires C, 68.8; H, 9.0%). The substance is so soluble in most organic solvents that it can only be conveniently crystallised from light petroleum. 0.1008 Gram, made up to 20 c.c. with absolute alcohol, gave  $\alpha_{Hg \text{ green}} = +2.58^\circ$  in a 2-dcm. tube at 20°; whence  $[\alpha]_{Hg \text{ green}} = +256^\circ$ .

This compound, when treated by the bromine method of Pope and Read, yielded only resinous products from which alanine could not be separated; it is, however, hydrolysed by distillation in steam after admixture with concentrated hydrochloric acid. Hydroxy-methylenecamphor distils away and *l*-alanine hydrochloride remains behind; the hydrochloric acid is removed with the aid of lead hydroxide, the excess of the latter by hydrogen sulphide, and the *l*-alanine then separated by crystallisation from the residual aqueous solution. 1.8761 Gram, made up to 20 c.c. with 1.25*N*-hydrochloric acid solution, gave  $\alpha_{Hg \text{ green}} = -3.22^\circ$  in a 2-dcm. tube at 20°; whence  $[\alpha]_{Hg \text{ green}} = -12.2^\circ$ ; this value is numerically identical with that given by *d*-alanine prepared from silk, but is, of course, of opposite sign. This simple type of method will be further studied in its applications to the resolution of racemic aminocarboxylic acids.

*Reduction of l-Lactimide.*—*l*-Alanine was converted into its ethyl ester and preserved for several weeks until solidification had apparently become complete; after crystallisation from alcohol a 70% yield of *l*-lactimide was obtained. The product melted at 272° and showed  $[\alpha]_D^{20} = +29.1^\circ$  in a 2% alcoholic solution. The *l*-lactimide (6 g.) was treated with absolute alcohol (300 c.c.), and sodium (32 g.) gradually added with constant shaking. After removal of the alcohol, the reduction product was benzoylated; the only separable product was the optically inactive dibenzoyl-*trans*-2:5-dimethylpiperazine (0.8 g.) of Pope and Read. The identity of the product was confirmed by mixed melting-point determinations with a sample of the latter substance; each, and the mixtures, melted at 227–228°.

No better yields were obtained by reducing the *l*-lactimide in amyl-alcoholic solution and it is noteworthy that Gaurilov (*Bull. Soc. chim.*, 1925, 37, 1651) obtained only a 15% yield of piperazine by this mode of reducing 2:5-diketopiperazine. The lactimide

could not be reduced by colloidal palladium or platinum, by calcium or calcium hydride and alcohol, or by aluminium amalgam in aqueous-alcoholic solution.

## NOTES.

*Air Oxidation of Titanous Sulphate Solution. Vanadous Sulphate, a New and Powerful Reducing Agent.* By A. S. RUSSELL.

THE powerful reducing agent, titanous sulphate, is used less than it might be on account of the trouble of preserving it from oxidation by air. I am not aware than any worker with this reagent has said that this is unnecessary. Knecht and Hibbert ("New Reduction Methods in Volumetric Analysis," 2nd ed., 1925, p. 62), who have the largest experience of this reagent, say that any results obtained without taking the precaution of preventing air oxidation are valueless. My experience is different. When a solution of titanous sulphate in 4*N*-sulphuric acid is prepared from titanous sulphate by Nakazono's rapid method (*J. Chem. Soc. Japan*, 1921, 42, 526), and kept in a burette exposed to air, I find that its titre when standardised with *N*/10-permanganate remains constant for 12 hours. It follows that precautions to exclude air are unnecessary. It is also a consequence that if titanium itself be determined by reducing titanous sulphate with zinc amalgam and titrating the liquid after separation with permanganate, the work can be carried out in air if the acidity of the titanium solution is 4*N*-sulphuric acid. I confirmed this by alternately reducing with zinc amalgam and oxidising with *N*/10-permanganate four times a volume of titanous sulphate of known concentration without excluding air. The titres were constant and equal to that calculated on the assumption that the reduction was quantitative. Titanous sulphate thus resembles ferrous and uranous sulphates in being stable in air at the ordinary temperature if in 4*N*-sulphuric acid.

It is not necessary to adopt the excellent but elaborate method of Knecht and Hibbert (*op. cit.*, p. 63) for preserving titanous sulphate solution for a long time. It is simpler to have a solution of titanous sulphate in 4*N*-sulphuric acid and, whenever titanous sulphate is needed, to reduce the volume required with zinc amalgam for 1 minute, decant the liquid into a flask, transfer to a burette, and

immediately before use standardise it against  $N/10$ -permanganate. I find it is not oxidised by the air when run into hot or boiling solutions reduced by it. I find also that titanous sulphate is not less powerful as a reducing agent than the chloride and that the reducing power is unaffected by the presence of the free sulphuric acid. The sulphate solution is consequently simpler to use than the chloride, because in practice back titrations are done with permanganate as well as with ferric alum.

Vanadous sulphate has not, I think, been previously used as a reducing agent. I find that it is a more powerful reducing agent than titanous sulphate, reducing with greater ease all the inorganic and organic substances reduced by the latter. It reduces titanous sulphate itself in the cold. It lies between cadmium and tin in its reducing power in  $2N$ -sulphuric acid, whereas titanous sulphate was found to lie between lead and copper. It is, as is to be expected, much more susceptible to air oxidation, but not to such an extent that precautions to exclude air when using it are essential. A  $N/10$ -solution in  $10N$ -sulphuric acid is not measurably oxidised by air when kept for an hour in a burette. It may therefore be used without excluding air in volumetric work which can be completed within that time. It is prepared by the same method and as quickly as titanous sulphate.—DR. LEE'S LABORATORY, CHRIST CHURCH, OXFORD. [Received, November 3rd, 1925.]

*The Effect of Heat on Chloral Hydrate.* By JAMES DENIS  
MOUNFIELD and JOHN KERFOOT WOOD.

THE temperature at which the dissociation of chloral hydrate commences is unknown. It is complete at  $78^{\circ}$ , and the variability of the melting point suggests that it may occur to a considerable extent at about  $50^{\circ}$ . Pope (J., 1899, 75, 455) has suggested that two modifications of chloral hydrate may exist, but the work of Van Rossem and Jaeger (*Z. physikal. Chem.*, 1908, 62, 701) would appear to discredit this view.

To obtain further information on these matters, the authors have conducted dilatometric and tensimetric measurements with chloral hydrate. Repeated experiments with "liquid paraffin B.P." as the indicating liquid showed that chloral hydrate suffers a change of volume at  $32^{\circ}$ ; similar indications were given by samples which had been maintained at  $20^{\circ}$  and  $40^{\circ}$  for several days and which were slowly heated and cooled, respectively.

In the tensimeter experiments, the vapour pressure was measured at small intervals of temperature between  $15^{\circ}$  and  $40^{\circ}$ . The results are in Tables I and II, the former referring to rising and the

latter to falling temperature; the pressures indicate millimetres of  $\alpha$ -bromonaphthalene.

31.50	17.81	19.45	8.42
31.20	17.56	—	—

The values obtained in the two series of experiments are in agreement and show the complete absence of a break in the vapour pressure curve in the vicinity of 32°; Ramsay and Young (*Phil. Trans.*, 1886, **177**, 76), from observations made at much larger intervals of temperature, also obtained a smooth curve. From the absence of a break in the vapour pressure curve it would appear most probable that the change which occurs at 32° does not correspond to a change of modification, but marks the commencement of the dissociation of chloral hydrate.—MUNICIPAL COLLEGE OF TECHNOLOGY, UNIVERSITY OF MANCHESTER. [Received, October 10th, 1925.]

*Preparation of Ethylene Bromohydrin.* By FREDERICK HENRY McDOWALL.

IN the method of preparation of ethylene bromohydrin described by Read and Williams (J., 1917, **111**, 240) and Read and Brook (J., 1920, **117**, 359, 1214), bromine is carried over into the reaction chamber in the form of vapour by a current of air. This has several disadvantages. The ethylene becomes considerably diluted by the air, and a great deal is carried away, so that of the total amount used, only one-third is absorbed. Furthermore, the supply of bromine is not easily regulated.

These disadvantages can be obviated by dropping the bromine from a small, finely-pointed burette down a guide-tube of small bore, the lower part of which reaches to the bottom of the reaction vessel, and is placed as far as possible from the ethylene inlet. The bromine can thus be introduced slowly and, with an efficient stirrer, it becomes dissolved in the water before contact with gaseous ethylene is possible. The yields obtained in two experiments coincided with the average of those obtained by Read and Brook

(*loc. cit.*, p. 1214), while the quantity of ethylene used was only slightly in excess of that absorbed. [Received, January 12th, 1926.]

*An Automatic Siphonic Gas Circulator.* By GEORGE M. GREEN.

THE apparatus described is the result of an unsuccessful attempt to construct a gas-circulating device of the type communicated by Pearson and Thomas (J., 1925, 127, 2450). It does not contain a mechanical device of the plunger variety, and the advantages claimed for it are simplicity of construction and perfect continuity of action, once started. Its disadvantages lie in its comparative slowness and its well-defined intermittency. For certain kinds of laboratory work, however, the latter might recommend themselves.

The apparatus consists of two concentric glass tubes, *B* and *E*, about 6 feet long, one of which slides within the other, the annular space between them being about 1 mm. The inner tube, about 1 inch in internal diameter, is sufficiently heavy to resist the upward-moving tendency produced by the developing hydrostatic pressure. The siphon tube, the length of which can be varied by means of rubber tubing, should be of the greatest possible diameter con-

sistent with rapid and efficient siphonage, and be placed at a suitable height above the working bench. The inflowing water, preferably under a constant pressure head, requires careful regulation at the commencement. The diameter of the upper portions of the U-tube, *C*, containing the oscillating mercury is 2 inches. The valves are of the ordinary mercury seal type. With this apparatus, a constant circulation of at least 50 c.c. of gas per minute is obtainable.—

TECHNICAL COLLEGE, HUDDERSFIELD. [Received, December 28th, 1925.]

# LXV.—*A Comparison of Some of the Physical Properties of the Alkali Cyanates and Azides.*

By JOHN ARNOLD CRANSTON and ALEXANDER YOUNG  
LIVINGSTONE.

ACCORDING to modern ideas of the structure of atoms, the chemical and physical properties of elements depend on the number and arrangement of the outer electrons of the atom of the element.

The cyanate and azide ions have the same number of external electrons in their alkali salts, and it is possible that these electrons are arranged in the same way. According to the older views of valency, however, it was more common to find a ring structure assigned to azides and a straight-chain structure to cyanates. The constitutional formulæ were thus represented as

The appearance of these formulæ does not suggest any close resemblance between the physical properties of the compounds. The formulæ suggested by the octet theory for these compounds are

and their great similarity suggests a close resemblance of the physical properties of these two salts. As far as previously published data go, the evidence favours the formulæ of the octet theory, and it was the object of this investigation to supplement the data, which were rather meagre.

*Preparation of Salts.*—The following salts were prepared and purified according to the recognised text-book methods: Potassium cyanate, potassium azide; sodium cyanate, sodium azide.

*Investigation of Physical Properties.*—1. *Densities of solutions.* Since comparative, rather than absolute, values for the data for the various physical properties were aimed at, great care was taken to carry out all measurements for the cyanates and azides under uniform conditions.

A pycnometer of about 17 c.c. capacity was used for the determination of the densities of the solutions that were made up. Cyanates are decomposed by water, but the rate of decomposition

is greatly reduced in presence of alcohol. The solvent employed for the various dilutions was accordingly a mixture of about equal volumes of alcohol and water. All measurements were carried out after the pycnometer containing the solutions had been immersed in a thermostat at 16° for 20 minutes. The results are in Table I.

2. *The refractive indices of the various solutions* were determined by the Abbé refractometer at the same temperature at which their densities had been observed. The results are also in Table I.

TABLE I.

Strength of soln.	Density.		Refractive index.		Density.		Refractive index.	
	KN <sub>3</sub> soln.	KCNO soln.	KN <sub>3</sub> soln.	KCNO soln.	NaN <sub>3</sub> soln.	NaCNO soln.	NaN <sub>3</sub> soln.	NaCNO soln.

3. *The densities of the crystalline salts* were determined by immersing a weighed quantity, about 5 g., in benzene contained in an ordinary specific gravity bottle. Previous experiment had shown that the solubility of these salts in benzene at room temperature is less than 0.1 g. in 100 c.c. Too great reliance cannot be placed on the value obtained for sodium cyanate, owing to the instability of this salt; although different determinations gave consistent values, there was always a detectable quantity of carbonate formed during the measurements. The mean values obtained were as follows:

TABLE II.

	KN <sub>3</sub> .	KCNO.	NaN <sub>3</sub> .	NaCNO.
Density at 20° .....	2.056	2.056	1.846	1.937

4. *Determination of solubilities.* The solubilities of these salts in alcohol ( $d^{20}_4$  0.799) were determined at 0° and at the boiling point of the saturated solution. Definite volumes of the solutions were withdrawn by means of a pipette, and the solutions weighed. The cyanates were estimated volumetrically by the method suggested by Masson (*Chem. News*, 1906, 90, 5, 17), the azides by the method suggested by Raschig (*Chem. Ztg.*, 1908, 1203).

Solubilities were also measured in 20% water and 80% alcohol at 0° and at the boiling point of the saturated solution, and as well as in benzene at the boiling point.

TABLE III.

Solvent.	Weight dissolved in 100 g. of solvent.			
	KN <sub>3</sub> .	KCNO.	NaN <sub>3</sub> .	NaCNO.
Alcohol at 0° .....	0.16	0.16	0.22	0.22
Alcohol at b. p. ....	0.54	0.53	0.46	0.52
80% Alcohol } at 0° .....	1.8	1.9	—	—
20% Water } .....				
" " } at b. p. ....	5.9	6.2	—	—
Benzene at b. p. ....	0.15	0.18	0.10	0.13

5. *Conductivity of solutions.* A preliminary attempt to determine the hydron concentration of a solution of an alkali azide by the electrometric method showed that the salt is decomposed by water in presence of platinum black. This decomposition is very rapid when hydrogen is present occluded in the platinum. Nitrogen and ammonia are liberated, and the solution becomes progressively more alkaline. Apparently the reaction is as follows:  $3\text{KN}_3 + 3\text{H}_2\text{O} = 3\text{KOH} + 4\text{N}_2 + \text{NH}_3$ .

Since cyanates are also decomposed by water, the solvent used in the conductivity measurements was methyl alcohol ( $d^{20}$  0.789).

The following results were obtained.

TABLE IV.

Strength of solution.	Equivalent conductivity at 25°.			
	NaN <sub>3</sub> .	NaCNO.	KN <sub>3</sub> .	KCNO.
N/10	58.7	58.3	62.8	60.3
N/20	69.0	68.0	68.0	68.6
N/40	78.8	75.6	77.2	77.6
N/80	90.4	88.0	88.8	88.8

The investigations of Carrara (*Gazzetta*, 1896, 26, i, 134) have shown that the ionic conductivities of sodium and potassium are approximately equal in methyl alcohol.

### Discussion of Results.

It will be seen from the above tables that all the physical properties investigated have shown the great resemblance between sodium azide and sodium cyanate on the one hand and potassium azide and potassium cyanate on the other. This, taken in conjunction with the similarity of crystal structure noted by Langmuir (*J. Amer. Chem. Soc.*, 1919, 41, 1543), is strong evidence that the arrangement of electrons and atoms in the cyanate and azide ions is the same.

ROYAL TECHNICAL COLLEGE, GLASGOW. [Received, October 31st, 1925.]

LXVI.—*Studies on the Dependence of Optical Rotatory Power on Chemical Constitution. Part VI. Rotatory Powers of Phenyl, o, m, p-Tolyl and  $\beta$ -Naphthyl Derivatives of d-Camphorimide and d-Camphoramic Acid.*

By BAWA KARTAR SINGH and AMAR NATH PURI.

THE rotatory powers of a number of aryl derivatives of *d*-camphorimide and *d*-camphoramic acid in three solvents at different concentrations have been studied with the object of finding some relation between their optical activity and chemical constitution, and the following conclusions drawn :

1. Substitution of an aryl group for the imido-hydrogen atom increases the rotatory power, and more so than does substitution of the benzyl group (Singh and Biswas, J., 1924, 125, 1895).

2. The influence of the solvent on the rotatory power is considerable in the case of derivatives of *d*-camphoramic acid, but it is small in the case of those of *d*-camphorimide.

The order of the dielectric constants of the solvents employed is methyl alcohol (32.5) > ethyl alcohol (26.0) > acetone (21.2). In most cases (see Tables I and II), the order of the rotatory powers in these solvents is methyl alcohol > ethyl alcohol > acetone. It thus appears that in the case of these solvents the order of the rotatory powers generally runs parallel to their dielectric constants, although there is no direct proportionality between them.

3. The relative magnitude of the rotatory powers of phenyl and tolyl derivatives of *d*-camphorimide and *d*-camphoramic acid varies with the nature of the solvent and the concentration of the solution, as is seen in Tables I and II.

TABLE I.

Derivatives of <i>d</i> -camphoramic acid.	2% Solution.			1% Solution.		
	EtOH.	MeOH.	Me <sub>2</sub> CO.	EtOH.	MeOH.	Me <sub>2</sub> CO.
Phenyl	+131°	+150°	+101°	+133°	+152°	+101°
<i>o</i> -Tolyl	144	146	98	158	151	91
<i>m</i> -Tolyl	118	140	89	122	147	92
<i>p</i> -Tolyl	144	167	120	146	170	122

*o* = *p* > *un.* > *m*; *p* > *un.* > *o* > *m*; *p* > *un.* > *o* > *m*; *o* > *p* > *un.* > *m*; *p* > *un.*, *o* and *m*; *p* > *un.* > *m* and *o*.

For none of these derivatives do Frankland's and Cohen's rules hold.

TABLE II.

Derivatives of <i>d</i> -camphorimide.	1.5% Solution.			0.75% Solution.		
	EtOH.	MeOH.	Me <sub>2</sub> CO.	EtOH.	MeOH.	Me <sub>2</sub> CO.
Phenyl	+48°	+49°	+44°	+48°	+52°	+48°
<i>o</i> -Tolyl	45	46	36	53	56	43
<i>m</i> -Tolyl	48	48	50	55	53	37
<i>p</i> -Tolyl	46	52	54	42	48	49

In the case of the derivatives of *d*-camphorimide, the differences in the rotatory powers of the position isomerides are in many cases so small, and within the limits of experimental error, that it is not permissible to draw any general conclusions.

The variation of the optical rotatory power with concentration was more fully investigated in the case of *d*-camphor-*p*-tolylamic acid in ethyl and methyl alcohols for concentrations varying from 1 to 10%. In both solvents the rotatory power decreases as the concentration increases. This may be due to the decrease in the number of optically active molecules in more concentrated solutions owing to molecular association.

4. The rotatory power of a cyclic compound is usually considerably greater than that of the corresponding open-chain derivative. Thus the rotatory powers of esters of 1-methyl-3-cyclopentanone-4-carboxylic acid are about thirty times as great as those of the corresponding esters of methyladipic acid (Haller, *Compt. rend.*, 1905, 140, 1205), and the hexahydrophthalic acids have much lower rotatory powers than their anhydrides (Werner, *Ber.*, 1899, 32, 3046). This rule is more strikingly borne out in the case of derivatives of monosaccharides. The rotatory power of *d*-mannitol is  $[\alpha]_D^{20} = -0.2^\circ$  (Fischer, *Ber.*, 1890, 23, 3684), whereas that of *d*-mannonolactone is  $+53.8^\circ$  (Fischer, *Ber.*, 1889, 22, 3219). The high rotatory power of most of the sugars as compared with the corresponding polyhydric alcohols is a proof of the ring structure of the former. The increase which is brought about in the rotatory power of sugar alcohols by boric acid is attributed to the formation of ring complexes. Camphoramides and their anhydrides form an exception to the rule, the acids having  $[M]_D$  89.45° ( $\alpha$ ), 119.4° ( $\beta$ ) in ethyl alcohol, whilst the anhydride has  $[M]_D$  10.99°. It was pointed out (J., 1924, 125, 1895) that opening the rings of *d*-camphorimide and its derivatives increases the rotation considerably; e.g. the following are values of  $[M]_D$  in ethyl alcohol: camphorbenzylimide 30.19°, camphorbenzylamic acid 99.88°, camphor-*m*-nitrobenzylimide 31.92°, camphor-3-nitrobenzylamic acid 106.7°. The differences in the molecular rotatory powers of the aryl derivatives

of *d*-camphorimide and *d*-camphoramidic acid are of the same order as of the foregoing substances, except in the case of  $\beta$ -naphthyl derivatives, for which the difference is much greater; e.g., the following are values of  $[M]_D$  in ethyl alcohol: camphor- $\beta$ -naphthylimide 60°, *d*-camphor- $\beta$ -naphthylamidic acid 229°. From the foregoing instances it may be concluded that when an open-chain, optically active compound is transformed into a ring compound, there is a marked change (not necessarily an increase) in the rotatory power.

#### EXPERIMENTAL.

*Aryl Derivatives of d-Camphoramidic Acid.*—*d*-Camphorphenylamidic acid,  $\text{CO}_2\text{H}\cdot\text{C}_8\text{H}_{14}\cdot\text{CO}\cdot\text{NHPh}$ , was prepared by heating camphoric anhydride and aniline in molecular proportions in chloroform on the water-bath for 4–5 hours. The solid obtained on cooling crystallised from aqueous alcohol in needles, m. p. 209–210°. Auwers and Schleicher (*Annalen*, 1899, **309**, 341) give m. p. 203–204°.

*d*-Camphor-*p*-tolylamidic acid,  $\text{CO}_2\text{H}\cdot\text{C}_8\text{H}_{14}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_7\text{H}_7$ , was prepared like the foregoing substance as leaflets, m. p. 214–215°. Wootton (J., 1910, **97**, 405), who obtained it by heating an intimate mixture of camphoric anhydride and the substituted amine for a few minutes at 150–180°, gives the melting point 212–214°, whereas Abati and Notaris (*Gazzetta*, 1909, **39**, ii, 219) give 201–209°.

*d*-Camphor-*m*-tolylamidic acid was prepared by Wootton's method (*loc. cit.*) and purified by dissolving it in alcohol and adding animal charcoal. It was recrystallised as needles, m. p. 208–209°.

*d*-Camphor-*o*-tolylamidic acid, prepared in the foregoing way, melted at 196–197°.

*d*-Camphor- $\beta$ -naphthylamidic acid,  $\text{CO}_2\text{H}\cdot\text{C}_8\text{H}_{14}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_{10}\text{H}_7$ , was prepared by both methods as white leaflets, m. p. 212–213°. The yield was, however, better when the condensation was carried out without any solvent.

*N-Aryl Derivatives of d-Camphorimide.*—These compounds were prepared by heating camphoric anhydride and the substituted amines in molecular proportions with the addition of a little anhydrous sodium sulphate in an oil-bath (215–230°) for 2 to 3 hours. The products of condensation were extracted with alcohol, decolorised by animal charcoal, and precipitated by adding water. They were twice recrystallised from aqueous alcohol, and gave the following melting points: phenyl, 117–118°; *o*-tolyl, 105–106°; *m*-tolyl, 121–122°; *p*-tolyl, 127–128°;  $\beta$ -naphthyl, 171–172°.

The tolyl and  $\beta$ -naphthyl derivatives of camphorimide were prepared by Wootton (*loc. cit.*) by boiling a solution of the corresponding *N*-substituted *d*-camphoramidic acid in glacial acetic acid with acetyl chloride for 2 hours. Wootton gives the melting point

for the *o*-tolyl derivative 195—196°, which is obviously wrong. We also prepared this substance by his method and found the melting point 105—106°.

Before their rotatory powers were determined, the compounds were recrystallised three times in order to ensure their "optical" purity. Wootton has recorded the rotatory powers of these sub-

stances in acetone; his exact concentrations are not stated. In the case of derivatives of camphoramic acid, his values agree with ours, except in the case of the *p*-tolyl derivative, his value (107°) being lower than ours (120° to 122°, according to concentration). In the case of the *p*-tolyl derivative of *d*-camphorimide, his value ( $[\alpha]_D^{34}$ ) is again lower than ours (49° to 54°, according to concentration).

The rotatory powers recorded in Table III were determined by dissolving a given weight of the substance in a solvent, and making up the solution to a definite volume. The readings were taken in a 2-dm. tube within 45 minutes of making up the solution. There was no mutarotation.

The rotatory powers and dispersion ratios of *d*-camphorbenzylamic acid and *d*-camphor-*m*-nitrobenzylamic acid (higher-melting form) were omitted from Part V of this series (*loc. cit.*). They are given below for the sake of completeness.

## LXVII.—Conditions of Formation of Rings Attached to the *o*-, *m*-, and *p*-Positions of the Benzene Nucleus. Part II. The Reduction of *m*- and *p*-Phenylene-diacetonitrile.

By ALAN FRANCIS TITLEY.

IN the course of some work on ring formation, the scope of which is outlined in Part I of this series (J., 1922, 121, 1562), and a further account of which will be published shortly, it was found desirable

to repeat some investigations recently carried out by von Braun and his collaborators.

While attempting to prepare *m*-phenylene- $\beta\beta'$ -diethylamine by the reduction of *m*-phenylenediacetonitrile with sodium and alcohol, von Braun, Karpf, and Garn (*Ber.*, 1920, 53, 98) claimed to have isolated a secondary amine of the composition  $C_{10}H_{13}N$ , to which they assigned the structure (I), where the heterocyclic ring is joined to the benzene nucleus in the meta-position. From this amine, by thermal decomposition of the quaternary dimethylammonium hydroxide with loss of dimethylamine and water, they stated that they obtained an unsaturated hydrocarbon and, by further reduction, a saturated hydrocarbon, to which they assigned the structures (II) and (III), respectively.

More recently, von Braun and Engel (*Ber.*, 1925, 58, 281) have described a homologue of this type, obtained in a similar manner by reducing 5-methyl-1 : 3-phenylenediacetonitrile.

The remarkable ease with which examples of this meta-ring system, generally supposed to be incapable of existence, are formed, together with their close structural relationship to the products it was hoped to obtain by the action of sodium on *m*-phenylene-diacetic ester (Part I, *loc. cit.*), rendered a re-examination of this work desirable. It was not found possible, however, to confirm the results of von Braun and his co-workers and, in the present paper, evidence is brought forward to show that the amine (I) described by von Braun, Karpf, and Garn (*loc. cit.*) is in reality  $\beta$ -*m*-tolylethylamine (VII), and the unsaturated hydrocarbon derived from it *m*-methylstyrene (IX).\*

The reduction of *m*-phenylenediacetonitrile, when carried out in accordance with the directions of these authors and using the same quantities and conditions, led to the formation of a mixture

\* The proof of this paper was sent to Professor von Braun, and he wishes me to say that he has been engaged for some time in repeating the researches in question and has arrived at results which are identical with those contained in the present communication.—W. H. PERKIN.

of products, basic and non-basic. The non-basic substances were removed, together with the excess of alcohol, by steam-distillation of the acidified reaction mixture. These proved to be *m*-tolyl-acetonitrile (IV), which was identified by conversion into the beautifully crystalline amide, m. p. 141° (compare Radziszewski and Wispek, *Ber.*, 1885, **18**, 1281), *m*-xylene (V), identified by b. p. and analysis, and a little unchanged *m*-phenylenediacetonitrile. Considerable quantities of free hydrocyanic acid could also be detected.

The basic products, after liberation from the acid solution by excess of sodium hydroxide, proved to be a mixture of *m*-phenylene- $\beta\beta'$ -diethylamine (VI), b. p. 162°/18 mm., formed in accordance with the observation of von Braun in a 10–15% yield, and a monoamine of b. p. 97–98°/15 mm., obtained in about 40% yield, which appeared to be identical with the substance  $C_{10}H_{13}N$  described by von Braun as a secondary amine.

This monoamine gave a hydrochloride, which crystallised in large, glistening leaflets of m. p. 160°, a sulphur-yellow picrate, m. p. 174°, a benzoyl derivative, m. p. 72°, a phenylthiocarbamide, m. p. 86–87°, a platinum salt which, after blackening between 230° and 240°, melted with vigorous decomposition at 246°, and a quaternary methiodide, m. p. 237°. (The substance described by von Braun as a secondary amine had in almost every respect the same properties, viz., b. p. 97–98°/16 mm., the hydrochloride, m. p. 160°, the picrate, m. p. 176°, the benzoyl derivative, m. p. 72°, the phenylthiocarbamide, m. p. 87°, the platinum salt, m. p. 232°, and the quaternary methiodide, m. p. 236°.)

The amine, however, prepared in this way, did not give analytical results corresponding to the composition  $C_{10}H_{13}N$ , but invariably showed a higher hydrogen content. It was at first thought that it had the composition  $C_{10}H_{15}N$ , but careful analyses of several samples, including one prepared from the recrystallised hydrochloride, clearly suggested the composition  $C_9H_{13}N$ .

On treating a solution of the base in dilute hydrochloric acid with sodium nitrite, a brisk evolution of nitrogen occurred and a pale yellow oil separated. This oil, which had a characteristic pungent and rather sweet odour, dissolved readily in ether and, after shaking with dilute sodium carbonate to remove nitrous acid, gave no response to the Liebermann test.

In view of these results and the nature of the non-basic products of the reaction, it seems quite clear that the normal reduction of *m*-phenylenediacetonitrile to the diamine (VI) is largely accompanied by the conversion of first one and then the other  $-CH_2-CN$  group into  $-CH_3$  groups, the intermediate stage being itself reduced to a monoamine. The process is best made clear by the following scheme:

The monoamine described above, although evidently identical, except in its behaviour towards nitrous acid, with the monoamine (I) of von Braun, is in reality  $\beta$ -*m*-tolylethylamine (VII).

In order to establish the identity of the monoamine beyond question,  $\beta$ -*m*-tolylethylamine was prepared by the reduction of *m*-tolylacetonitrile (IV) with sodium and alcohol. Using approximately twice the theoretical quantity of reducing agent, a yield of about 50% of  $\beta$ -*m*-tolylethylamine was obtained, practically the whole of the rest of the nitrile being reduced to *m*-xylene.

The amine had b. p. 216°/762 mm. and 98°/15 mm. and gave a hydrochloride, m. p. 160°, and a picrate, m. p. 174°, in accordance with the observations of Sommer (*Ber.*, 1900, **33**, 1079).

The benzoyl compound, phenylthiocarbamide, and quaternary methiodide also had the same melting points as the corresponding compounds, prepared from the specimen of monoamine which had been obtained by reducing *m*-phenylenediacetonitrile. There was no depression of the m. p. on mixing samples of these derivatives.

This reduction of the  $-\text{CH}_2 \cdot \text{CN}$  group to  $-\text{CH}_3$ , although apparently of rare occurrence, is not unknown, and a few instances are recorded in the literature—for example, the reduction of cyanomethylbenziminazole to methylbenziminazole with sodium and alcohol (Bloch, *J. Soc. Chem. Ind.*, 1919, **38**, 118).

$\beta$ -*m*-Tolylethylamine combines readily with piperonal, the condensation product crystallising well and melting at 53–54°. After being heated in a sealed tube with a slight excess of methyl iodide and then decomposed with aqueous alcohol, the latter yields  $\beta$ -*m*-tolylethylmethylamine hydriodide, m. p. 104°, from which the free base (VIII) was obtained, b. p. 88°/12 mm.

This base was prepared because of the very definite statement made by von Braun regarding the secondary nature of his monoamine. It was thought possible that interaction might occur between  $\beta$ -*m*-tolylethylamine and methylamine, formed by reduction of the free hydrocyanic acid present during the reaction, with the formation of  $\beta$ -*m*-tolylethylmethylamine (VIII), and that this secondary amine ( $\text{C}_{10}\text{H}_{15}\text{N}$ ), in itself and in its derivatives, might closely resemble the primary amine ( $\text{C}_9\text{H}_{13}\text{N}$ ).

This, however, was not found to be the case, since the secondary amine gave a hydrochloride extremely soluble in alcohol and most other solvents, which, when crystallised from chloroform-ligroin, had m. p. 134°. The picrate had m. p. 127°, whilst the benzoyl compound was an oil which could not be induced to crystallise.

No evidence of the formation of any secondary amine by the reduction of *m*-phenylenediacetonitrile was forthcoming, and since the properties of  $\beta$ -*m*-tolylethylamine and its derivatives agree in almost every respect with those of the monoamine described by von Braun, there seems little doubt that the two are identical.

As previously mentioned, von Braun, Karpf, and Garn found that the quaternary ammonium hydroxide of their base, on distillation, lost dimethylamine and water with the formation of an unsaturated hydrocarbon,  $C_{10}H_{10}$  (II), which had b. p. 62–63°/18 mm. and added two atoms of bromine with the formation of a dibromide, m. p. 48°.

It was found that the quaternary methiodide of  $\beta$ -*m*-tolylethylamine, on boiling with methyl-alcoholic potash, lost trimethylamine (identified by means of the picrate and platinum salt), with the formation of *m*-methylstyrene (IX), b. p. 62°/18 mm., which by the addition of two atoms of bromine gave the corresponding dibromide (X), m. p. 47° (Müller, *Ber.*, 1887, 20, 1216, found m. p. 45°).

The hydrocarbon described by von Braun is stated to have an abnormally low density ( $d^{20}_4$  0.900) as compared with "the isomeric hydrocarbons 3-methylindene ( $d$  0.968) and  $\Delta^1$ -dihydronaphthalene ( $d$  0.997)," whilst it resembled a styrene in polymerising under the action of light. The density of *m*-methylstyrene was found to be 0.906 at 16° and its tendency to polymerise has been noted by previous workers (Müller, *loc. cit.*).

The saturated hydrocarbon (III) prepared by von Braun had the low density  $d^{20}_4$  0.852 as compared with 1-methylhydrindene ( $d$  0.966) and 1:2:3:4-tetrahydronaphthalene ( $d$  0.968), whilst the refractive index was  $n^{20}_D = 1.497$ .

The reduction of *m*-methylstyrene to *m*-tolylethane was not investigated, but it may be noted that the density of the latter is recorded by Wroblewski (*Annalen*, 1878, 192, 198) as 0.869 at 20°. The refractive index of *m*-tolylethane has not apparently been measured, but that of the isomeric *p*-tolylethane is stated to have the value  $n^{20}_D = 1.494$  (Klages and Keil, *Ber.*, 1903, 36, 1637).

*Reduction of p-Phenylenediacetonitrile.*

The reduction of *p*-phenylenediacetonitrile with sodium and alcohol was also investigated. In this case, the  $-\text{CH}_2\cdot\text{CN}$  groups are reduced to methyl groups even more readily than those in the *m*-isomeride, a yield of about 50% of  $\beta$ -*p*-tolylethylamine being obtained. The rest of the nitrile was almost wholly reduced to *p*-xylene, whilst no appreciable quantity of *p*-phenylene- $\beta\beta'$ -diethylamine was formed.

The identity of the monoamine was again established by reducing *p*-tolylacetonitrile, which yielded the same product.

$\beta$ -*p*-Tolylethylamine has b. p.  $94-95^\circ/13$  mm. and absorbs carbon dioxide rapidly from the air. It forms a sparingly soluble hydrochloride, m. p.  $216^\circ$  (compare Ciesielski, *Anzeiger Akad. Wiss. Krakau*, 1906, 270; *Centr.*, 1907, I, 1793). On treatment with nitrous acid, it passes into an alcohol, which has the same characteristic sweet odour as that derived from  $\beta$ -*m*-tolylethylamine. This  $\beta$ -*p*-tolylethyl alcohol boils at  $112^\circ/12$  mm. and combines with *p*-nitrobenzoyl chloride, yielding an ester which crystallises well and melts at  $91^\circ$ .

The amine forms a *picrate*, m. p.  $155^\circ$ , a platinum salt, m. p.  $234^\circ$ , a *benzoyl* derivative, m. p.  $89^\circ$ , and a quaternary *methiodide*, m. p.  $244^\circ$ . With piperonal, it forms a beautifully crystalline condensation product, m. p.  $107^\circ$ , which, by treatment with methyl iodide in the manner already described, is converted into  $\beta$ -*p*-tolylethylmethylamine hydriodide, m. p.  $149^\circ$ . The free base obtained from this had b. p.  $96^\circ/12$  mm. and yielded a readily soluble hydrochloride, m. p.  $191^\circ$ , a *picrate*, m. p.  $135^\circ$ , and an oily benzoyl compound.

The quaternary methiodide of the base, on boiling with methylalcoholic potash, was converted into *p*-methylstyrene, b. p.  $59-60^\circ/12$  mm., which yielded a dibromide, m. p.  $45-46^\circ$  (compare Klages and Keil, *loc. cit.*).

No evidence of any ring formation was obtained during these experiments.

## EXPERIMENTAL.

$\omega\omega'$ -Dibromo-*m*-xylene.—The bromination of *m*-xylene to the  $\omega\omega'$ -dibromo-compound was studied under various conditions, but the best results were obtained by following the directions of Atkinson and Thorpe (*J.*, 1907, 91, 1696). In this method, *m*-xylene is treated with rather more than the theoretical quantity of bromine required for monobromination, and the mixture of mono- and di-bromoxylenes separated by fractional distillation.

*m*-Xylene (200 g.) was treated at  $130^\circ$ , under reflux, with dry

bromine (405 g.) during about 6 hours. The product was freed from hydrogen bromide by 2 days' standing over solid caustic soda in a vacuum desiccator. The bulk of the monobromoxylene passed over at 110—115°/20 mm., and when the temperature reached 125° the distillation was stopped and the residue in the flask, which solidified almost completely on cooling, was broken up on a Büchner funnel, washed with a little low-boiling ligroin, and recrystallised from acetone. Large, colourless prisms, m. p. 76°, were obtained. The yield of dibromo-compound is about 35%.

The  $\omega$ -monobromoxylene was refractionated through a column, and the fraction 100—101°/14 mm. collected and used for the preparation of *m*-tolylacetonitrile (see later). The yield of monobromide is about 45% (Found: Br, 43.0. Calc., Br, 43.2%).

$\omega\omega'$ -Dibromo-*p*-xylene.—The bromination of *p*-xylene was carried out in the same manner as the above, using a quantity of bromine equal to twice the weight of the *p*-xylene taken. The reaction product solidified completely, and after pressing on a porous plate was extracted with ligroin (b. p. 40—50°) in a Soxhlet apparatus, which dissolved all the monobromide. The crude dibromo-compound crystallised from a small volume of warm chloroform in compact clusters of prisms, m. p. 143—144°.

The monobromo-compound, obtained by evaporation of the ligroin extract, after another crystallisation from the same solvent, separated in very long, colourless needles, m. p. 35.5°.

*m*-Phenylenediacetonitrile.—The conversion of the dibromoxylenes into the corresponding nitriles is usually attended by side-reactions leading to the formation of oily or amorphous by-products. These effects are minimised if the reaction is carried out as rapidly as possible, and the following method was found, in the case of dibromo-*m*-xylene, to give practically quantitative results.

A boiling solution of potassium cyanide (50 g.) in water (110 g.) and ethyl alcohol (350 c.c.) is rapidly stirred mechanically while finely powdered dibromo-*m*-xylene (88 g.) is added as rapidly as the violence of the reaction will permit. The hot solution is filtered at once from traces of brown, amorphous material. A litre of water is then added and the nitrile extracted with ether, dried, and distilled. The nitrile boiled at 230—231°/20 mm. and solidified, on cooling, to a snow-like mass of needles, m. p. 27°. Yield, 47 g.

*m*-Tolylacetonitrile.—Monobromo-*m*-xylene (128 g.) was treated with potassium cyanide (49 g.) dissolved in a mixture of water (120 g.) and alcohol (400 c.c.) in exactly the same manner as the above. The nitrile (yield about 85%) boiled at 245—247°/745 mm. with slight decomposition (compare Radziszewski and Wispek,

*loc. cit.*) and was better distilled under reduced pressure; it then had b. p.  $133^{\circ}/15$  mm.

*p-Phenylenediacetonitrile*.—The nitrile was prepared in the same manner as the meta-isomeride, the same quantities and conditions being used. The maximum possible yield, however, seems to be about 70%. The remainder of the bromo-derivative is converted into a bright yellow, infusible, amorphous, highly insoluble product, which does not appear to contain any nitrogen or halogen and was not further investigated. The nitrile separates from alcohol in colourless prisms, m. p.  $96^{\circ}$ .

*p-Tolylacetonitrile*.—This nitrile was obtained from monobromo-*p*-xylene by the usual method. It was found necessary in this case to boil the reaction mixture for a short time to complete the conversion. The nitrile has b. p.  $135^{\circ}/14$  mm. and solidifies in ice to a white mass which melts at  $17^{\circ}$ .

*Reduction of m-Phenylenediacetonitrile*.—Sodium (36.8 g.) in the form of small chips was placed in a 3-litre flask, closed with a cork through which passed an air condenser about 4 feet in length and  $1\frac{1}{2}$  inches in diameter. This was itself fitted at the top with a water-condenser. (In some experiments, the sodium was previously granulated under toluene, but this did not appear to affect the yield materially.)

A nearly boiling solution of *m*-phenylenediacetonitrile (14.6 g.) in absolute alcohol (550 g.) was then rapidly added. When the extremely violent reaction had subsided, a solution of 90 g. of concentrated sulphuric acid in 300 c.c. of water was added and the mixture distilled in steam. The acid solution was filtered from traces of a brown, sticky by-product, and, if necessary, extracted with ether. It was then rendered alkaline with caustic soda (30 g.) and thoroughly extracted with ether. After the ethereal solution had been dried with anhydrous magnesium sulphate and the ether removed, 8 g. of a pale yellow oil were obtained, from which 5–6 g. of b. p.  $97$ – $98^{\circ}/15$  mm. or  $101$ – $102^{\circ}/18$  mm. were isolated (Found: C, 80.1, 80.2; H, 9.8, 9.7; N, 10.25.  $C_9H_{13}N$  requires C, 80.0; H, 9.6; N, 10.4%).

The combined aqueous-alcoholic steam distillates from three such experiments were distilled through a column until about three-quarters of the alcohol had been removed. Water was then added to the residue, and the insoluble material extracted with ether. After removal of the ether, about 15 g. of non-basic products were obtained, and from these, by careful fractionation, 8–9 g. of a liquid, b. p.  $138$ – $141^{\circ}/758$  mm., which had a xylene-like odour and burned with a smoky flame (Found: C, 90.1; H, 9.3. Calc. for  $C_8H_{10}$ : C, 90.6; H, 9.4%).

From the residue about 4—5 g. of a liquid, b. p. 138—140°/18 mm., were obtained which, after shaking with dilute hydrogen peroxide and standing over-night, were converted into a crystalline mass. Recrystallised from hot water, the substance formed colourless leaflets, m. p. 141—142°, and analysis left no doubt that it was identical with *m*-tolylacetamide (compare Radziszewski and Wispek, *loc. cit.*) (Found : N, 9.6. Calc. for  $C_9H_{11}ON$  : N, 9.7%).

The amine, b. p. 97—98°/15 mm., described above, absorbed carbon dioxide readily from the air, with the formation of a solid carbonate.

The hydrochloride of the base was readily obtained by passing dry hydrogen chloride into its alcoholic solution. It separated in large, transparent laminae, m. p. 160° (Found : C, 63.4; H, 8.35.  $C_9H_{13}N.HCl$  requires C, 63.0; H, 8.2%).

The picrate, obtained by adding an alcoholic solution of the base to a saturated alcoholic solution of picric acid, formed sulphur-yellow needles, m. p. 174° (176° corr.) (compare Sommer, *loc. cit.*) (Found : N, 15.4. Calc., N, 15.4%).

The platinum salt, which separated in small, orange-brown needles on mixing warm solutions of the hydrochloride of the base and chloroplatinic acid, blackened between 230° and 240° and melted with vigorous decomposition at 246° (von Braun found m. p. 232° for this substance) (Found : Pt, 28.85. Calc. for  $2C_9H_{13}N.H_2PtCl_6$  : Pt, 28.7%).

The benzoyl derivative was best obtained by mixing 1 g. of the hydrochloride with 0.9 g. of benzoyl chloride and adding 15 c.c. of a 5% solution of sodium hydroxide. The sticky, white mass gradually solidified; recrystallised either from a very small volume of alcohol or from alcohol-ligroin, it formed colourless prisms, m. p. 72°.

The phenylthiocarbamide was obtained by boiling a solution of equal weights of the base and of phenylthiocarbimide in alcohol for about 10 minutes and adding ligroin; the thiocarbamide separated in colourless needles, which were recrystallised from a little warm alcohol and then had m. p. 86—87°.

The quaternary methiodide was easily prepared by shaking a mixture of the base (4.5 g.) with methyl iodide (20 g.) and 75 c.c. of a 5% solution of sodium hydroxide. Considerable heat was developed and the quaternary salt was deposited in white crusts. It crystallised from alcohol, in which it was only very moderately soluble in the cold, in colourless prisms, m. p. 237°.

*Reduction of m-Tolylacetonitrile.*—This reduction was carried out in the same apparatus and by the same method as that of the dinitrile already described. Thirty g. of sodium were used to reduce a solution of 15 g. of *m*-tolylacetonitrile in 450 g. of absolute alcohol.

The reaction products were worked up in the same manner, giving a yield of about 7 g. of  $\beta$ -m-tolylethylamine, b. p.  $98^{\circ}/15$  mm. or  $112^{\circ}/25$  mm., and about 5 g. of m-xylene (Found : C, 79.9; H, 9.8; N, 10.2. Calc. for  $C_9H_{13}N$  : C, 80.0; H, 9.6; N, 10.4%).

*Condensation of  $\beta$ -m-Tolylethylamine with Piperonal.*—A mixture of the base (10 g.) with piperonal (11 g.) was warmed on the water-bath for  $\frac{1}{2}$  hour. The product, which solidified on cooling, crystallised from about 100 c.c. of hot alcohol in yellowish-white leaflets, m. p.  $54^{\circ}$  (Found : C, 76.5; H, 6.6.  $C_{17}H_{17}O_2N$  requires C, 76.4; H, 6.4%).

*$\beta$ -m-Tolylethylmethylaniline.*—The carefully dried piperonal compound (15 g.) was mixed with an equal weight of methyl iodide and heated for 6 hours in a sealed tube at  $100^{\circ}$ . The excess of methyl iodide was boiled off and the residue dissolved in about 75 c.c. of 95% alcohol. On diluting the solution with three times its volume of ether, the *hydriodide* of the secondary base was precipitated in needles which, after being washed with ether, were faintly yellow and had m. p.  $107^{\circ}$  (Found : I, 45.5.  $C_{10}H_{15}N, HI$  requires I, 45.8%).

The free base, obtained by dissolving the hydriodide in an excess of 10% sodium hydroxide and extracting with ether, had b. p.  $88$ – $89^{\circ}/12$  mm. (Found : C, 80.5; H, 9.8; N, 9.6.  $C_{10}H_{15}N$  requires C, 80.5; H, 10.1; N, 9.4%).

The *hydrochloride* was best prepared by passing dry hydrogen chloride into a solution of the base in chloroform and adding ligroin, when it separated in greasy-looking leaflets, m. p.  $134^{\circ}$ . It is very soluble in alcohol and water and is usually obtained from these solvents, on evaporation, as an oil.

The *picrate* separated in orange needles, on mixing strong alcoholic solutions of the base and picric acid, and had m. p.  $126$ – $127^{\circ}$  (Found : N, 14.7.  $C_{10}H_{15}N, C_6H_3O_7N_3$  requires N, 14.8%).

The benzoyl derivative was obtained as a viscous oil on mixing the base with benzoyl chloride and dilute caustic soda. It showed no signs of crystallisation even on cooling in a freezing mixture.

*m-Methylstyrene.*—The quaternary methiodide of  $\beta$ -m-tolylethylamine (9 g.) was heated on the water-bath with 25% methyl-alcoholic potash (20 g.) in a small flask fitted with a reflux condenser closed with a cork, through which passed a delivery tube dipping into dilute hydrochloric acid. After 1 hour, when the decomposition appeared to be complete, water was added, the insoluble oily layer extracted with ether, and the ethereal solution washed with very dilute hydrochloric acid, dried, and distilled. The hydrocarbon obtained (3–4 g.) had b. p.  $61$ – $62^{\circ}/18$  mm. (Found : C, 91.3; H, 8.5.  $C_9H_{10}$  requires C, 91.5; H, 8.5%).

From the hydrochloric acid solution through which the gaseous products of the decomposition had been passed, trimethylamine hydrochloride, m. p.  $280^{\circ}$  (decomp.) (compare Wagner, *Z. Kryst. Min.*, 1906, 43, 167) was obtained. The chloroplatinate prepared therefrom formed brown scales, m. p.  $242-243^{\circ}$  (compare Willstätter, *Ber.*, 1895, 28, 3287), and the picrate formed golden-yellow prisms, m. p.  $216^{\circ}$ , from alcohol (compare Delépine, *Ann. Chim.*, 1896, 8, 452). Conclusive evidence was thus obtained that trimethylamine, and not dimethylamine, is eliminated during this decomposition.

From the density and the observed value of the refractive index ( $n_D^{20}$  1.54029), von Braun calculated the molecular refraction of his hydrocarbon, assuming, of course, the composition (II), and obtained the value  $[R_L]_D$  45.33, whilst that calculated for the composition  $C_{10}H_{10}$  was 42.11. He attributes this large exaltation of 3.2 units to the presence of the meta-ring structure. If, however, the molecular refraction is calculated from the same data, but assuming the composition  $C_9H_{10}$ , the value 41.15 is obtained, whilst that predicted theoretically (using Conrady's constants) is 39.70—giving an exaltation of only 1.4 units. This exaltation is of the order to be expected in a substance of the structure (IX) ( $EM_a$  for the isomeric  $\beta$ -methylstyrene is 1.01 units).

*$\alpha\beta$ -Dibromo- $\alpha$ -m-tolylethane.*—*m*-Methylstyrene (1.5 g.) dissolved in 10 c.c. of carbon disulphide was cooled in ice and gradually treated with a solution of 2.1 g. of bromine in 10 c.c. of carbon disulphide. After evaporation of the solvent, the crystalline residue was dissolved in a small volume of warm alcohol, from which it separated in well-formed, large prisms, m. p.  $47^{\circ}$  (compare Müller, *loc. cit.*) (Found: C, 39.2; H, 3.8; Br, 57.5. Calc., C, 38.8; H, 3.6; Br, 57.6%).

*Reduction of p-Phenylenediacetonitrile and p-Tolylacetonitrile.*—The reduction of these two substances was carried out in precisely the same manner as that of the meta-isomerides.

The same product, viz.,  $\beta$ -*p*-tolylethylamine, was obtained from both, as well as recognisable quantities of *p*-xylene.

The  $\beta$ -*p*-tolylethylamine, obtained in about 50% yield by reducing the dinitrile and in nearly 60% yield from the mononitrile, had b. p.  $94-95^{\circ}/13$  mm. (Found: C, 79.6; H, 9.7; N, 10.7.  $C_9H_{13}N$  requires C, 80.0; H, 9.6; N, 10.4%).

The hydrochloride, which is quite sparingly soluble in water and nearly insoluble in cold alcohol, crystallises in large plates, m. p.  $218^{\circ}$  (Found: C, 63.4; H, 8.25.  $C_9H_{13}N \cdot HCl$  requires C, 63.0; H, 8.2%). The picrate forms pale yellow needles, m. p.  $155^{\circ}$ , from alcohol (Found: N, 15.7.  $C_9H_{13}N \cdot C_6H_3O_7N_3$  requires N, 15.4%).

The *benzoyl* derivative is very readily soluble in most solvents, but can be crystallised from a small volume of alcohol in colourless prisms, m. p. 89° (Found: C, 80.5; H, 7.1.  $C_{16}H_{17}ON$  requires C, 80.3; H, 7.2%). The quaternary *methiodide* has m. p. 244° and is sparingly soluble in cold alcohol.

On treatment with an excess of an acid solution of sodium nitrite, the amine was converted into  $\beta$ -*p*-tolylethyl alcohol, which had b. p. 112°/12 mm., and when warmed with *p*-nitrobenzoyl chloride was converted into a solid ester, which separated from alcohol in small, colourless needles, m. p. 91° (Found: C, 67.0; H, 5.45.  $C_{16}H_{15}O_4N$  requires C, 67.3; H, 5.3%).

With piperonal, the amine formed a beautifully crystalline condensation product, m. p. 107°, only sparingly soluble even in hot alcohol (Found: C, 76.7; H, 6.55.  $C_{17}H_{17}O_2N$  requires C, 76.4; H, 6.4%).

$\beta$ -*p*-Tolylethylmethylamine.—The piperonal compound was heated in a sealed tube with an excess of methyl iodide in the manner previously described. The hydriodide of the secondary base, obtained on decomposition of the product with aqueous alcohol, had m. p. 149°. From this the free base was obtained, b. p. 96°/12 mm. (Found: C, 80.4; H, 10.25; N, 9.4.  $C_{10}H_{15}N$  requires C, 80.5; H, 10.1; N, 9.4%).

The hydrochloride is readily soluble in most solvents, but does not exhibit the extreme solubility of the meta-isomeride. It separates from cold alcohol in plates, m. p. 191°. The picrate forms deep orange prisms, m. p. 135°, from alcohol (Found: N, 14.7.  $C_{16}H_{18}O_7N_4$  requires N, 14.8%).

*p*-Methylstyrene.— $\beta$ -*p*-Tolylethylamine hydriodide is readily converted into the hydrocarbon by boiling with 25% methyl-alcoholic potash.

*p*-Methylstyrene has b. p. 59–60°/12 mm. and does not appear to undergo polymerisation as rapidly as the meta-isomeride (Found: C, 91.2; H, 8.7.  $C_9H_{10}$  requires C, 91.5; H, 8.5%).

Treated in carbon disulphide solution with the equivalent of two atoms of bromine, it is converted into  $\alpha\beta$ -dibromo- $\alpha$ -*p*-tolylethane, m. p. 46° (compare Klages and Keil, *loc. cit.*) (Found: Br, 57.15. Calc., Br, 57.6%).

My thanks are due to the Ramsay Memorial Trustees for a Fellowship during the tenure of which this work was carried out. I also wish to thank Professor W. H. Perkin for his interest and advice and Dr. R. D. Haworth for some valuable suggestions.

LXVIII.—*The Action of Hydrogen Fluoride on Compounds of Selenium and Tellurium. Part II. Tellurium Dioxide.*

By EDMUND BRYDGES RUDEHALL PRIDEAUX and  
JOHN O'NEIL MILLOTT.

THE action of hydrofluoric acid upon tellurium dioxide was studied by Metzner (*Ann. Chim. Phys.*, 1898, 15, 203). The oxide dissolved in the 43–55% acid. On cooling to about  $-50^{\circ}$ , crystals were obtained which contained 53% of hydrogen fluoride. The solutions crystallised on evaporation to small bulk, and successive crops corresponded best with the formulæ  $2\text{TeF}_4 \cdot 3\text{TeO}_2 \cdot 6\text{H}_2\text{O}$  and  $\text{TeF}_4 \cdot \text{TeO}_2 \cdot 2\text{H}_2\text{O}$ , the analyses of the latter compound being the more concordant and agreeing better with the formula assigned. The mother-liquor from this preparation was treated with hydrofluoric acid "pur." (from potassium hydrogen fluoride) and cooled to  $-70^{\circ}$ . It then formed transparent crystals containing 3.8 atoms of fluorine for each atom of tellurium. This compound was regarded as  $\text{TeF}_4$ . The author remarks that its preparation in the pure state would require very concentrated acid. We have used anhydrous hydrogen fluoride throughout our investigation, but have not so far observed the crystallisation of this compound. We have, however, confined our experiments mainly to the preparation of that fluoride which is obtained at the ordinary temperature.

EXPERIMENTAL.

Tellurium, supplied by the courtesy of the Baltimore Copper Company, was dissolved in nitric acid, and the solution evaporated to dryness. The product was slightly green owing to the presence of copper, which was removed by fusion with sodium carbonate and extraction with water followed by filtration. The solution was made faintly acid with nitric acid, and the precipitated tellurous acid was filtered off, dried at  $100^{\circ}$ , heated to its melting point, and powdered.

The anhydrous hydrogen fluoride, prepared as already described (Part I, this vol., p. 167), was passed over the dioxide in a platinum boat or crucible, contained in a copper tube or copper-plated cylinder, respectively. A colourless liquid was produced and a white solid, consisting apparently of unchanged tellurium dioxide, remained. This dissolved completely in excess of hydrogen fluoride. The liquid was exposed for several days in a vacuum desiccator, covered inside with ceresin and containing calcium chloride and solid sodium hydroxide. It became slightly more viscous and remained clear.

On cooling to  $-70^{\circ}$ , it became very viscous, but no crystals appeared on stirring and rubbing. After standing for another day, it suddenly set to a mass of white crystals. This is the product A mentioned below.

The preparation was repeated with slight variations. The hydrogen fluoride vapour was passed until some of the oxide had dissolved and some had been converted into silky crystals, which adhered firmly to the crucible. The liquid was then decanted into a platinum capsule. The undissolved dioxide and the silky crystals were dissolved in more liquid hydrogen fluoride which had been condensed in a platinum bottle. Both solutions were placed at once in the desiccator described above, which was then evacuated. After about 2 days, a mass of white nodules of radiating crystalline structure separated from each solution. This is sample B.

These crystals were kept, in a desiccator, unchanged for days at atmospheric pressure. When the desiccator was evacuated over phosphorus pentoxide for a night, 0.5525 g. of the substance lost only 3 mg. But when this treatment was continued for several days (sample B1) or when the compound was kept over alkali in a desiccator for months (sample A1), the composition changed in the manner indicated by the analyses given below.

*Analysis.*—Since the accurate gravimetric estimation of fluoride in the presence of tellurite is difficult (Metzner, *loc. cit.*), we have devised a method of estimating it as hydrogen fluoride after hydrolysis. When a solution of tellurous acid in dilute hydrofluoric acid is titrated with alkali in the presence of *p*-nitrophenol, precipitation of tellurous acid begins at once and continues until the indicator turns yellow. When tellurous acid is suspended in water, a single drop of alkali produces this colour change. Therefore, on account of its sparing solubility, the tellurous acid gives a solution of  $[H^{+}] = 1 \times 10^{-5}$  or even less. A weighed amount of hydrofluoric acid, when titrated in the presence of tellurous acid, required exactly the same amount of alkali as the same weight of hydrofluoric acid when titrated alone. Tellurous acid, therefore, can be disregarded at the *p*-nitrophenol end-point. Although this titration gives concordant figures, these do not, as shown in Part I (*loc. cit.*), correspond with the absolute amount of hydrofluoric acid present until multiplied by a factor 1.03.

The samples were analysed after being crushed and rubbed between filter-paper.

Tellurium was estimated as usual after precipitation by sulphur dioxide from a hydrochloric acid solution.\*

\* In the volumetric analysis, the titrated liquid was proved to be free from tellurium, and the precipitate free from fluoride.

Sample A : 0.273 g. required 28.57 c.c. of *N*/10-alkali and gave 0.1805 g. of tellurium. Sample B : 0.9005 g. required 92.3 c.c. of *N*/10-alkali, and 0.382 g. gave 0.2545 g. of tellurium.

	A.	B.	A1.	B1.
% Te	66.1	66.6	68.7	70.2
% F	20.4	20.0	18.6	18.9

$\text{TeF}_4 \cdot \text{TeO}_2 \cdot \text{H}_2\text{O}$  requires Te, 66.8; F, 20.0%.  $\text{TeF}_4 \cdot \text{TeO}_2 \cdot 2\text{H}_2\text{O}$  requires Te, 63.8; F, 19.1%.

The use of anhydrous hydrogen fluoride therefore leads to a compound different from either of those prepared by Metzner. In the presence of more water, more hydrated compounds would doubtless be formed. Since the only water present in our experiments was that formed in the reaction, it is evident that at least one molecule is thus produced and evaporates in the desiccator. The other molecule, if it is really eliminated, is held as water of crystallisation but has only a low vapour pressure.

We regard this compound as the least hydrated which it is possible to prepare from the dioxide and hydrogen fluoride with subsequent evaporation. It is not at present possible to decide between the formulæ  $\text{TeF}_4 \cdot \text{TeO}_2 \cdot \text{H}_2\text{O}$ ,  $2\text{TeOF}_2 \cdot \text{H}_2\text{O}$ , and  $\text{TeOF}_2 \cdot \text{TeO}_2 \cdot 2\text{HF}$ . In material kept in the desiccator after a long time (A1), or in a vacuum over phosphorus pentoxide (B1), the percentage of tellurium increases considerably, whilst the percentage of fluorine diminishes only slightly. These results suggest that, under the conditions employed, more water is lost than hydrogen fluoride, so that the compound behaves rather as a hydrate than as a fluoride.

One of us wishes to repeat his grateful acknowledgment to the Royal Society of a grant which has supplied some of the apparatus required for this and the preceding research. The other (J. O'N. M.) wishes to thank the Department of Scientific and Industrial Research for a maintenance grant.

UNIVERSITY COLLEGE, NOTTINGHAM.

[Received, November 9th, 1925.]

## LXIX.—*The Action of Alcoholic Potassium Hydroxide upon Chloronitrobenzene.*

By DONALD HENRY RICHARDSON.

LEUMANN (*Ber.*, 1872, 5, 910) obtained *pp'*-dichloroazoxybenzene by boiling *p*-chloronitrobenzene with alcoholic potash. Willgerodt (*Ber.*, 1879, 12, 767) showed that *p*-nitrophenetole and *p*-nitrophenol also are products of the reaction, and later (*Ber.*, 1882, 15, 1002) found that dilution of the alcohol with water diminishes the form-

ation of dichloroazoxybenzene. Blom (*Helv. Chim. Acta*, 1921, 4, 297) studied the kinetics of the reaction and found that by using aqueous alcohol at 70° no dichloroazoxybenzene is formed.

In an investigation with the object of discovering the conditions under which the maximum yield of nitrophenetole free from chloronitrobenzene could be most easily obtained, it was found that the formation of dichloroazoxybenzene could be avoided without dilution of the alcohol if the temperature was reduced to 60°, and the alkali strength to 0.2 normal. Excellent results having been obtained on the small scale, some large-scale trials were made in which 362 lb. of chloronitrobenzene were heated at 60° with 145 gallons of 0.2*N*-95% alcoholic soda, the alkali strength being maintained by the addition of the estimated amount of the powdered solid at frequent intervals. At the first attempt, in spite of considerable accidental loss, the yield amounted to 277 lb. of nitrophenetole, free from chloronitrobenzene, and containing only 3.4% of dichloroazoxybenzene, but in all subsequent experiments at least 17% of the theoretical amount of azoxy-compound was formed. It was not realised at the time that the alcohol used in the first experiment had been specially purified for pharmaceutical purposes, and the systematic investigation to be described was undertaken to discover the cause of the failure of the process.

The conclusions are as follows :

1. The presence of as much as 0.1% of acetaldehyde in the alcohol causes considerable reduction of the chloronitrobenzene, and the larger the percentage of acetaldehyde, the greater is the yield of dichloroazoxybenzene.

2. The formation of dichloroazoxybenzene may be avoided without dilution of the alcohol with water if chloronitrobenzene is heated for 140 hours at 60° in a 0.5*N*-solution of caustic potash in 95% ethyl alcohol free from acetaldehyde.

3. Under these conditions, 92% of the theoretical yield of pure *p*-nitrophenetole, 90% of *o*-nitrophenetole, and 96% of *p*-nitroanisole (using methyl alcohol) may be obtained, nitrophenol being the only by-product.

4. As the temperature or alkali concentration is raised, dichloroazoxybenzene is formed in rapidly increasing amount, even if the alcohol is free from acetaldehyde.

5. Under conditions resulting in the formation of a considerable amount of dichloroazoxybenzene, *p*-chloroaniline is also formed in appreciable quantity.

6. Although the reducing action of alcoholic alkali is decreased by dilution of the alcohol with water (Willgerodt, *loc. cit.*), this diminishes the rate of conversion of chloronitrobenzene into nitrophenetole.

7. Nitrophenol is always a by-product when chloronitrobenzene is heated with alcoholic alkali solution, and the yield is increased as the temperature and the strength of alkali are raised, but is not greatly affected by dilution of the alcohol with water.

### EXPERIMENTAL.

Five series of experiments were carried out, in each of which only one factor was subjected to variation. Pure chloronitrobenzene was heated at a constant temperature in a large excess of a standard solution of potash in alcohol of known strength. After a noted time, the solution was nearly neutralised with sulphuric acid, the alcohol distilled off, and the nitrophenetole isolated by blowing steam through the residue. Its weight and melting point were determined after filtering off and drying over calcium chloride in a vacuum desiccator. Nitrophenetole was appreciably volatile in alcohol vapour, and was estimated in the alcohol recovered by evaporating a known volume in a vacuum desiccator at laboratory temperature, and weighing the residue. Ether extraction of the filtered steam distillate showed that nitrophenetole was soluble in water at 15° to the extent of 0.11 g. per litre. The insoluble dichloroazoxybenzene was filtered off from the residual liquors, washed, dried, and weighed without further purification. After evaporation to smaller bulk, the filtrate and washings were acidified with sulphuric acid and the *p*-nitrophenol was extracted with ether.

The conditions in each series of experiments are described below, and the yields given in tabular form.

*Series 1.—Variation in strength of alkali.* A solution of caustic potash in 95% alcohol was standardised and diluted with the calculated volume of alcohol so that 250 c.c. each of a 0.1, 0.2, 0.3, 0.4, and 0.5 *N*-solution of potash were obtained. Exactly 4 g. of pure chloronitrobenzene were dissolved in each solution, and all were heated together in a thermostat at 60°. After 187 hours' heating, 5 c.c. of each solution were titrated with *N*/10-sulphuric acid to determine the final concentration of the potash, and the reaction products analysed as previously described. The results are tabulated below:

Experiment.	1.	2.	3.	4.	5.
Strength of KOH ( <i>N</i> ): initial ...	0.1	0.2	0.3	0.4	0.5
final ...	0.013	0.064	0.165	0.226	0.405
Wt. of nitrophenetole (g.) .....	3.19	3.61	3.24	2.86	1.91
M. p. of nitrophenetole .....	46°	57°	57°	57°	57°
Wt. of dichloroazoxybenzene (g.) ..	0.02	0.10	0.37	0.70	0.92
Wt. of <i>p</i> -nitrophenol (g.) .....	0.04	0.09	0.13	0.28	0.50
% Theoretical yield:					
Nitrophenetole .....	75.3	85.1	76.4	67.5	44.8
Dichloroazoxybenzene .....	0.6	2.9	10.9	20.6	27.1
Nitrophenol .....	1.1	2.6	3.7	7.9	14.2
Total .....	77.0	90.6	91.0	96.0	86.1

The low melting point of the nitrophenetole obtained in experiment 1 showed that some unchanged chloronitrobenzene remained, as would be expected in view of the small final concentration of the potash in this case. A considerable amount of tarry matter was noted during the extraction of the nitrophenol in experiment 5, and a smaller amount in experiment 4. It was not found possible to account for the remainder of the yield at this point.

The results indicated that an increase in the concentration of alkali causes a greater production of both dichloroazoxybenzene and nitrophenol, this being most marked in the case of the azoxy-compound.

*Series 2.—Variation in strength of alcohol.* Five 0.5*N*-potash solutions were prepared, one in absolute alcohol, and the other four in 95% alcohol diluted with noted volumes of water to a total of 250 c.c. each. The five solutions were heated in a constant-temperature water-bath at 60° for 24 hours, after which 4 g. of chloronitrobenzene were dissolved in each and the heating was continued for 187 hours.

The products were analysed with the following results :

Experiment.	6.	7.	8.	9.	10.
Strength of alcohol (%) .....	100	87	80	70	60
Wt. of nitrophenetole (g.) .....	3.834	3.497	3.453	3.348	3.019
M. p. of nitrophenetole .....	57°	57°	57°	56°	56°

Nitrophenol .....	?	13.7	13.8	13.3	12.9
Total .....	(91.1)	100.0	99.8	94.3	87.2

The melting point of the nitrophenetole obtained in experiments 9 and 10 showed that a small amount of chloronitrobenzene remained unchanged, indicating that dilution of the alcohol retards the rate of conversion of chloronitrobenzene into nitrophenetole. The most remarkable result was the very small yield of dichloroazoxybenzene in all five experiments, in spite of a concentration of potash equal to that in experiment 5, in which a 27% yield of the azoxy-compound was obtained.

The use of absolute alcohol having resulted in the smallest production of dichloroazoxybenzene, it seemed probable that some impurity in the alcohol was the cause of the formation of the azoxy-compound. Since the chloronitrobenzene is reduced to dichloroazoxybenzene, acetaldehyde would be the most likely impurity to cause this reduction. The preliminary 24 hours' heating of the alcoholic potash before the introduction of the chloronitrobenzene would have at least partly resinified the aldehyde, so accounting

for the small yield of dichloroazoxybenzene in these five experiments. It was noted that a yellow colour developed in the alcoholic potash solutions during the preliminary heating, indicating the formation of aldehyde-resin.

*Series 3.—Effect of acetaldehyde upon the production of dichloroazoxybenzene.* To determine the effect of acetaldehyde upon chloronitrobenzene in alcoholic potash solution, a third series of five experiments was commenced, using 250 c.c. of 0.5 *N*-alkali in 95% alcohol. The chloronitrobenzene was added before heating in experiment 11, but after 66 hours' preliminary heating in experiment 12, while 25 c.c. of hydrogen peroxide solution were added in experiment 13. Methylated spirit known to contain acetaldehyde was used in experiment 14, and 10 c.c. of acetaldehyde were added to the alcohol in experiment 15, in both cases the chloronitrobenzene being added before heating was commenced. The five solutions were heated simultaneously for 235 hours at 60°, and gave the following yields on analysis:

Experiment.	11.	12.	13.	14.	15.
Wt. of nitrophenetole (g.) .....	3.69	3.77	3.58	2.13	0.82
Wt. of dichloroazoxybenzene (g.) .....	0.04	0.02	0.015	0.315	2.29*
Wt. of nitrophenol (g.) .....	0.43	0.41	0.52	0.68†	0.67†
% Theoretical yield:

Total .....	100.4	101.0	99.6	79.0	105.8.

\* Includes aldehyde-resin.

† Includes tar.

The very large yield of dichloroazoxybenzene in the presence of acetaldehyde left little cause for doubt that the latter plays an important part in the reduction of the chloronitrobenzene. It was resolved to test this conclusion by heating chloronitrobenzene with alcoholic potash containing known small quantities of acetaldehyde.

Acetaldehyde was eliminated from ethyl alcohol as completely as possible by refluxing with 0.2% of *m*-phenylenediamine hydrochloride for 12 hours, after which the alcohol was distilled off through a fractionating column, the first 100 c.c. of the distillate being rejected. The product gave no colour on standing with Schiff's reagent, and remained practically colourless after heating for 24 hours with 0.5*N*-potash at 60°.

A standard solution of acetaldehyde was prepared by dissolving about 10 c.c. of freshly distilled acetaldehyde (b. p. 21°) in 100 c.c. of aldehyde-free alcohol and estimating its strength by the sodium sulphite method.

*Series 4.—Effect of variation in concentration of aldehyde.* Three solutions were prepared containing measured volumes of the standard acetaldehyde solution diluted to 250 c.c. with aldehyde-free

alcohol in which was dissolved sufficient potash to give 250 c.c. of a 0.5*N*-solution. Four g. of chloronitrobenzene were dissolved in each, and all were heated simultaneously with a blank experiment, using the same aldehyde-free alcohol, for 160 hours at 60°. The following table gives the yields in the four experiments :

Experiment.	16.	17.	18.	19.
Strength of acetaldehyde (%) .....	0.0	0.14	0.2	0.67
Wt. of nitrophenetole (g.) .....	3.902	3.434	2.685	1.121
Wt. of dichloroazoxybenzene (g.) ...	Nil	0.317	0.536	2.178†
Wt. of nitrophenol (g.) .....	0.276	0.210	0.405*	0.463*
% Theoretical yield :				
Nitrophenetole .....	92.0	81.0	63.3	26.4
Dichloroazoxybenzene .....	0.0	9.3	15.8	64.2†
Nitrophenol .....	7.8	5.9	11.5*	13.3*
Total .....	99.8	96.2	90.6	103.9

\* Includes tar.

† Contained aldehyde-resin.

From these results, it is evident that the complete elimination of acetaldehyde from the reaction mixture prevents the formation of dichloroazoxybenzene, under the conditions obtaining in these experiments. As little as 0.1% of acetaldehyde appears to be capable of causing a considerable amount of reduction of the chloronitrobenzene, and an increase in the concentration of the aldehyde, within the limits investigated, causes a corresponding increase in the formation of dichloroazoxybenzene.

Experiments were now made to determine whether, with the use of aldehyde-free alcohol, the temperature and the alkali concentration could be increased without the formation of dichloroazoxybenzene. It had been noted that whenever the latter appeared in the reaction product in any quantity, the total yields of nitrophenetole, dichloroazoxybenzene, and nitrophenol did not account for the whole of the chloronitrobenzene employed. It was thought possible that a small amount of the latter might have become completely reduced to *p*-chloroaniline.

To investigate this possibility, the solutions obtained in the following series of experiments were acidified with dilute sulphuric acid before distilling off the alcohol. After steam distillation of the nitrophenetole and filtration of the dichloroazoxybenzene, the acid filtrate was made alkaline and distilled to a small volume. The distillate was extracted with ether, and the residue after its evaporation weighed.

The residue melted at 66°, was soluble in dilute acids and reprecipitated by alkali, and could be diazotised and coupled with  $\beta$ -naphthol to give a red dye. It was acetylated with acetyl chloride, and the product melted at 171–173°. After recrystallisation from dilute alcohol, it melted sharply at 177°. These facts indicated that the residue was *p*-chloroaniline.

*Series 5.—Effect of higher temperature, and greater concentration of alkali, on the reaction of chloronitrobenzene with aldehyde-free alcoholic potash.* Five solutions of potash in 250 c.c. of aldehyde-free alcohol were prepared so that two contained 0.5*N*-alkali, and the other three 1.0, 1.5, and 2.0 *N*-alkali, respectively. In each were dissolved 4 g. of chloronitrobenzene, and, whilst one of the 0.5 *N*-solutions was refluxed for 24 hours, the other four were heated for 140 hours at 60°.

The yields of nitrophenetole, nitrophenol, dichloroazoxybenzene, and chloroaniline in each of the five experiments were estimated as described above, with the following results :

Experiment.	20.	21.	22.	23.	24.
Strength of potash ( <i>N</i> ) .....	0.5	0.5	1.0	1.5	2.0
Wt. of nitrophenetole (g.) .....	1.241	3.800	2.134	0.778	0.328
Wt. of nitrophenol (g.) .....	0.553	0.279	0.434	0.364	0.304
Wt. of dichloroazoxybenzene (g.) .....	1.526	Nil	0.988	2.243	2.372
Wt. of <i>p</i> -chloroaniline (g.) .....	0.205	Nil	0.338	0.293	0.572
% Theoretical yield :					
Nitrophenetole.....	29.3	89.6	50.3	18.4	7.7
Dichloroazoxybenzene .....	45.0	0.0	29.1	66.2	70.0
Chloroaniline .....	6.3	0.0	10.4	9.1	17.7
Nitrophenol .....	15.7	7.9	12.3	10.3	8.6
Total .....	96.3	97.5	102.1	104.0	104.0

Refluxed.

The dichloroazoxybenzene  
was very impure.

These results proved conclusively that the absence of aldehyde from the alcohol does not preclude the formation of dichloroazoxybenzene under all conditions. They confirm the conclusion that higher temperature and higher concentration of alkali favour the reduction of the chloronitrobenzene, an appreciable quantity of which becomes completely reduced to *p*-chloroaniline whenever dichloroazoxybenzene is formed to any extent.

In order to determine the minimum time required for the conversion of chloronitrobenzene into nitrophenetole under the conditions giving the maximum yield, 63 g. of chloronitrobenzene in 2 litres of 0.5*N*-95% aldehyde-free alcoholic potash were heated at 60°, whilst 5 c.c. of the solution were titrated at intervals with *N*/10-acid, and the melting point of the precipitated chloronitrobenzene-nitrophenetole mixture was determined.

#### Experiment 25.

Time (hours).	<i>N</i> /10- $\text{H}_2\text{SO}_4$ (c.c.) for 5 c.c.	Strength of KOH ( <i>N</i> ).	Equivs. of KOH M. neutralised.	p. of pptd. product.
0	25	0.5	0.0	83°
28½	18.45	0.369	0.655	49—51
50	16.85	0.337	0.815	54—55
78½	15.75	0.315	0.925	55—56
142	15.0	0.300	1.0	56—57

After 142 hours, the whole solution was neutralised with dilute sulphuric acid, and the alcohol distilled off on the water-bath. The residue of nitrophenetole was well washed with dilute caustic soda to remove nitrophenol, then with water, and dried over calcium chloride in a vacuum desiccator. The mother-liquors and washings were evaporated down, acidified, and extracted with ether.

Yield :	61.1 g. of nitrophenetole, m. p. 56.5°	= 91.5% of theor.
	3.3 g. of nitrophenol	= 6.0 " "
	20 c.c. of solution withdrawn for titration	= 1.0 " "
	Total	= 98.5 " "

This experiment confirmed the conclusion that *p*-chloronitrobenzene can be converted into nitrophenetole by heating at 60° for approximately 140 hours in 0.5 *N*-95% alcoholic potash, without the formation of any dichloroazoxybenzene, if the alcohol is free from acetaldehyde.

Under similar conditions, 65 g. of *o*-chloronitrobenzene, dissolved in 1 litre of aldehyde-free ethyl alcohol, gave a yield of 62.2 g. of *o*-nitrophenetole (90.3% of the theoretical), whilst 4 g. of *p*-chloronitrobenzene in 250 c.c. of methyl alcohol gave 3.750 g. of *p*-nitroanisole (96.5% of the theoretical).

No dichloroazoxybenzene was formed in either case.

NORTHERN POLYTECHNIC, LONDON, N.7. [Received, October 30th, 1925.]

## LXX.—Action of Mercurous Nitrate on Chloroauric Acid.

By WILLIAM BRANCH POLLARD.

THE action of mercurous nitrate on chloroauric acid has been stated to give (1) gold, or a mixture of gold and mercurous chloride (Proust, *Nicholson's J.*, 1806, **13**, 244); (2) a combination of aurous and mercuric oxides (Fischer, *Schweigger's J.*, 1829, **56**, 363), (3) aurous oxide (Figuier, *Ann. Chim. Phys.*, 1844, **11**, 336).

The author has studied the reaction under two distinct conditions; first, the reaction which occurs when an excess of some halide is present, and, secondly, the reaction which occurs in the absence of halides.

### EXPERIMENTAL.

*Action of Mercurous Nitrate on Chloroauric Acid in Presence of Halides.*—Mercurous nitrate was prepared by shaking a solution of mercuric nitrate in dilute nitric acid with excess of mercury, a little carbamide being added to prevent the formation of nitrites. The solution was titrated as described below, and then diluted until 50 c.c. reduced exactly 0.5 g. of gold.

Gold (0.5 g.) was dissolved in 4 c.c. of aqua regia (3 : 1). The fumes were blown out with a current of air, but the excess of nitric and hydrochloric acids was not removed. The solution was diluted with 50 c.c. of water, 1 c.c. of concentrated hydrochloric acid was added, and mercurous nitrate solution run in. The black colour of the precipitate of metallic gold that instantly formed slowly changed to brown. The particles of the precipitate cohered on shaking, leaving the liquid clear. As the end-point was approached, the yellow colour of the chlorauric acid disappeared, the precipitate took on a transient purple tint, and finally white, mercurous chloride formed. During the titration, no evidence of reduction to the aurous state was obtained, even when a large amount of alkali-metal chloride was present (Diemer, *J. Amer. Chem. Soc.*, 1913, **35**, 552). Addition of such chlorides or of bromides or iodides appears to increase the velocity of the reaction. The amount of mercurous nitrate required to precipitate the gold when in combination with chlorine, bromine, or iodine was, however, practically identical in the three cases, provided there was sufficient halide to combine with the whole of the mercury present.

In order to obtain the quantitative relation between mercurous nitrate and chlorauric acid, the volume of solution required to precipitate 0.5 g. of pure gold was taken and precipitated with sodium chloride. The resulting mercurous chloride was equivalent to 2.0039 g. of mercurous nitrate as against 1.9947 g. required by the equation :

To test whether this relation held at very great dilutions, the mercurous nitrate and chlorauric acid were titrated at a dilution one hundred times as great as that employed above. The gold separated in the red, colloidal condition. It was flocculated with a little hydrochloric acid, and the end-point found by addition of o-tolidine (*Trans. Inst. Min. Met.*, 1923, **32**, 242), which gives a yellow colour with one part of chlorauric acid in twenty million parts of solution. At this dilution, the relationship found above still held.

From this experiment it is inferred that the precipitate which forms when strong solutions react consists of colloidal gold which has been flocculated by the acids and salts present in the liquid, and this would also account for the very marked adsorption effects which have been observed.

When 0.5 g. of the precipitated gold was shaken with a solution containing a few mg. of chlorauric acid, this substance was so completely adsorbed that it could not be detected in the solution.

The adsorbed substance reacted quite readily with solutions of reducing agents when these were applied to the precipitate.

When solutions of certain dyes were shaken with the precipitate, these became colourless, and in the case of methyl-red this was adsorbed more readily in an acid than in an alkaline solution.

In the course of these experiments it was noticed that if a very small amount of brucine or one of the quinine alkaloids was added to the chloroauric acid before precipitation with mercurous nitrate, the gold remained dispersed through the liquid and did not flocculate. Up to the present this result has not been observed except with the class of substances mentioned.

*Action of Mercurous Nitrate on Chloroauric Acid in the Absence of Halides.*—Gold (0.5 g.) was converted into chloroauric acid, and all excess of nitric and hydrochloric acids was removed; 50 c.c. of water were added and mercurous nitrate solution was run in. The precipitate did not "clear" on shaking and the end-point was difficult to find, but much less mercurous nitrate was needed to precipitate the gold completely in the absence of halides than in their presence.

To a fresh solution of chloroauric acid a little mercurous nitrate was added, in order to precipitate only a small part of the gold. The black precipitate, on standing over-night in the solution, was converted into metallic gold. The gold was separated from the solution, and a further amount of mercurous nitrate added. The black, colloidal precipitate which formed was centrifuged, and the clear solution, which had changed from yellow to reddish-brown, was further examined. When heated, a reddish-brown precipitate resembling ferric hydroxide formed, and the same substance was deposited when the solution was kept.

The substance was difficult to filter and wash, and after drying in a vacuum over sulphuric acid gained weight when exposed to the air. When heated, it gave off oxygen, water, and mercuric chloride, and left a residue of metallic gold. It dissolved in hydrochloric acid with the reformation of chloroauric acid.

If the equation for the reaction between mercurous nitrate and chloroauric acid is written omitting the hydrochloric acid from the left-hand side, this will require the addition of mercuric nitrate to the right-hand side:

Now Proust (*loc. cit.*, p. 224) showed that when "gold chloride" was added to an excess of mercuric nitrate solution a yellow precipitate formed. This compound gave oxygen, water, mercuric chloride, mercurous chloride, and gold on heating. The brown

compound prepared by the author gave no mercurous chloride when heated.

On adding a small amount of mercuric nitrate to chloroauric acid, a slight darkening of the solution occurred. Further additions produced a reddish-brown solution similar to that previously obtained after centrifuging. When heated, a brown, colloidal precipitate separated identical with that previously described. The brown substance is therefore formed when chloroauric acid is in excess and Proust's yellow substance is formed when mercuric nitrate is in excess.

Proust explained the formation of his compound as being due to the very strong affinity of mercury for chlorine, which it is able to displace even from chloroauric acid.

Jacobson (*Compt. rend.*, 1908, **146**, 1213) has shown that silver nitrate also can remove chlorine from chloroauric acid with formation of a brown basic compound :

Attempts to discover the exact composition of the brown substance failed, as different preparations did not show sufficient agreement among themselves, and it is doubtful whether it has been prepared as yet in a state of purity. The following results, obtained by heating the substance in a Penfield tube, may, however, be taken as an approximate indication of its nature: Loss on heating (oxygen), 9.42;  $\text{H}_2\text{O}$ , 7.18;  $\text{HgCl}_2$ , 19.71; Gold (by difference), 63.69%.

The black precipitate formed by the action of mercurous nitrate on chloroauric acid which had been centrifuged out of the solution was now examined to see whether it consisted of a mixture of gold and the brown substance. After washing and drying, it was heated and gave off oxygen, water, and mercuric chloride and left a residue of gold. When it was treated with hydrochloric acid, chloroauric acid passed into solution and a residue of metallic gold was left. The black precipitate may therefore be regarded as a kind of "Purple of Cassius" in which stannic acid is replaced by the brown substance. It results from two reactions occurring simultaneously, which explains why, in the absence of halides, less mercurous nitrate is required to remove the gold completely from solution.

The author takes this opportunity of thanking Professor Carpenter and the staff of the Royal School of Mines for all the facilities which he has been afforded.

LXXI.—*Halogenation of 2:6-Dimethylbenzbisthiazole and of 3:5-Diphenylimino-2:4-diphenyltetrahydro-1:2:4-thiodiazole.*

By ROBERT FERGUS HUNTER.

THE slight unsaturation of the nitrogen atoms of the heterocyclic nuclei in 1:1-bisbenzthiazole (I) and the consequent great lability of the tetrabromide (II), which is so unstable that it decomposes appreciably into the original bisthiazole (I) and bromine on exposure to air for a few minutes (J., 1925, 127, 1319), must, in view of the stability of 1-substituted benzthiazole bromides such as 1-phenylbenzthiazole tetrabromide (*loc. cit.*), clearly be due to the presence of the second thiazole nucleus.

That is to say that the two thiazole nuclei joined as in (I) by way of their  $\mu$ -carbon atoms, mutually "saturate" each other.

Regarding this effect, it seems reasonable to suggest that the phenomenon is due to partial self-neutralisation of the valencies of the nitrogen atoms after the manner in which the central pairs of partial valencies in conjugated systems neutralise each other according to Thiele's theory (*Annalen*, 1899, 306, 87). This supposition can be represented by means of a dotted line as in (I).

In view of this, it was clearly desirable to examine the unsaturation of the benzbisthiazole system in which the thiazole nuclei are separated from each other by a benzene ring which should inhibit or prevent the self-saturation effect displayed by 1:1-bisbenzthiazole. The example chosen was 2:6-dimethylbenzbisthiazole (III) (Edge, J., 1922, 121, 772).

The reactive nitrogen atoms in this case are not linked by way of the  $\cdot\text{N}:\text{C}:\text{C}:\text{N}\cdot$  system, but this is immaterial, since the supposed double bonds in the thiazole nucleus are aromatic in character, and the usual formula for the thiazole ring really can represent only one

of the transient phases of the intra-annular semi-aromatic heterocyclic nucleus.

2 : 6-Dimethylbenzbisthiazole in presence of excess of bromine readily passes into a bright yellowish-orange, relatively stable *hexabromide*, the most probable constitution of which is (IV). This bromo-additive compound is quite devoid of the properties of 1 : 1-bisbenzthiazole tetrabromide; for instance, it only loses appreciable halogen on exposure to the atmosphere for several days and is in many ways similar to the stable tribromo-additive compounds of the arylaminobenzthiazoles (J., 1925, 127, 2024). The self-saturation effect of the thiazole nuclei is therefore removed by the intervention of the common aromatic nucleus. There is, however, another effect which arises in connexion with the unsaturation of the benzbisthiazole complex, namely, the alternation of the affinity effect of carbon chains (Flürscheim, *J. pr. Chem.*, 1902, 66, 321; J., 1909, 95, 718; 1910, 97, 84; Ingold, J., 1925, 127, 513), which operates in the manner described hereunder.

In the bromination of 2 : 6-dimethylbenzbisthiazole, the first reaction must necessarily consist in the addition of bromine to *one* of the ring nitrogen atoms. The consequent formation of the  $\text{:NBr}_2$  group at once causes an alternation in affinity along the carbon chain connected to the second nitrogen atom, which therefore becomes partly saturated. Now there can be very little doubt, from the facts already described in connexion with the bromo-additive compounds of the benzthiazoles (*loc. cit.*), that the *centre* of unsaturation in a thiazole ring is the *nitrogen* atom. The obvious result is that in the bromination of the benzbisthiazole system one thiazole nucleus is much more *reactive* than the other, and hence one ring is responsible for the addition of four bromine atoms, whilst the other is fully satisfied by the addition of two. In this connexion, it does not matter whether the hexabromide has the constitution (IV) or the less probable formula (V).

The above is well borne out by the behaviour of 2 : 6-dimethylbenzbisthiazole towards other reagents such as methyl iodide; even in the presence of a large excess of methyl iodide, it will form only a monomethiodide (Edge, *loc. cit.*).

Since benzbisthiazole is in a sense a dithio-di-azo-heterocyclic compound, it was of interest to examine the thiodiazole complex. The example chosen was 3 : 5-diphenylimino-2 : 4-diphenyltetrahydro-1 : 2 : 4-thiodiazole (Hector, *Ber.*, 1890, 23, 357), which would be expected to pass under suitable conditions into the octabromide (VI).

Actually an *octabromide* having the expected properties was readily isolated as a bright red, crystalline compound, which gradually lost bromine on exposure to the atmosphere and was reduced by sulphurous acid (Hunter, *loc. cit.*) with regeneration of the original thiodiazole.

There are, however, alternative formulæ for this compound involving the  $\text{Br}\cdot\text{N}\cdot\text{Br}$   $\begin{smallmatrix} \text{Br} \\ | \\ \text{N} \\ | \\ \text{Br} \end{smallmatrix}$  group. In view of the lesser affinity of iodine as compared with bromine for sulphur (compare Bogert and Abrahamson, *J. Amer. Chem. Soc.*, 1922, **44**, 826) and the facility iodine atoms have for combining with one another, which is greater even than that of bromine atoms, if the octabromide is indeed (VI), it might be expected that the thiodiazole on treatment with iodine would yield an additive compound of a *lower* order; whilst if the existence of the octabromide were due to the presence of the  $\text{Br}\cdot\text{N}\cdot\text{Br}$  group, an octaiodide would be formed. Actually the only iodo-additive compound isolated was a *hexaiodide*, which is best represented by the formula (VII). Its formation is by no means a crucial test, but is in favour of the formulæ suggested for these additive compounds.

#### EXPERIMENTAL.

Dithioacetyl-*m*-phenylenediamine was prepared from diacetyl-*m*-phenylenediamine (20 g.) and oxidised with potassium ferricyanide according to Edge's directions (*loc. cit.*). The product isolated from the ethereal extract was allowed to crystallise spontaneously from light petroleum-alcohol and recrystallised (without distillation) from light petroleum, 2 : 6-dimethylbenzbisthiazole being thus obtained in shining prisms, *m. p.* 105°.

2 : 6-Dimethylbenzbisthiazole *Hexabromide*.—The benzbisthiazole (0.25 g.) dissolved in chloroform (5 c.c.) was slowly treated with bromine (0.3 c.c.). The solution was then either warmed and rapidly treated with a further quantity of bromine (0.3 c.c.), when the *hexabromide* crystallised, or the addition was continued in the usual way and the resulting solution warmed, cooled, and scratched. The *hexabromide* crystallised in small, yellowish-orange prisms, which were dried in a vacuum over phosphorus pentoxide; *m. p.* 117–118° (decomp.) (Found: Br, 68.2.  $\text{C}_{10}\text{H}_8\text{N}_2\text{Br}_6\text{S}_2$  requires Br, 68.6%). The yield was nearly quantitative. The hexabromide showed no change on exposure to air for several hours; on exposure for 5 days, the compound lost appreciable bromine, very slowly becoming red. It was reduced in the usual way by sulphurous acid (*loc. cit.*). It dissolved readily in warm alcohol; on dilution and warming, acetaldehyde was evolved. A pure bromo-substitution derivative could not be isolated.

3 : 5-Diphenylimino-2 : 4-diphenyltetrahydro-1 : 2 : 4-thiodiazole.—*s*-Diphenylthiocarbamide (15 g.) dissolved in absolute alcohol (300 c.c.) was gradually treated with bromine until a permanent yellow colour was obtained (Hugershoff, *Ber.*, 1903, **36**, 3121). The solution was filtered from coagulated sulphur into cold water (5 vols.), and the mixture made strongly alkaline with ammonia ( $d$  0.880); the compound then separated in brittle, white granules. On crystallisation from ether, the thiodiazole separated in white plates, m. p. 136°, as recorded in the literature (yield, about 60%).

3 : 5-Diphenylimino-2 : 4-diphenyltetrahydro-1 : 2 : 4-thiodiazole Octabromide.—The thiodiazole (1 g.) dissolved in chloroform (10 c.c.) was gradually treated with bromine (1 c.c.), and the resulting solution warmed and kept  $\frac{1}{2}$  hour. On scratching, the octabromide separated in glistening, orange-red prisms, which were dried in a vacuum over potassium hydroxide; m. p. 103–105° (Found: Br, 66.2.  $C_{26}H_{20}N_4Br_8S$  requires Br, 66.6%). The bromide dissolved in glacial acetic acid, giving a solution which became colourless and evolved bromine and hydrogen bromide on prolonged boiling. The solution, on being made alkaline, furnished a product which crystallised from alcohol, on persistent scratching, in minute prisms, m. p. 200° (decomp.; after sintering at 110°). The quantity was much too small for investigation, but the product was doubtless an impure bromo-substitution derivative (*loc. cit.*).

3 : 5-Diphenylimino-2 : 4-diphenyltetrahydro-1 : 2 : 4-thiodiazole Hexaiodide.—The thiodiazole (3.8 g.) dissolved in 20 c.c. of glacial acetic acid was gradually added to a warm solution of iodine (5 g.) in the same solvent (250 c.c.), and the resulting solution warmed and kept for 3 hours; a part of the iodo-additive compound then separated in small, black, glistening prisms, which were washed with a little acetic acid and dried in a vacuum; m. p. 120°. A second crop separated over-night in shining, black prisms having a dark green reflex, which were thoroughly washed with glacial acetic acid and dried in a vacuum as before; m. p. 122° (decomp.) (Found: I, 66.5.  $C_{26}H_{20}N_4I_6S$  requires I, 66.8%).

The hexaiodide was practically unacted upon by sulphurous acid owing to its insolubility, but was readily reduced by sulphur dioxide in acetic acid solution. It was readily decolorised by sodium thiosulphate [0.1120 g. in glacial acetic acid (redistilled over potassium permanganate) required 27.5 c.c. of 1.97*N*/100-sodium thiosulphate. I, 57.4%]. The iodide was readily soluble in ether, ethyl acetate, and alcohol, but could not be recrystallised.

A number of experiments were also carried out on the halogenation of 3 : 5-di-*p*-tolylimino-2 : 4-di-*p*-tolyltetrahydro-1 : 2 : 4-thiodiazole, m. p. 138°, which was obtained in the same way as the

phenyl derivative (Hugershoff, *loc. cit.*), but definite compounds could not be isolated; bromination and iodination in different solvents and under various conditions led to uncrystallisable gums or resins.

The author desires to express his gratitude to Professor J. F. Thorpe, F.R.S., for the kind interest he has taken in this work.

[Received, November 11th, 1925.]

## LXXII.—Bromination of some 5-Substituted 1-Phenylbenzthiazoles.

By ROBERT FERGUS HUNTER.

THE bromination of 1-phenylbenzthiazole has been investigated by Bogert and Abrahamson (*J. Amer. Chem. Soc.*, 1922, **44**, 826), who obtained a red unstable tetrabromo-additive compound, to which they assigned the constitution (I), which on boiling with dilute acetic acid yielded 5-bromo-1-phenylbenzthiazole.

The tetrabromide thus prepared gradually loses bromine on exposure to air, becoming almost colourless, and is instantaneously reduced to 1-phenylbenzthiazole by sulphurous acid and sodium bisulphite (compare J., 1925, **127**, 1319, 1488, 2023). The compound must therefore be a *perbromide*; and may have the constitution (I) or (II), the latter being analogous to that of the tetrabromides of pyridine and quinoline (Trowbridge, *J. Amer. Chem. Soc.*, 1897, **19**, 558; Grimaux, *Bull. Soc. chim.*, 1882, **38**, 124).

The formation of a *di-iodo*-additive compound and not a *tetraiodo*-derivative by 1-phenylbenzthiazole (*loc. cit.*) is in favour of the formula (I); the slight ionisation of 1-phenylbenzthiazole tetrabromide in glacial acetic acid solutions is, moreover, in accordance with the presence of a "thiazonium" sulphur atom as in (I), but the question cannot be fully discussed until the behaviour of substances such as dimethyl sulphide dibromide (Cahours, *Annalen*, 1865, **135**, 355) has been thoroughly reinvestigated.

The passage of phenylbenzthiazole tetrabromide into 5-bromo-1-phenylbenzthiazole (Bogert and Abrahamson, *loc. cit.*) suggests that there is probably an intimate connexion between the ring nitrogen atom (2) of the fused thiazole nucleus and the carbon atom (5) of the homocyclic ring of the benzthiazole system. The transformation is indeed a sort of "para-migration," and no doubt takes

place by way of a para-bridged intra-annular phase of the benzene ring. It might be expected, therefore, that the substitution of groups of varying polar character on the carbon atom (5) would have a profound effect on the unsaturation of the nitrogen atom (2) as exhibited by a tendency towards the formation of bromo-additive compounds (compare also Fries, *Annalen*, 1906, **346**, 128). It is, moreover, clear that this effect will manifest itself whether the tetrabromide has the constitution (I) or (II), for in the former case the effect on the nitrogen atom (2) will be communicated to the sulphur atom (7) by way of the well-known alternation of affinity effect in carbon chains.

Actually, it was found in connexion with the 5-substituted 1-phenylbenzthiazoles (III) that the electro-polar character of the 5-substituent has a remarkable effect on the tendency of these bases to form bromo-additive compounds.

Thus the negative nitro-group ( $\text{R} = \text{NO}_2$ ) in 5-nitro-1-phenylbenzthiazole depresses the unsaturation of the thiazole system to such an extent as to render the formation of bromo-additive compounds impossible in acetic acid solutions, and to allow the formation only with considerable difficulty of the dibromide (IV) in chloroform. The less negative bromine atom in 5-bromo-1-phenylbenzthiazole ( $\text{R} = \text{Br}$ ), on the other hand, allows the formation of a very unstable tetrabromo-additive compound with difficulty; whilst the positive amino-group ( $\text{R} = \text{NH}_2$ ) enhances unsaturation of the thiazole system in 5-amino-1-phenylbenzthiazole to such an extent as to cause the immediate formation of a stable tetrabromide in the case of the latter benzthiazole derivative.

Bromination of 1-phenylbenzthiazole in chloroform gave rise to two isomeric forms of the tetrabromo-additive compound (m. p.  $126^\circ$  and  $153^\circ$ ), just as di- $\beta$ -naphthylthiocarbamide yields two forms of the hexabromide of 2- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole (Hunter, J., 1925, **127**, 2273). Both forms of the tetrabromide were reduced by sulphurous acid and passed into the substitution derivative on boiling with dilute alcohol and acetic acid (*loc. cit.*). It is highly probable that the lower-melting tetrabromide is identical with that formed in the bromination of the phenylbenzthiazole in glacial acetic acid solution, which usually commences to sinter at about  $130^\circ$ .

The bromo-additive compounds of the benzthiazole series, like the *p*-bromophenyltrimethylammonium perhalides (Reade, J.,

1924, 125, 150), decompose rapidly at the temperature of fusion (and frequently below this: J., 1925, 127, 2026), and therefore the melting point is not a real criterion of purity. For this reason, too much stress cannot be laid on the isolation of isomeric forms of the compounds, for the melting point (which is also the decomposition point) is appreciably affected by the crystalline form of the compound.\* It is hoped to investigate this question more fully at an early date.

#### EXPERIMENTAL.

1-Phenylbenzthiazole was prepared from benzyldeneaniline by Bogert and Abrahamson's method (*loc. cit.*). The finely crushed melt was added in a slow stream to boiling 60% sulphuric acid, and the resulting mixture boiled for an hour (water being added to make up for that lost by evaporation). The acid extract was filtered into cold water (10 vols.), and the precipitated base was washed, dried at 70°, dissolved in the minimum of boiling alcohol (to remove resinous material), and the filtered solution poured into cold water. The product, after drying, crystallised from light petroleum-alcohol (3:1) in pale yellow prisms, m. p. 114°, having the odour of geraniums and other properties described by Hofmann (*Ber.*, 1879, 12, 2359).

*Bromination.* (A). Phenylbenzthiazole (2 g.) dissolved in glacial acetic acid was gradually treated with bromine (Bogert and Abrahamson, *loc. cit.*). The tetrabromide separated in red needles or prisms, which were dried in a vacuum over potassium hydroxide; m. p. 137° after sintering at 130° (Found: Br, 60.6. Calc., Br, 60.3%). On boiling with dilute acetic acid or alcohol, 5-bromo-1-phenylbenzthiazole was produced which crystallised from glacial acetic acid in shining prisms, m. p. 152°.

Since this method of preparing the tetrabromide invariably gave resinous products, the bromination of 1-phenylbenzthiazole in chloroform was examined.

(B). Phenylbenzthiazole (2 g.) dissolved in chloroform (30 c.c.) was gradually treated with bromine (2 c.c.), and the resulting solution boiled, and cooled in ice. On scratching, reddish-brown needles of phenylbenzthiazole tetrabromide separated which were dried in a vacuum over potassium hydroxide; m. p. 126° (decomp.) (Found: Br, 60.6.  $C_{13}H_9NBr_4S$  requires Br, 60.3%). The filtrate from this compound, on concentration and cooling, furnished slender, orange needles of a second *tetrabromide*, which were dried as before; m. p. 153° (decomp.) (Found: Br, 59.8%).

\* Thus specimens of 1-anilinobenzthiazole tetrabromide crystallised from chloroform under different conditions may have melting points anywhere between 112° and 117° (Hunter, J., 1925, 127, 2025).

5-Nitro-1-phenylbenzthiazole was obtained by the direct nitration of phenylbenzthiazole with nitric acid (*d* 1.5) and by nitration with a mixture of sulphuric acid and nitric acid (*d* 1.4) as described in the literature (*loc. cit.*). After two crystallisations from glacial acetic acid, the nitrobenzthiazole was obtained in small, orange prisms, *m. p.* 188°. In both cases the yield exceeded 90%.

5-Nitro-1-phenylbenzthiazole Dibromide.—5-Nitro-1-phenylbenzthiazole was recovered unchanged after a saturated solution of the compound in glacial acetic acid had been treated with bromine. The nitrophenylbenzthiazole (2 g.) suspended in chloroform (40 c.c.) was gradually treated with bromine (2 c.c.); after  $\frac{1}{2}$  hour, the mixture was boiled and filtered, and the filtrate kept over-night. The somewhat pasty precipitate of the dibromide was collected and agitated with an ethereal solution of bromine, when vermilion prisms were obtained which were dried in the usual way. They softened at 120° and melted at 144° (Found: Br, 37.8.  $C_{13}H_8O_2N_2Br_2S$  requires Br, 38.5%). The dibromide lost bromine on exposure to air and was reduced by sulphurous acid in the usual way. On boiling with dilute acetic acid, bromine was evolved with regeneration of the original nitrobenzthiazole.

5-Bromo-1-phenylbenzthiazole Tetrabromide.—When 5-bromo-1-phenylbenzthiazole (1 g.) in chloroform (12 c.c.) was gradually treated with bromine (1.6 c.c.), a dark red solution was obtained which deposited red prisms of a tetrabromo-additive compound, *m. p.* 206–208° (decomp.) (Found: Br, 64.8.  $C_{13}H_8NBr_5S$  requires Br, 65.6%). This compound was most unstable and lost bromine immediately on exposure to air; bromine was also eliminated with regeneration of the original 5-bromo-substitution derivative by boiling with dilute acetic acid, or by treating with sulphurous acid. By using a smaller quantity of bromine, red needles of another bromide were obtained which changed colour at 85°, became orange at 110°, and showed signs of loss of bromine at 175°; *m. p.* 208° (decomp.). The bromine content was that of a tribromo-additive compound [Found: Br, 60.9.  $(C_{13}H_8NBr_4S)_2$  requires Br, 60.4%]. This bromide had similar properties to the tetrabromide already described; it was converted into 5-bromo-1-phenylbenzthiazole by sulphurous acid or by boiling dilute acetic acid.

5-Amino-1-phenylbenzthiazole, prepared by reduction of the 5-nitro-derivative (*loc. cit.*), on repeated crystallisation from boiling aniline or toluene, was obtained in small prisms, *m. p.* 208°, as recorded. In cases where the reduction had proceeded too vigorously, the product after crystallisation was very dark and resinous; attempts were therefore made to work up the base by way of the benzyldene derivative (*loc. cit.*). The product separated from

alcohol in pale yellow plates, m. p.  $190^{\circ}$  ( $39^{\circ}$  above the recorded temperature); the m. p. was unaltered by recrystallisation. 5-Benzylideneamino-1-phenylbenzthiazole prepared from pure 5-amino-1-phenylbenzthiazole had the melting point of  $151^{\circ}$  recorded in the literature. The nature of the high-melting product has not yet been investigated.

*5-Amino-1-phenylbenzthiazole Tetra-bromide.*—5-Amino-1-phenylbenzthiazole (1 g.) suspended in chloroform (30 c.c.) was gradually treated with bromine (1.1 c.c.) dissolved in a small amount of the same solvent; an ochre-coloured precipitate of the bromo-additive compound appeared on the addition of the first drop of halogen. The mixture was boiled and filtered, the residue digested with dry ether containing bromine, and the product dried in the usual way. A dark brown, microcrystalline powder was thus obtained which melted at  $216^{\circ}$  after showing colour change between  $180^{\circ}$  and  $190^{\circ}$  (Found: Br, 60.1.  $C_{13}H_{10}N_2Br_4S$  requires Br, 58.6%). The filtrate from this bromide, on slight concentration, furnished red prisms of another *tetra-bromide*, m. p.  $210$ – $211^{\circ}$ , which were dried in a vacuum as before (Found: Br, 60.3%). The brown *tetra-bromide* was remarkably stable to air and in this respect resembled the dibromide of 4'-amino-1-phenyl-5-methylbenzthiazole (J., 1925, 127, 1318). On boiling with acetic acid a red solution was obtained which deposited prisms of the second *tetra-bromide*, m. p.  $210^{\circ}$ . Both bromides were reduced in the usual way by sulphurous acid, etc. On boiling the red crystals with dilute acetic acid, a dark product was obtained; this was digested with dilute alkali, dried, and repeatedly extracted with boiling alcohol, which removed a purple impurity. The brown residue was washed with ether and dried. It appeared to be an impure bromo-substitution product and softened at about  $170^{\circ}$ ; its analysis corresponded most closely with a *dibromo*-derivative (Found: Br, 39.3.  $C_{13}H_9N_2Br_2S$  requires Br, 41.8%). The purple alcoholic extracts on evaporation furnished a quantity of dark-coloured product insufficient for investigation.

The experiments here described were commenced early in 1924 with the object of studying the effect of the substitution of groups of varying polar and spatial character on the unsaturation of the fused thiazole nucleus. Since the work has been temporarily abandoned, it has seemed desirable to publish the results so far obtained.

The author desires to express his gratitude to Professor J. F. Thorpe and Dr. M. A. Whiteley for the kind interest they have taken in this work.

LXXIII.—*Studies in Colour and Constitution. Part I.*  
*The Influence of the Methylthiol Group, alone and*  
*in Conjunction with the Methoxy-group.*

By HERBERT HENRY HODGSON and FREDERICK WILLIAM HANDLEY.

THE superior bathochromic influence of the methylthiol group in comparison with the methoxy-group was discovered by Brand (*Ber.*, 1909, 42, 3463). The work of Waldron and Reid (*J. Amer. Chem. Soc.*, 1923, 45, 2399) and of Foster and Reid (*ibid.*, 1924, 46, 1936), however, indicated this influence was stronger or weaker than that of the methoxy-group according as the methylthiol group was in the para- or ortho-position with respect to it.

Dyes were prepared from 2- and 4-thioanisidines by one of the authors (H. H. H.) in 1918 (Brit. Pat. 235334 of 1924), and his study of meta-halogenated phenols has afforded the opportunity of comparing the bathochromic effects of the methylthiol and methoxy-groups in ortho- and para-positions, and vice versa, in the same amine.

For this purpose, the action of sodium disulphide on 3-chloro-2-, -4-, and -6-nitrophenols (Hodgson and Moore, *J.*, 1925, 127, 1925) has been investigated. No replacement of chlorine in the free phenols and in 3-chloro-2-nitroanisole took place, but the methyl ethers of 3-chloro-4- and -6-nitrophenols were readily converted into disulphides. These ethers were prepared in good yield by Haworth and Lapworth's method (*J.*, 1923, 123, 2986) and have been described by Hodgson and Moore (this vol., p. 157). Conversion of the disulphides into thioethers and subsequent reduction produce respectively 4-anisidine-2- and 2-anisidine-4-methyl thioethers, in which the positions of the methoxy- and methylthiol groups are interchanged.

Azo-dyes were prepared from the above amines with Schäffer salt, R-salt, and H-acid (in alkaline solution) as second components, and also, for comparison purposes, from 2- and 4-anisidines and 2- and 4-thioanisidines. From the dyeings on wool, the colorimetric estimation of the dye solutions by the Lovibond tintometer, and the colours given by the solid dyes with concentrated sulphuric acid, the superiority of the bathochromic influence of the methylthiol group in the para-position was found to be most pronounced. The methoxy-group in the Schäffer and R-salt dyes, however, exhibited the converse influence, i.e., it produced the optimum effect when it was in the ortho-position. The *o*-methylthiol and *p*-methoxy-groups appear to produce the same effect. The maximum effect was obtained with the *p*-methylthiol group in conjunction with an

*o*-methoxy-group, viz., very pronounced violet colour with the Schäffer and R-salt dyes and an almost indigo-blue colour with the H-acid dye. Chlorine exerts the same influence as the methylthiol group, but to a less degree; the shades, however, are brighter. In all cases the dyes from 4-thioanisidine are the strongest in tinctorial power.

#### EXPERIMENTAL.

**3-Chloro-4- and -6-nitroanisoles.**—The respective chloronitrophenols (8 g.) dissolved in xylene (40 c.c.) were heated under reflux on the water-bath for 8 hours in presence of potassium carbonate (10 g.), and methyl sulphate (10 c.c.) was gradually added. The mixture was rendered strongly alkaline and steam-distilled; xylene and a little ether passed over first and were followed by the main bulk (yield 7 g.; 81%).

**4-Chloro-2- and 2-Chloro-4-anisidines.**—The above ethers (1 g.) were each heated under reflux on the water-bath with concentrated hydrochloric acid (5 c.c.) and water (15 c.c.), with gradual addition of granulated tin (3 g.). After the ether had dissolved, the mixture was made alkaline and the products were removed by steam distillation. For convenience, the hydrochlorides were prepared (yield 0.8 g.). They formed long needles, m. p. 238° and 228°, respectively (Found: Cl, 36.4 and 36.5.  $C_7H_8ONCl \cdot HCl$  requires Cl, 36.6%).

**2:2'-Dinitro- and 4:4'-Dinitro- 5:5'-dimethoxydiphenyl Disulphides.**—3-Chloro-4- and -6-nitroanisoles (8 g.) were each dissolved in alcohol (50 c.c.) and gently boiled under reflux during the cautious addition of aqueous sodium disulphide (crystallised sodium sulphide, 6 g.; sulphur, 0.8 g.; water, 40 c.c.); heating was then continued for 4–5 hours. The respective disulphides separated and the contents were filtered hot, unchanged nitroanisole being removed by warm alcohol (yield 6.5–7 g.; 88–90%).

**2:2'-Dinitro-5:5'-dimethoxydiphenyl disulphide** is insoluble in water, alcohol, or benzene, but soluble in carbon disulphide or glacial acetic acid, from which it crystallises in white needles, m. p. 152° (uncorr.); these rapidly turn yellow in sunlight (Found: N, 7.4; S, 18.0.  $C_{14}H_{12}O_6N_2S_2$  requires N, 7.6; S, 17.4%). The last trace of free sulphur was retained even after repeated crystallisation. Concentrated aqueous or alcoholic alkali hydroxides give violet-red solutions. Concentrated sulphuric acid gives a pale yellow solution in the cold, unchanged by moderate heating or dilution. Chlorosulphonic acid gives a crimson solution in the cold, which becomes yellow on heating and remains so on dilution, whilst oleum (23%  $SO_3$ ) produces a brownish-yellow colour, which

changes to yellow on heating and lemon-yellow on subsequent dilution.

*4:4'-Dinitro-5:5'-dimethoxydiphenyl disulphide* resembles the preceding isomeride in solubility. It crystallises from glacial acetic acid in white, glistening micro-plates, m. p.  $194^{\circ}$  (uncorr.) (Found : N, 7.6; S, 17.9%). The solutions in alkalis are deep red. Concentrated sulphuric acid produces an orange-yellow colour in the cold, which becomes successively red, brown, and green on heating, and brownish-purple on subsequent dilution. Chlorosulphonic acid or oleum (23%) produces a green colour in the cold, which changes to reddish-brown on heating; a reddish-brown precipitate forms on dilution.

*2-Nitro- and 4-Nitro-5-methoxythioanisoles.*—The above disulphides (2 g.) were each heated on the water-bath for 15 minutes with alcohol (10 c.c.), crystallised sodium sulphide (1 g.), sodium hydroxide (2.4 g.), and water (10 c.c.). The mixture was then stirred into water (35 c.c.), filtered if necessary, and warmed with methyl sulphate (2–2.5 c.c.), when the thioanisole separated (yield 2 g.; 92%).

*2-Nitro-5-methoxythioanisole* is insoluble in cold but slightly soluble in hot water and is very slowly volatile in steam. It crystallises from alcohol in yellow needles, m. p.  $112$ – $113^{\circ}$  (uncorr.), and is very slowly decomposed by nitric acid (Found : N, 7.2.  $C_8H_9O_3NS$  requires N, 7.0%). The crimson solution in concentrated sulphuric acid becomes violet on heating and thereafter yellow on dilution. The corresponding colorations produced by oleum (23%) and chlorosulphonic acid are blood-red, reddish-brown and yellow, and blue, violet and yellow, respectively.

*4-Nitro-5-methoxythioanisole* resembles the preceding isomeride in solubility and volatility in steam, but crystallises from alcohol in paler yellow needles, m. p.  $79$ – $80^{\circ}$  (uncorr.) (Found : N, 6.9%). The colorations produced by solution, heating, and subsequent dilution are : for concentrated sulphuric acid, scarlet, blood-red to reddish-violet, blood-red; for oleum, chocolate-brown, blood-red, yellow; for chlorosulphonic acid, red, orange, yellow.

*2-Anisidine-4-methyl- and 4-Anisidine-2-methyl Thioethers.*—The respective nitro-compounds (2 g.) were heated under reflux with granulated tin (4 g.), concentrated hydrochloric acid (10 c.c.), and water (10 c.c.) until all had dissolved. The solution was made distinctly alkaline with sodium hydroxide and steam-distilled. In both cases, the bases passed over as oils, but only 2-anisidine-4-methyl thioether crystallised on standing. The 4-anisidine isomeride was converted into the hydrochloride.

*2-Anisidine-4-methyl thioether* is very soluble in alcohol and

crystallises from water in white, feathery needles, m. p.  $44^{\circ}$  (uncorr.), which become discoloured in air (yield 1.3 g.; 77%) (Found: N, 8.5; S, 19.1.  $C_8H_{11}ONS$  requires N, 8.3; S, 18.9%). Concentrated sulphuric acid gives a yellow solution which remains unchanged on heating or dilution. The pale violet solution in oleum changes to deep violet on warming, but becomes colourless on prolonged heating.

The *hydrochloride* crystallises from hydrochloric acid in colourless needles which turn pink in air; m. p.  $235^{\circ}$  (approx.) (Found: Cl, 17.5; S, 15.2.  $C_8H_{11}ONS, HCl$  requires Cl, 17.3; S, 15.6%).

4-Anisidine-2-methyl thioether is an oil which is very soluble in alcohol, but only slightly so in water. Concentrated sulphuric acid gives a violet solution in the cold, which becomes reddish-violet on heating. The corresponding colorations with oleum and chloro-sulphonic acid are blue-violet and reddish-purple and purple and reddish-purple, respectively.

The *hydrochloride* forms white needles, m. p.  $210-211^{\circ}$ , which become steel-grey on exposure to light (Found: N, 7.4; Cl, 17.25; S, 15.3.  $C_8H_{11}ONS, HCl$  requires N, 7.0; Cl, 17.3; S, 15.6%).

*The Dyes.*—These were prepared in the usual way and sodium chloride was removed as completely as possible.

*Dyeing trials.* Wet strips of wool (2.5 g.) were introduced into a bath of water (250 c.c.) containing the dyes (0.025 g.), sodium sulphate (0.25 g.), and sulphuric acid (0.05 g.). The solution was gradually heated to the boiling point and there maintained until the dyeing was complete.

*Dye solutions.* These were evaluated in terms of red, yellow, and blue components by means of the Lovibond tintometer.

The colours produced by sulphuric acid on the dry dye powders were also examined.

For convenience, the dyes are referred to by the attached numerals, which indicate the particular amine employed: 2-anisidine (I), 4-anisidine (II), 4-chloro-2-anisidine (III), 2-chloro-4-anisidine (IV), 2-anisidine-4-methyl thioether (V), 4-anisidine-2-methyl thioether (VI), 2-thioanisidine (VII), 4-thioanisidine (VIII).

The order of increasing redness is from left to right.

## LXXIV.—*Iodination in the Carbazole Series.*

By STANLEY HORWOOD TUCKER.

OXIDATION of carbazole brought about the formation of the two dicarbazyls described by Perkin and Tucker (J., 1921, 119, 216). Attempts to synthesise these compounds and their possible isomerides have led to the preparation of iodo-derivatives of carbazole and of its alkyl and acyl compounds. Except the iodo-compounds described by Stevens and Tucker (J., 1923, 123, 2146) and Tucker (J., 1924, 125, 1144), the only one prepared was di-iodocarbazole (Classen, D.R.-P. 81929, 1894). Classen's description of it is inaccurate.

3-Iodocarbazole has been synthesised from 3-aminocarbazole (Tucker, *loc. cit.*). It has now been obtained directly from carbazole by the action of potassium iodide and iodate in glacial acetic acid solution, working according to the equation  $3C_{12}H_9N + 2KI + KIO_3 + 3CH_3 \cdot CO_2H = 3C_{12}H_8NI + 3H_2O + 3CH_3 \cdot CO_2K$ , except that potassium iodate and acetic acid are used in excess. The iodine at first liberated is gradually used up and the solution finally becomes colourless. The 3-iodocarbazole so obtained is mixed with considerable quantities of di-iodocarbazole. Much of the 3-iodocarbazole can be separated by crystallisation, but to obtain the di-iodocarbazole it is necessary to utilise the acetyl or benzoyl derivative.

The di-iodocarbazole described by Classen, and prepared by a different method from the above, was alleged to be yellow, and to melt at 184°; repetition of his work gave only colourless di-iodocarbazole, m. p. 202–204°. The di-iodocarbazole is almost cer-

tainly 3 : 6-di-iodocarbazole by analogy with other disubstitution products of carbazole.

Iodination of 9-methyl and 9-ethylcarbazole by the above method likewise gives the respective 3-iodo- and di-iodo-compounds.

Like carbazole and the 9-alkylcarbazoles, 9-benzoylcarbazole may be iodinated by means of potassium iodide and iodate in glacial acetic acid to give a corresponding yield of its 3-iodo-derivative, but the discharge of the iodine coloration is much less rapid, viz., 10 minutes for carbazole (less for the 9-alkylcarbazoles) and 75 minutes for 9-benzoylcarbazole. Incomplete iodination of 9-toluene-*p*-sulphonylcarbazole took place under similar conditions in 2 hours. Iodination of 9-acetylcarbazole did not proceed to any appreciable extent. Judged, therefore, by this process of iodination, resistance to replacement of hydrogen in the carbazole nucleus increases in the order 9-alkylcarbazoles, carbazole, 9-benzoyl-, 9-toluene-*p*-sulphonyl-, and 9-acetyl-carbazole. All may be iodinated by the action of the more vigorous iodinating reagent, iodine and nitric acid in glacial acetic acid (Datta and Chatterjee, *J. Amer. Chem. Soc.*, 1919, **41**, 292). The 9-alkylcarbazoles and carbazole give at once idonitro-compounds.

There is no evidence of the formation of any 1-iodo-derivatives.

#### EXPERIMENTAL.

*Iodination of Carbazole.*—(i) *Using potassium iodide and potassium iodate in glacial acetic acid.* Pure \* carbazole (16.7 g.) was dissolved in boiling glacial acetic acid (250 c.c.), and potassium iodide (11 g.) added. The solution was cooled somewhat, finely-powdered potassium iodate (16 g., i.e., approximately twice the amount theoretically required) added, and the mixture then boiled until it acquired a clear straw-coloured tint (10 minutes). The hot solution was decanted from the undissolved potassium iodate and allowed to cool slowly to 45°. The faintly brown, nacreous plates which separated were rapidly filtered off and recrystallised from glacial acetic acid (or alcohol), the solution being allowed to cool to 45° and filtered as before from the white, nacreous plates (10–12 g.) of 3-iodocarbazole, m. p. 192–194°. From the united filtrates, on standing, there separated 3 : 6(?)*-di-iodocarbazole*, m. p. 202–204° (Found : I, 60.6.  $C_{12}H_7NI_2$  requires I, 60.6%), but since the

\* The yield of 3-iodocarbazole is considerably diminished if the carbazole used is impure. Pure carbazole exhibits a faint violet fluorescence, and melts at 238° when the melting point is taken in the usual way with a long emergent stem; when taken with a short Anschütz thermometer having the stem immersed, the m. p. is 245° (compare Graebe and Glaser, *Ber.*, 1872, **5**, 12; Täuber, *ibid.*, 1891, **24**, 2597; Kirby, *J. Soc. Chem. Ind.*, 1921, **40**, 274r; Senseman and Nelson, *Ind. Eng. Chem.*, 1923, **15**, 382).

quantity was very small it was found better to proceed thus: The united filtrates were poured into water and the white precipitate was dried (16.5 g.). Crystallisation of this product from various solvents did not raise the melting point above 160°. Accordingly, the material was boiled with acetic anhydride and a trace of concentrated sulphuric acid. After a short time, a white, crystalline precipitate suddenly separated. It was washed with boiling glacial acetic acid and recrystallised several times from benzene. 3:6(?)*-Di-iodo-9-acetylcarbazole* was thus obtained in long, colourless needles, grouped in porcupine-like tufts, m. p. 224—225° (Found: I, 55.4.  $C_{14}H_9ONi_2$  requires I, 55.1%). The acetic anhydride filtrate was poured into water, and the precipitate produced was crystallised from glacial acetic acid. Colourless needles separated in rosettes very like those of 3-iodo-9-acetylcarbazole (m. p. 145—147°), but repeated crystallisation from glacial acetic acid, alcohol, and benzene—light petroleum failed to raise the melting point above 133—137°. However, by boiling this material with alcoholic potassium hydroxide solution for a few minutes, pouring into water, and recrystallising the precipitate from glacial acetic acid as described under the isolation of 3-iodocarbazole, a good yield of pure 3-iodocarbazole was obtained.

The separation of 3-iodocarbazole and 3:6-di-iodocarbazole can also be effected by benzoylation.\* The product (16.5 g., obtained after removal of 3-iodocarbazole by preliminary crystallisation) was dissolved in acetone (100 c.c.), and powdered potassium hydroxide (12 g.) added. The mixture was boiled, allowed to cool slightly, and benzoyl chloride (10 c.c.) added slowly; a vigorous reaction took place. The liquid was swirled round after each addition of benzoyl chloride, but not shaken vigorously until the end; it was then poured into water. The pale brown oil at first precipitated, which solidified to a pasty, white solid, was dissolved in acetone. The crystals which separated were much less soluble in acetone than the crude material, and were best recrystallised

\* The method of benzoylation of carbazole (Stevens and Tucker, *loc. cit.*, p. 2146) proceeds as given for the quantities used, but with larger quantities of carbazole (16.7 g., e.g.) vigorous shaking must be avoided; the liquid, after addition of benzoyl chloride, should be gently swirled, and only shaken finally. (The author is indebted to Mr. A. Kent, M.A., B.Sc., of this Department, for this observation.) To separate 9-benzoylcarbazole from unchanged carbazole, the mixture is dissolved in benzene and allowed to cool; carbazole then separates, and more is obtained by concentrating the filtrate to half-bulk. The benzene (in which 9-benzoylcarbazole is very soluble) is evaporated and the residue crystallised from much alcohol. Pure 9-benzoylcarbazole, m. p. 98°, is obtained. If carbazole is not thus removed, the m. p. of the product does not rise above 90° even after repeated crystallisation. The above applies generally to all benzoylations described in this paper.

from pyridine to which a drop of water was added, or from carbon tetrachloride, giving 3 : 6-di-iodo-9-benzoylcarbazole, m. p. 204—205° (Found : I, 48.9.  $C_{19}H_{11}ONI_2$  requires I, 48.6%). Concentration of the acetone filtrate gave a further crop, the total yield of pure material being 3.2 g. The very concentrated acetone filtrate deposited 3-iodo-9-benzoylcarbazole (0.8 g.), m. p. 145—146° (Found : I, 31.9.  $C_{19}H_{12}ONI$  requires I, 32.0%). A thick, brown oil was left. When macerated with cold glacial acetic acid, much dissolved; but a yellow powder remained insoluble. After several crystallisations from carbon tetrachloride or light petroleum, it melted at 184—186°, but appears to be 3-iodocarbazole (0.2 g.).

(ii) *Using iodine and yellow mercuric oxide in alcohol* (Classen, *loc. cit.*). Classen's procedure was followed as described, then the product was recrystallised three times from carbon tetrachloride, and red crystals were obtained, m. p. 201—204°. These were boiled in glacial acetic acid with animal charcoal, and recrystallised from alcohol in colourless, long, rectangular laminæ of 3 : 6-di-iodocarbazole, m. p. 202—204°.

**3-Iodo-9-acetylcarbazole.**—The best method of preparing this compound is acetylation of 3-iodocarbazole (Tucker, *loc. cit.*); but it is readily prepared from 9-acetylcarbazole thus : 9-Acetylcarbazole (2 g.) and iodine (1 g.) were dissolved in glacial acetic acid (40—50 c.c.), the solution cooled to about 60°, and a solution of 2 c.c. of concentrated nitric acid in 8 c.c. of glacial acetic acid added drop by drop. When 1 c.c. of the solution had been added, the mixture was boiled and the addition of the nitric acid solution continued at intervals during the boiling until the iodine coloration had just vanished. Yellow crystals separated on cooling. They recrystallised from glacial acetic acid, and from alcohol, in colourless crystals, slightly soluble in light petroleum. Attempts to iodinate 9-acetylcarbazole by means of iodide and iodate, as for the iodination of carbazole, showed that after several hours' boiling some iodine had been used up, but no iodo-compounds could be isolated.

3 : 6(?)*-Di-iodo-9-acetylcarbazole* was prepared from 3 : 6(?)*-di-iodocarbazole* by boiling with acetic anhydride containing a trace of concentrated sulphuric acid. The solution set at once to a pure white solid, which crystallised from benzene, much glacial acetic acid, or alcohol in clusters of long needles, m. p. 224—225°. It was readily hydrolysed by boiling alcoholic potassium hydroxide solution to 3 : 6-di-iodocarbazole.

**3-Iodo-9-benzoylcarbazole** was prepared (a) from 3-iodocarbazole by the method described under the separation of 3-iodocarbazole and 3 : 6-di-iodocarbazole. Using theoretical quantities (2.9 g. of 3-iodocarbazole, 1.4 g. of benzoyl chloride, and 0.6 g. of solid

potassium hydroxide in 20 c.c. of acetone), the yield was practically as good. Twenty-five per cent. of the 3-iodocarbazole was recovered; (b) from 9-benzoylcarbazole—(i) 9-Benzoylcarbazole (4 g.), potassium iodide (1.6 g.) and potassium iodate (excess) in glacial acetic acid (40 c.c.) were boiled until the solution became colourless ( $1\frac{1}{2}$  hours). It was then decanted from unchanged iodate into water, and the salmon-pink, powdery solid recrystallised from acetone. The yield of pure 3-iodo-9-benzoylcarbazole was 2.2 g. A small amount, m. p.  $201^{\circ}$ , was obtained from the residues by crystallisation from pyridine. It is therefore probably 3 : 6-di-iodo-9-benzoylcarbazole : (ii) 9-Benzoylcarbazole (5.4 g.) and iodine (2.5 g.) were dissolved in glacial acetic acid (100 c.c.), and a solution of nitric acid in acetic acid was added as in the preparation of 3-iodo-9-acetylcarbazole. The solution became clear in about 20 minutes, was poured into water, and the precipitated yellow solid crystallised from pyridine with addition of a drop of water. The crystals so obtained dissolved in alcohol except a small amount of insoluble, white substance, which, after recrystallisation from pyridine, melted at  $204\text{--}205^{\circ}$  and was 3 : 6-di-iodo-9-benzoylcarbazole. The alcoholic filtrate therefrom deposited 3-iodo-9-benzoylcarbazole. It crystallised well from alcohol, but the crystals were ill-defined and resembled seaweed in shape and arrangement. On certain occasions when the alcoholic solutions were left standing, the crystals assumed a plate shape, but this could not be repeated at will. The acetone solution of 3-iodo-9-benzoylcarbazole deposited clusters of very long needles, which could be removed and were stable out of the solution, whereas the crystals remaining in solution, if scratched, immediately changed into thick, six-sided plates. The acetone solution usually deposited a mixture of needles and plates. Pyridine, in which it is very soluble, and light petroleum, in which it is soluble with difficulty, also gave plate crystals. It is sparingly soluble in glacial acetic acid, but crystallisation therefrom does not purify the substance. Benzene and carbon tetrachloride solutions gave small, colourless crystals. The two crystalline forms mentioned above melted at  $145\text{--}146^{\circ}$ , and a mixed m. p. was unchanged. The substance is therefore dimorphic. Exposure to light turns it faintly brown; a property possessed also by 9-benzoylcarbazole. It is readily hydrolysed to 3-iodocarbazole by alcoholic potassium hydroxide solution.

**3 : 6-Di-iodo-9-benzoylcarbazole.**—3 : 6-Di-iodocarbazole (1 g.) was treated with benzoyl chloride (0.6 g.) and potassium hydroxide (0.5 g.) in acetone (20 c.c.) in the usual way. 3 : 6-Di-iodo-9-benzoylcarbazole was precipitated, and after washing with hot acetone, in which 3 : 6-di-iodocarbazole is very soluble, was obtained

pure (0.8 g.), m. p. 204—205°. A mixed m. p. with 3 : 6-di-iodo-carbazole (m. p. 202—204°) was much lower. It crystallises best from a dilute solution in pyridine, to which a few drops of water are subsequently added, in long rods. It is much less soluble in carbon tetrachloride, and soluble with difficulty in acetone, from which microcrystals are obtained. It is readily hydrolysed by alcoholic potassium hydroxide solution to 3 : 6-di-iodocarbazole.

3-Iodo-9-toluene-*p*-sulphonylcarbazole was prepared thus : (i) 3-Iodocarbazole (1.5 g.), toluene-*p*-sulphonyl chloride (1.0 g.), and potassium hydroxide (0.3 g.) in acetone (10 c.c.) were boiled together for 10 minutes, and poured into water. The precipitated solid crystallised from alcohol, in which it was sparingly soluble, in colourless, diamond-shaped rhombs (1.3 g.), m. p. 170—171° (Found : I, 28.5.  $C_{19}H_{14}O_2NIS$  requires I, 28.4%). 3-Iodocarbazole (0.3 g.) was recovered from the alcoholic filtrate. 3-Iodo-9-toluene-*p*-sulphonylcarbazole is easily soluble in cold pyridine, hot acetone, benzene, glacial acetic acid, ethyl acetate, aniline, or carbon tetrachloride, and less soluble in light petroleum, from all of which it crystallises, but best from acetone, benzene, alcohol-acetone, or alcohol-pyridine. (ii) 9-Toluene-*p*-sulphonylcarbazole\* (2.6 g.) and iodine (0.8 g.) were dissolved in glacial acetic acid (50 c.c.), and a solution of nitric acid in glacial acetic acid (usual strength) was slowly added to the boiling solution. In 10 minutes, about 3 c.c. of the nitric acid solution had been added, and the solution was free from iodine coloration. The pale yellow solution poured into water gave a canary-yellow solid, which was extracted with alcohol. A white, insoluble portion crystallised from much glacial acetic acid in colourless needles, m. p. 257°. It is 3 : 6-di-iodo-9-toluene-*p*-sulphonylcarbazole (Found : I, 43.7.  $C_{19}H_{13}O_2NI_2S$  requires I, 44.3%). The alcoholic extract deposited impure 3-iodo-9-toluene-*p*-sulphonylcarbazole, a substance melting at 175°, and colourless rods melting at 118—121° (Found : I, 11.4; *M*, by Rast's method, 334. A mixture of 9-toluene-*p*-sulphonylcarbazole and 3-iodo-9-toluene-*p*-sulphonylcarbazole,  $C_{19}H_{15}O_2NS + C_{19}H_{14}O_2NIS$ , requires I, 16.5%; *M*, 384).

(iii) 9-Toluene-*p*-sulphonylcarbazole (1 g.) was boiled with potassium iodide (0.34 g.) and excess of potassium iodate in glacial acetic acid (10 c.c.) for several hours, but the iodine coloration did not disappear. In another experiment, using half the quantity of

\* Compare footnote on benzoylation of carbazole. Application of the same method of removal of carbazole after preparation of 9-toluene-*p*-sulphonylcarbazole produced the latter in large, colourless, prismatic crystals, softening at 128°, and giving a clear melt at 133° (compare Cassella, D.R.-P. 224951, 1909; Herz, A.P. 966092, 1910).

potassium iodide, the colour was discharged in  $2\frac{1}{2}$  hours and a nearly theoretical yield of the substance (m. p.  $118-121^\circ$ ) mentioned under (ii) was obtained.

3 : 6 - *Di-iodo-9-toluene-p-sulphonylcarbazole*.—9-Toluene-*p*-sulphonylcarbazole (2.5 g.), iodine (2.0 g.), and glacial acetic acid (50 c.c.) were boiled together during addition of nitric acid in acetic acid (usual strength) until the iodine colour disappeared (45—60 minutes). Before the colour had vanished, needle-shaped crystals began to separate. The mixture was allowed to cool; the separated crystals crystallised from glacial acetic acid and then from benzene in tetrahedral prisms, m. p.  $257^\circ$ . It is only slightly soluble in glacial acetic acid, carbon tetrachloride or acetone, but readily soluble in hot benzene.

*Iodination of 9-Methylcarbazole*.—The methylation of 3-iodo-carbazole has been described (Stevens and Tucker, *loc. cit.*, 2146). Iodination of 9-methylcarbazole was effected as follows : 9-Methylcarbazole (0.8 g.), potassium iodide (0.47 g.), and excess of potassium iodate were boiled in glacial acetic acid (10 c.c.) for 2 minutes, in which time a green solution was obtained. By the usual treatment there were separated in small quantity by means of alcohol 3-iodo-9-methylcarbazole and a product, m. p.  $181^\circ$ . The latter is 3 : 6-*di-iodo-9-methylcarbazole* (Found : I, 58.6.  $C_{13}H_9NI_2$  requires I, 58.7%). It was also prepared by the action of methyl sulphate on 3 : 6-di-iodocarbazole in presence of acetone and solid potassium hydroxide. It is readily soluble in glacial acetic acid, very sparingly soluble in alcohol, and, although sparingly soluble, crystallises from acetone in long, thin rods, m. p.  $181-182^\circ$ .

*Iodination of 9-Ethylcarbazole*.—9-Ethylcarbazole (19.5 g.) and potassium iodide (11.0 g.) were dissolved in glacial acetic acid (200 c.c.), and potassium iodate (16 g.) was added in portions to the hot solution. A gentle reaction set in, and the colour soon gave place to green. The solution was poured into water, and a pasty solid possessing a silky sheen was deposited. This was dissolved in excess of glacial acetic acid. In sufficiently dilute solution, no oil separated, but impure green crystals (11 g.), m. p.  $71^\circ$ . The filtrate from these on concentration deposited colourless crystals, m. p.  $80^\circ$  (3.5 g.). By further concentration, a final crop (5.5 g.) of green crystals, m. p.  $140-144^\circ$ , was obtained. The crystals, m. p.  $80^\circ$ , were purified by recrystallisation from glacial acetic acid or alcohol, and separated in long needles, m. p.  $83-84^\circ$ , identical with 3-iodo-9-ethylcarbazole (Stevens and Tucker, *loc. cit.*). The green crystals, m. p.  $140-144^\circ$ , crystallised from much glacial acetic acid and finally from alcohol in colourless needles, m. p.  $152-153^\circ$ , and were shown to be 3 : 6-*di-iodo-9-ethylcarbazole* (Found :

I, 56.9.  $C_{14}H_{11}NI_2$  requires I, 56.8%). It is only slightly soluble in alcohol or in glacial acetic acid.

3-Iodo-9-isopropylcarbazole was prepared by Mr. W. H. Chalmers, B.Sc., A.I.C., by boiling a mixture of 3-iodocarbazole (2 g.), isopropyl iodide (4 g.), and potassium hydroxide (2 g. in 1 c.c. of water) in acetone (6 c.c.) for 6 hours. The usual procedure, and crystallisation of the product from glacial acetic acid, gave white, silvery leaflets, m. p. 95—97° (Found: I, 38.2.  $C_{15}H_{14}NI$  requires I, 37.9%).

3-Iodocarbazole could not be obtained from carbazole by the action of iodine and nitric acid in glacial acetic acid. It crystallises well from light petroleum, and is very soluble in benzene, pyridine, or acetone. As already stated, it is best crystallised from carbon tetrachloride or glacial acetic acid.

3:6-Di-iodocarbazole, isolated in small yield in the iodination of carbazole, was prepared from carbazole by method (i), using twice the quantity of potassium iodide used to obtain monoiodocarbazole, and proceeding as before. Purification of the pink product was difficult, but it was effected as given under the mercuric oxide experiment, method (ii). It was found best, in order to obtain pure 3:6-di-iodocarbazole, to acetylate or benzoyleate the material (as described above), and hydrolyse the product with alcoholic potassium hydroxide solution. 3:6-Di-iodocarbazole is very soluble in acetone. It crystallises best from glacial acetic acid or alcohol, in long laminae.

## LXXV.—Optical Activity and the Polarity of Substituent Groups. Part III. Menthyl Acetophenone-o-carboxylate.

By HAROLD GORDON RULE and JOHN SMITH.

IN certain cases it has now been established that the influence of substituents on the optical rotatory power of an organic compound is similar to their influence on acidity. This has been shown to hold true for the condensation products of an optically active base with substituted benzaldehydes (Betti, *Gazzetta*, 1923, 53, 417) and for the menthyl esters of monosubstituted acetic acids (Rule and Smith, *J.*, 1925, 127, 2188).

On the other hand, the menthyl esters of substituted benzoic acids prepared by Cohen reveal an influence of a quite different type. Here the relative changes in rotation produced by a number of simple

ortho-substituents (substitution in the *m*- or *p*-position has little effect) are given by  $\text{NO}_2 > \text{CO}_2\text{H} > \text{H} > \text{I} > \text{CH}_3 > \text{Br} > \text{Cl} > \text{F} > \text{O}\cdot\text{CH}_3$ . As has already been pointed out (Rule, J., 1924, 125, 1122; Rule and Paterson, *ibid.*, 2159), this series is in very close agreement with the relative polarity of the groups as deduced from the molecular inductive capacities of compounds, and with the relative effect of the substituents on the nitration of benzene as we pass from the strongly positive (meta-directive) nitro-group to the strongly negative (para-directive) fluoro-group.

Only two positive groups occur in the above series and, unfortunately, few other simple groups of this type can be readily tested in the case of the menthyl benzoates. Acetophenone-*o*-carboxylic acid, however, is a comparatively accessible compound and figures are available relating to the influence of the acetyl group on benzene substitution.

It has been shown by Camps (compare Holleman, "Die direkte Einführung von Substituenten," 1910, p. 190) that when acetophenone is nitrated at 15° it yields a mixture of about 55% of the *m*-compound and 45% of the *o*-compound. Comparing these figures with those previously quoted for the nitration of nitrobenzene and of benzoic acid (Rule and Paterson, *loc. cit.*), we obtain:

	$\text{NO}_2$ .	$\text{CO}_2\text{H}$ .	$\text{CO}\cdot\text{CH}_3$ .
<i>m</i> -Compound.	93	76	55%

The determination of the relative polarity of the acetyl group from molecular inductive capacity data is inconclusive, as will be seen from the following values ( $\text{X} = \text{CH}_3\cdot\text{CO}$ ):

Series.		Dielec. const.	Density.	Mol. ind. capac.
HX.	Acetaldehyde.	18.5	0.80	10.1
EtX.	Methyl ethyl ketone.	17.8	0.81	15.8
$\text{C}_6\text{H}_5\text{X}$ .	Acetophenone.	18.1	1.03	21.0

On comparing these figures with those calculated by Rule and Paterson (*loc. cit.*), it is found that the *m*-directive groups fall into the order:

Series	HX.	—	CN,	$\text{CO}_2\text{H}$ ,	$\text{CO}\cdot\text{CH}_3$ ,	H.
	EtX.	$\text{NO}_2$ ,	CN,	$\text{CO}\cdot\text{CH}_3$ ,	$\text{CO}_2\text{H}$ ,	H.
	$\text{C}_6\text{H}_5\text{X}$ .	$\text{NO}_2$ ,	CN,	$\text{CO}\cdot\text{CH}_3$ ,	$\text{CO}_2\text{H}$ ,	H.

From the evidence of the benzene substitution data, which is partly supported by that of inductive capacity, it may be concluded that the acetyl group falls between the carboxyl group and hydrogen.

The menthyl ester of acetophenone-*o*-carboxylic acid has now been prepared, and the optical properties of the compound have been

examined for sodium light and that of the three chief mercury lines. Owing to the slight yellow colour of the melt, the rotation of the fused ester could only be determined over the range  $\lambda_D$  to  $\lambda_{gr}$ , but the rotatory power in benzene and in acetone solution was examined over the range  $\lambda_D$  to  $\lambda_{vi}$ . The values of  $1/\alpha$  when plotted against  $\lambda^2$  gave straight lines. In addition, the dispersion ratio  $\alpha_{gr}/\alpha_D$  for the fused ester at  $94^\circ$  and for solutions in benzene and acetone at the ordinary temperature remained approximately constant in the neighbourhood of 1.213. It may therefore be concluded that the compound exhibits normal and apparently simple rotatory dispersion in this region of the spectrum. The molecular rotations were as follows: fused ester,  $[M]_D^{94^\circ} = -261^\circ$ ; in benzene (5%),  $[M]_D^{80^\circ} = -284^\circ$ ; in alcohol (2%),  $[M]_D^{80^\circ} = -267^\circ$ ; in acetone (5%),  $[M]_D^{80^\circ} = -253^\circ$ .

Like other positive *o*-substituents, the acetyl group therefore brings about an increase in the rotation of menthyl benzoate. The influence of various *o*-substituents in this case is summarised in the following table, in which the additional figures for the molecular rotations were determined by Cohen and those for the dispersion ratios by Pickard and Kenyon:

Substit.	NO <sub>2</sub> .	CO <sub>2</sub> H.	CO·CH <sub>3</sub> .	H.	I.	CH <sub>3</sub> .	Br.	Cl.	F.	O·CH <sub>3</sub> .
$[M]_D$	-381*	332†	261†	239	237	231	205	195	194	148
$\alpha_{gr}/\alpha_D$	1.26	1.21	1.21	1.18	1.19	—	—	—	1.18	—
	* At $65^\circ$ .			† In solution.				‡ At $94^\circ$ .		

The remarkably close correspondence between the effect of substituents on the rotatory power of menthyl benzoate (I) and on benzene substitution (II) is seen by a comparison of the series given below, in which the agreement is broken only by a slight displacement of the iodine atom. Series III represents the relative polarity of the substituents as determined from the inductive capacities of compounds.

- I. NO<sub>2</sub> > CO<sub>2</sub>H > CO·CH<sub>3</sub> > H > I > CH<sub>3</sub> > Br > Cl > F > O·CH<sub>3</sub>
- II. NO<sub>2</sub>, CO<sub>2</sub>H, CO·CH<sub>3</sub>, H, CH<sub>3</sub>, Br, I, Cl, F
- III. NO<sub>2</sub>, CO<sub>2</sub>H (?), CO·CH<sub>3</sub>, CO<sub>2</sub>H (?), H, CH<sub>3</sub>, I, Br, Cl, F.

#### EXPERIMENTAL.

Acetophenone-*o*-carboxylic acid was prepared by the method of Gabriel and Neumann (*Ber.*, 1893, 26, 952). Phthalic anhydride, acetic anhydride, and potassium acetate were heated together to give phthalylacetic acid, and the latter, after purification, was converted into acetophenone-*o*-carboxylic acid by heating under pressure with water at  $200^\circ$ . After several recrystallisations from

water, the acid melted sharply at  $112^{\circ}$  (Gabriel and Michael, *Ber.*, 1877, **10**, 1554, quote 114—115°).

*Menthyl acetophenone-o-carboxylate* was prepared from the above acid by esterification in the presence of dry hydrogen chloride. The crude ester was freed from most of the excess menthol by heating at  $200^{\circ}$  under 10 mm. pressure, and was recrystallised from light petroleum until of constant rotation. The pure compound separated in colourless, odourless crystals, m. p.  $92^{\circ}$  (Found: C, 75.4; H, 8.6.  $C_{19}H_{26}O_3$  requires C, 75.5; H, 8.6%).

The compound dissolves comparatively readily in benzene, but is not very soluble in other organic solvents at the ordinary temperature.

The following figures refer to the rotatory power of the ester in the fused state at  $94^{\circ}$ . All rotations were measured in a 50 mm. tube and were negative in sign.  $D_4^{94} = 0.9898$  ( $\alpha_{vi}$  could not be determined owing to the slight yellow tint of the liquid).

$\alpha_D$ .	$\alpha_{Fe}$ .	$\alpha_{Gr}$ .	$\alpha_{Gr}/\alpha_D$ .	$[\alpha]_D$ .	$[\alpha]_{Fe}$ .	$[\alpha]_{Gr}$ .	$[M]_D$ .
42.84	45.04	51.98	1.213	86.56	91.01	105.0	261.4

In addition, a number of measurements were made of the rotatory power in solution at about  $20^{\circ}$ . In each case the highest concentration quoted represents the maximum at which it is convenient to work, and is not far removed from the saturation point. All rotations are negative in sign.

Solvent.	G. of ester in 100 c.c.	$\alpha$ obs.	( $l = 2$ ).	$[\alpha]_D$ .	$\alpha_{Gr}/\alpha_D$ .	$[M]_D$ .

LXXVI.—*The Chlorination and Bromination of 4-Aminodiphenyl.*

By HAROLD ARCHIBALD SCARBOROUGH and WILLIAM ALEXANDER WATERS.

THE action of chlorine or bromine on 4-aminodiphenyl and on its acetyl derivative appears to have been investigated in only one instance, where it was shown that, by direct bromination of 4-acetylaminodiphenyl, 4'-bromo-4-acetylaminodiphenyl resulted (Hübner, *Annalen*, 1881, 209, 339). Other halogen derivatives, however, have been prepared from benzidine and from tolidine by an adaptation of the Sandmeyer reaction (Taüber, *Ber.*, 1894, 27, 2627; Gelmo, *Ber.*, 1906, 39, 4175); the structure of these compounds necessarily follows from their method of preparation.

The present investigation had as its objects the preparation of the *N*-halogen derivatives and their conversion into ring-substituted products; and the direct introduction of chlorine or bromine into the molecule of 4-aminodiphenyl or 4-acetylaminodiphenyl.

It was found that a stable *N*-chloro-4-acetylaminodiphenyl (I) could be obtained from which 3-chloro-4-acetylaminodiphenyl (II) resulted; the latter compound again could be converted into a *N*-chloro-derivative which was unstable, lost chlorine, and from which a ring-substituted product could not be obtained. The corresponding *N*-bromo-4-acetylaminodiphenyl could be prepared only in an impure state, it lost bromine with ease, and the original acetyl derivative was not recovered.

The chlorination of the free base was attempted under various conditions, but only deeply coloured and tarry products were obtained. In contrast to this, the acetylated base could be substituted readily with the formation of 3-chloro-4-acetylaminodiphenyl, and on further chlorination 3:5:4'-trichloro-4-acetylaminodiphenyl (III) was obtained. It was found impossible to introduce more than these three atoms of chlorine into the molecule and obtain a product capable of being separated into individual compounds.

The bromination of the free base proceeded smoothly, yielding 3:5-dibromo-4-aminodiphenyl, and under altered conditions the latter compound could be further brominated to give 3:5:4'-tribromo-4-aminodiphenyl. Higher bromination products appear

to be formed; but from the mixture of substances produced it has been found impossible, so far, to isolate individual compounds. The acetyl derivative of the base on bromination yielded either 4'-bromo-4-aminodiphenyl or its acetyl derivative and a small quantity of a dibrominated product which has been shown to be 3:4'-dibromo-4-acetylaminodiphenyl. Bromination at a higher temperature yielded 3:5:4'-tribromo-4-aminodiphenyl.

The orientation of substituents in the nuclei of diphenyl is of a complex nature; thus whilst 4-aminodiphenyl and its acetyl derivative on chlorination or nitration yield a product substituted in the position adjacent to the amino-group, yet when the substituent in the 4-position is varied as widely as the halogens, the nitro-group and the carboxyl group the entering substituent goes to the 4'-position.

As the direct substitution of only 2- and 4-monosubstituted diphenyl derivatives has been investigated, it is impossible to put forward more than tentative suggestions. The following assumptions appear to be necessary :

(a) The usual directive influence is to be ascribed to all the simple groups.

(b) The phenyl group and the group  $C_6H_4X$  (where X may be an ortho-para or meta-directing group) have a strong ortho-para-directive influence.

(c) The amino-, hydroxy-, and derived groups promote substitution in the same nucleus.

Thus it appears that the position taken up by a substituent depends on the velocity with which substitution can be effected. This is in agreement with the experimental evidence that ortho-para-directing groups, and in particular the amino- or hydroxy-group, render substitution easy, whereas meta-directing groups tend to make substitution a comparatively slow process.

Alternatively, it might be suggested that substitution only occurs in the nucleus containing the directing group when this group is capable of being itself substituted and then undergoing a rearrangement which transfers the substituent to the ring. This would be in accord with the behaviour of amino- and hydroxy-groups.

The behaviour of 4-acetylaminodiphenyl on monobromination is very striking, since it appears to be the only known case among the substitution products of 4-amino- or 4-hydroxy-diphenyl in which the first substituent enters the 4'-position; this result is still more unexpected, since 4-aminodiphenyl itself gives rise to a normal sequence of substitution products.

This abnormal behaviour might be ascribed to (a) a mechanism for this bromination different from that involved in all other cases, or (b) steric influences. Three alternative mechanisms appear

possible: (1) the formation of a *N*-halogen compound followed by an *intramolecular* change; (2) the formation of a *N*-halogen compound followed by an *intermolecular* change; and (3) the direct interaction of the halogen and the aminodiphenyl molecules. Since *N*-bromo-4-acetylaminodiphenyl cannot be converted into a ring-substituted product, mechanism (1) cannot be the mechanism involved; since the corresponding *N*-chloro-compound can be thus transformed and since direct chlorination yields the same product, any one of the three mechanisms may be involved.

To ascribe the difference in behaviour to a steric factor would imply that by acetylation of the base the velocity of interaction of bromine with the more reactive hydrogen atoms in the 3- and 5-positions is decreased to such an extent that the less reactive hydrogen atom in the 4'-position is substituted almost exclusively.

It is the intention of the authors to complete a study of the chlorination and bromination of 2-aminodiphenyl and to extend the work to a consideration of 3-nitro- and 3-amino-diphenyl.

#### EXPERIMENTAL.

4-Aminodiphenyl was prepared by nitrating diphenyl by Ludens's method (*Ber.*, 1875, 8, 871) and reducing the product by Schlenk's method (*Annalen*, 1909, 368, 303).

*N*-Chloro-4-acetylaminodiphenyl.—To a suspension of 10.6 g. of 4-acetylaminodiphenyl in a solution of 13 g. of sodium bicarbonate in 200 c.c. of water, 150 c.c. of *N*-sodium hypochlorite were added during 2 hours. The product was collected after 12 hours, washed with water, dried, and extracted with light petroleum (b. p. 40–60°), in which 4-acetylaminodiphenyl is insoluble. The *chloroamine* crystallised from carbon tetrachloride in colourless needles, m. p. 129.5° (Found: Cl, 14.3.  $C_{14}H_{12}ONCl$  requires Cl, 14.4%).

3-Chloro-4-acetylaminodiphenyl.—(a) *Conversion of the chloroamine.* To a hot solution of 5 g. of the chloroamine in 100 c.c. of spirit and 2–3 c.c. of glacial acetic acid, sufficient water was added to start precipitation. The product separated on cooling, and crystallised from dilute alcohol in needles, m. p. 147°.

(b) *Direct chlorination of 4-acetylaminodiphenyl.* Chlorine was passed into a 2% solution of the acetylamine in glacial acetic acid, cooled in ice-water, until the theoretical gain in weight was obtained. The product, which was precipitated with water, contained higher chlorination products (Found: Cl, 14.7.  $C_{14}H_{12}ONCl$  requires Cl, 14.4%).

3-Chloro-4-aminodiphenyl hydrochloride was obtained on hydrolysis of the acetyl derivative with 10% alcoholic hydrochloric acid. The

salt separated from the solution, on cooling, in long needles, m. p.  $217^{\circ}$  (decomp.) (Found: HCl, 15.1.  $C_{12}H_{10}NCl$ , HCl requires HCl, 15.2%).

3-Chloro-4-aminodiphenyl was precipitated from the solution of the hydrochloride by dilute ammonia. It crystallised from dilute alcohol in needles, m. p.  $71^{\circ}$  (Found: Cl, 17.2.  $C_{12}H_{10}NCl$  requires Cl, 17.4%).

3:4-Dichlorodiphenyl, obtained from the amine by the usual methods, was a faintly yellow oil, b. p.  $195-200^{\circ}/15$  mm., which solidified to a pale yellow, crystalline mass, m. p.  $46^{\circ}$  (Found: Cl, 30.8.  $C_{12}H_8Cl_2$  requires Cl, 31.8%). On oxidation of this crude product with chromic anhydride in glacial acetic acid solution, 3:4-dichlorobenzoic acid was obtained (m. p.  $200^{\circ}$ ).

3-Chloro-4-acetylchloroaminodiphenyl.—The chloroamine was prepared in the manner described for 4-acetylchloroaminodiphenyl. It was a white powder soluble in non-aqueous solvents; it could not be obtained pure owing to the ease with which it lost chlorine. Several attempts were made, under various conditions, to bring about a rearrangement, but in each case chlorine was evolved and 3-chloro-4-acetylaminodiphenyl was obtained.

3:5:4'-Trichloro-4-acetylaminodiphenyl.—Chlorine and carbon dioxide were passed slowly into a 5% solution of 4-acetylaminodiphenyl, the temperature being kept as low as possible. Excess chlorine was removed with a current of air, and the solution diluted with water until precipitation commenced. The product crystallised from acetone in needles, m. p.  $236^{\circ}$  (Found: Cl, 33.6.  $C_{14}H_{10}ONCl_3$  requires Cl, 33.8%).

3:5:4'-Trichloro-4-aminodiphenyl.—The acetyl derivative was hydrolysed with alcoholic hydrochloric acid; the amine, which separated from the solution in long needles, was recrystallised from alcohol; m. p.  $128^{\circ}$  (Found: Cl, 38.9.  $C_{12}H_8NCl_3$  requires Cl, 39.05%). On oxidation with chromic anhydride in glacial acetic acid solution, *p*-chlorobenzoic acid was obtained (m. p.  $235^{\circ}$ ).

*N*-Bromo-4-acetylaminodiphenyl was obtained as was the corresponding chloro-compound. It was a pale yellow powder, easily soluble in non-aqueous solvents, and lost bromine very easily. As it could not be obtained pure, it was not further investigated.

4'-Bromo-4-aminodiphenyl.—To a well-cooled 10% solution of 4-acetylaminodiphenyl in glacial acetic acid was added slightly more than 1 mol. of bromine. After 24 hours, on pouring into water, a mixture of brominated products was obtained which, by fractional crystallisation from dilute acetic acid, was separated into a more soluble monobromo-derivative and a less easily soluble dibromo-derivative. The former was 4'-bromo-4-aminodiphenyl and not its

acetyl derivative (compare Hübner, *loc. cit.*). It crystallised from dilute acetic acid in long needles, m. p.  $145^{\circ}$  (Found: Br, 32.2.  $C_{12}H_{10}NBr$  requires Br, 32.1%). On oxidation with chromic anhydride in glacial acetic acid solution, *p*-bromobenzoic acid was obtained (m. p.  $251^{\circ}$ ).

3 : 4'-Dibromo-4-acetylaminodiphenyl.—The less soluble dibromo-derivative crystallised from acetone in colourless needles, m. p.  $197^{\circ}$  (Found: Br, 43.25.  $C_{14}H_{11}ONBr_2$  requires Br, 43.4%). The acetyl derivative was hydrolysed with alcoholic hydrobromic acid. The free base was not purified and analysed, as only a very small quantity was available; but was converted directly into a tribromo-derivative by bromination in glacial acetic acid solution. The product was crystallised from acetone and then from dilute acetic acid; it had m. p.  $148^{\circ}$ , alone or mixed with 3 : 5 : 4'-tribromo-4-aminodiphenyl. The original acetyl derivative was not identical with 3 : 5-dibromo-4-acetylaminodiphenyl, whence it follows that the acetyl derivative must have the bromine atoms in the 3- and 4'-positions.

3 : 5-Dibromo-4-aminodiphenyl.—The calculated quantity of a 10% solution of bromine in glacial acetic acid was added to a cold glacial acetic acid solution of 4-aminodiphenyl. The yellow precipitate was filtered off and washed with dilute sodium carbonate solution. It crystallised from alcohol in colourless needles, m. p.  $119^{\circ}$  (Found: C, 44.1; H, 2.9; Br, 48.8.  $C_{12}H_9NBr_2$  requires C, 44.05; H, 2.8; Br, 48.9%).

3 : 5-Dibromo-4-acetylaminodiphenyl was prepared by heating the base with acetic anhydride in glacial acetic acid solution. After crystallising from alcohol, it melted at  $162^{\circ}$  (Found: Br, 43.45.  $C_{14}H_{11}ONBr_2$  requires Br, 43.4%).

3 : 5-Dibromodiphenyl, obtained from the base by elimination of the amino-group in the usual manner, was a pale yellow oil, b. p.  $208^{\circ}/15$  mm., m. p.  $15^{\circ}$  (Found: Br, 51.3.  $C_{12}H_8Br_2$  requires Br, 51.3%). On oxidation with chromic anhydride in glacial acetic acid solution in a sealed tube at  $200^{\circ}$  3 : 5-dibromobenzoic acid was obtained (m. p.  $212^{\circ}$ ).

3 : 5 : 4'-Tribromo-4-aminodiphenyl.—Bromine (1 mol.) was added to a boiling solution of 3 : 5-dibromo-4-aminodiphenyl in glacial acetic acid, and the mixture refluxed until the colour of the bromine had disappeared (usually about 45 minutes). The product precipitated by addition of water crystallised from dilute acetone in white needles, m. p.  $149^{\circ}$ . The same substance was obtained by direct bromination of 4-acetylaminodiphenyl in boiling glacial acetic acid (Found: C, 35.4; H, 2.0; Br, 59.0.  $C_{12}H_8NBr_3$  requires C, 35.4; H, 2.2; Br, 59.0%). On oxidation with chromic anhydride

in glacial acetic acid solution *p*-bromobenzoic acid was obtained (m. p. 251°).

The *acetyl* derivative crystallised from acetone in white needles, m. p. 256° (Found: Br, 53.5.  $C_{14}H_{10}ONBr_3$  requires Br, 53.6%).

All m. p.'s recorded in this paper have been corrected, and where necessary the identity of a substituted benzoic acid was established by the "mixed m. p." method.

The authors wish to express their thanks to Dr. H. McCombie for the interest he has taken in the work. One of them (W. A. W.) is indebted to the Master and Fellows of Gonville and Caius College for a studentship which enabled him to collaborate in this work.

### LXXVII.—*The Influence of the Intensity of Illumination on the Velocity of Photochemical Changes. The Determination of the Mean Life of a Hypothetical Catalyst.*

By FRANK BRIERS, DAVID LEONARD CHAPMAN, and  
ERNEST WALTERS.

ONLY a few researches have been conducted on the variation of the rates of photochemical changes with the intensity of the light, and at present there is some degree of discordance in the conclusions drawn by different experimenters from the results of their experiments.

Draper (*Phil. Mag.*, 1843, 23, 401) announced that the rate at which chlorine and hydrogen combine in light is proportional to the intensity of the illumination. Baly and Barker (*J.*, 1921, 119, 653) maintained that the ratio of the rate of union of the two gases to the intensity of the light increases as the intensity of the light is increased. M. C. C. Chapman (*J.*, 1924, 125, 1521) obtained a result in substantial agreement with that of Draper. She found, however, that as the intensity of the radiation is increased the rate of formation of hydrochloric acid increases in a slightly smaller ratio. Berthoud (*Helv. Chim. Acta*, 1924, 7, 324) considered that the rate of union of chlorine and hydrogen in the absence of inhibitors would be proportional to the square root of the intensity of illumination, and he saw in some of Mrs. Chapman's results evidence that such is the case. Kornfeld and Müller (private communication from Professor Bodenstein) have confirmed Mrs. Chapman's results. They find

that the rate of formation of hydrochloric acid is proportional to the intensity of the light when the intensity is varied in the ratio of 1 : 64.

Draper, Baly and Barker, and Mrs. Chapman used electrolytic gas, which always contains a small amount of oxygen. Kornfeld and Müller removed oxygen from the hydrogen; but the chlorine they used may have contained a little oxygen.

It is possible that Berthoud's contention is right. The electrolytic gas used by Mrs. Chapman undoubtedly contained a little oxygen, and the small deviations from proportionality observed by her were in the direction required by Berthoud's view.

In a recent paper by Bodenstein and Lütkemeyer (*Z. physikal. Chem.*, 1924, **114**, 208) on the photochemical synthesis of hydrobromic acid it is concluded that the rate of formation of this compound from its elements is directly proportional to the square root of the intensity of the light. The striking difference, in this particular, of the influence of light on mixtures of bromine with hydrogen and of chlorine with hydrogen may possibly be due to the effect of small quantities of oxygen on the photochemical union of the latter gases. The question needs to be submitted to further investigation.

In connexion with the subject of this communication, the reaction between iodine and potassium oxalate is of especial interest. This reaction is represented by the equation :

It has been studied by Dhar (*Proc. K. Akad. Wetensch. Amsterdam*, 1916, **16**, 1097; *Ann. Chim.*, 1919, **11**, 130; *J.*, 1923, **123**, 1856) and by Berthoud and Bellenot (*Helv. Chim. Acta*, 1924, **7**, 307). In his first paper, Dhar maintained that the velocity of the action is proportional to the intensity of the light. On the other hand, Berthoud and Bellenot asserted that it is proportional to the square root of the intensity of the light, both for red and for blue light. In order to vary the intensity of the light the latter investigators inserted between the source of illumination and the solution a large disc of black cardboard which could be set in rapid rotation, and from which two equal sectors had been removed for the first series of measurements; four for a second series, and eight for a third series, so as to make the intensity vary in the ratios 1 : 2 : 4. They realised that this method of varying the intensity of the light would not be legitimate unless the duration of the secondary reactions considerably exceeded the intervals between successive illuminations, and they deduced that if this condition were fulfilled the velocity of reaction ought to diminish as the rate of rotation of

the disc is reduced. They observed the anticipated falling off in the velocity of the reaction, but they were unable to obtain the theoretical result when the disc was rotating very slowly.

We have repeated the experiments of Dhar and of Berthoud and Bellenot, and our results agree with those of the latter researchers. We have also examined more closely the theory of the effect of intermittent illumination on photochemical reactions of the same class, and have drawn conclusions from the theory and from our experimental results which will be given below.

The reaction between potassium oxalate and iodine, according to Berthoud and Bellenot, is of the same class as that between chlorine and hydrogen. One quantum of absorbed light is sufficient to cause the interaction of a large number of molecules of the reacting substances. For the explanation of such reactions several special hypotheses have been proposed. These hypotheses have one feature in common in that they postulate the formation of an unstable catalyst (or chain of catalysts) by the direct action of the light. We shall make no special assumption concerning the nature of the catalyst, but we shall assume that :

(I) the rate of formation of the catalyst is proportional to the intensity of illumination;

(II) the rate of reaction is proportional to the concentration of the catalyst; and

(III) the rate of destruction of the catalyst is proportional to a power of its concentration.

If  $[A]$  represents the concentration of the catalyst and  $I$  the intensity of the light, we have from assumptions I and III

$$\begin{aligned} d[A]/dt &= cI - k[A]^n \\ &= 0 \text{ in the steady state,} \end{aligned}$$

and therefore in the steady state

$$I^{1/n} \propto [A] \propto \text{the rate of reaction (from assumption II).}$$

Therefore in the case of the formation of hydrochloric acid from electrolytic gas  $n = 1$  if the experiments of Mrs. Chapman and of G. Kornfeld and H. Müller are trustworthy, whereas in the case of the interaction of iodine and potassium oxalate  $n = 2$  if the observations of Berthoud and Bellenot and of the authors are not subject to some unsuspected source of error.

We have spent 6 months in attempts to discover some explanation of Berthoud and Bellenot's results other than that given by the authors, namely, that in this reaction the velocity of change is not proportional to the intensity of illumination but to its square

root, and we have satisfied ourselves that none of the following causes could furnish such an explanation :

- (1) The presence of an inhibitor.
- (2) The varying rates of escape of the carbon dioxide produced in the reaction.
- (3) The more rapid removal of the iodine from that portion of the solution which is nearest to the light.
- (4) The method employed for varying the intensity of the light.\*

When the method of varying the intensity of the light was that of a rotating disc, consistent and reproducible results in agreement with those of Berthoud and Bellenot were obtained. The results were independent of the rate of rotation of the disc when this rate exceeded one thousand revolutions per minute. It must therefore be concluded that when the solution has been exposed to light the chemical action continues for some time after the light has been shut off: for otherwise the rate of chemical change would be

\* That inhibitors were not present was proved by the fact that the velocity of the reaction was not affected by the purification of the materials used (*i.e.*, by the fractional crystallisation of the potassium oxalate or by the sublimation of the iodine), the results being reproducible and, within reasonable limits, independent of the degree of purity of the reagents. Variation of the hydrogen-ion concentration had very little effect.

That the dissolved carbon dioxide had no effect was proved by the fact that the total amount of change in a given time, employing a constant intensity of light, was the same when the exposure was continuous and when it was intermittent, provided that the intervals of exposure were not too short.

Another method employed for varying the intensity of the light was the following. Two one thousand-watt lamps, A and B, were placed side by side so as to be symmetrically situated with respect to the reaction tube, which was contained in a thermostat. The currents passed through the lamps were separately adjusted so that each lamp emitted light of the same intensity. The reaction vessel was exposed for 4 hours to the light emitted by A alone, and then for 4 hours to the light emitted by B alone. The change was measured, and compared with that effected in half the time by an exposure of the reaction vessel, filled with a solution of the same composition, to the light emitted simultaneously by both lamps. The mean ratio of the change effected by the light from one lamp in 8 hours to that effected by the light from two lamps in 4 hours was 1.32 : 1, the theoretical result calculated on the assumption that the rate of change is proportional to the square root of the intensity of the light being 1.41 : 1. The fact that the theoretical ratio was greater than that found experimentally can be explained by the circumstance that the large size of the bulbs of the two lamps made it impossible to place their filaments close together. That the effect of this source of error would be in the direction stated can be seen immediately by considering the effect of placing the lamps on opposite sides of the comparatively strongly absorptive solution.

proportional to the number of sectors left open in the disc, and not to the square root of this number. In other words, the catalyst assumed above has a life of appreciable duration.

*Determination of the Life of the Catalyst or Chain.*—The rate of disappearance of the catalyst is given by  $k[A]^2$  and therefore in the steady state the mean life of the catalyst is

$$[A]/k[A]^2 = 1/k[A].$$

The problem is therefore to determine the value of  $k[A]$  when the solution is exposed to light of a given intensity and has reached the steady state.

In the light

$$d[A]/dt = cI - k[A]^2.$$

Multiply both sides of the equation by  $k$  and put  $ckI = a^2$  and  $k[A] = x$ .

The equation becomes

$$dx/dt = a^2 - x^2.$$

Or putting  $\tau$  for  $at$ , and  $y$  for  $x/a$ ,

$$dy/d\tau = 1 - y^2$$

the solution of which is

$$\frac{y_2}{y_1} \left[ \log_e \frac{1+y}{1-y} \right] = 2\tau_2 - 2\tau_1 \quad . \quad . \quad . \quad (1)$$

$y$  is the ratio of  $k[A]$  at the moment under consideration to its value in the steady state when the intensity of the light is  $I$ , and  $\tau$  is the ratio of the time,  $t$ , to the duration of a mean life.

The differential equation which holds in the dark is

$$d[A]/dt = -k[A]^2$$

and its solution in terms of the variable  $y$  and  $\tau$  is

$$\frac{1}{y_3} - \frac{1}{y_2} = \tau_3 - \tau_2 \quad . \quad . \quad . \quad (2)$$

in which  $y_3$  and  $y_2$  are the final and initial values of  $y$ , and  $\tau_3$  and  $\tau_2$  the corresponding values of  $\tau$ .

In our experiments, the disc has eight sectors, each of angle  $\pi/8$ , symmetrically situated. Accordingly, when the disc was rotating uniformly, the duration of illumination was equal to the time during which the light was shut off, i.e.,  $\tau_2 - \tau_1 = \tau_3 - \tau_2$ . Also under the same conditions  $y_1$  must attain a steady value which must be equal to  $y_3$ . Therefore from (1) and (2)

$$\log_e \frac{1+y_2}{1-y_2} + \frac{2}{y_2} = \log_e \frac{1+y_1}{1-y_1} + \frac{2}{y_1}.$$

For each value of  $y_1$  the corresponding value of  $y_2$  can be obtained from the above equation.

Moreover, if the value of  $\tau$  is selected such that when  $y = 0$   $\tau = 0$ , equation (1) becomes

$$\log_e \frac{1+y}{1-y} = 2\tau \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and for each value of  $y$  there is a corresponding value of  $\tau$ .

We shall now find the mean value of  $y$  for a given rate of rotation of the disc. From (3) the value of  $y$  during illumination is given by

$$y = \tanh \tau$$

and from (2) the value of  $y$  during the period of non-illumination is given by

$$y = 1 / \left( \tau + \frac{1}{y_2} \right)$$

in which  $\tau$  is the time (taking the mean life as the unit) during which the solution is in the dark and  $y_2$  is the value of  $y$  when the light is shut off.

The mean value of  $y$  during uniform rotation of the disc is manifestly given by

$$y = \frac{\log_e \cosh \tau_2 - \log_e \cosh \tau_1 + \log [(\tau_2 - \tau_1)y_2 + 1]}{2(\tau_2 - \tau_1)}$$

But the mean value of  $y$  when the disc is rotating very rapidly is  $1/\sqrt{2}$ . Consequently, since the mean value of  $y$  is proportional to the rate of chemical change,

$$\frac{\log_e \cosh \tau_2 - \log_e \cosh \tau_1 + \log [(\tau_2 - \tau_1)y_2 + 1]}{\sqrt{2}(\tau_2 - \tau_1)} = \frac{\text{rate of change when the disc rotates at the given rate}}{\text{rate of change when the disc rotates very rapidly}}$$

By trial a value of  $\tau_1$  is found which satisfies this equation. This can be done, since for every value of  $\tau_1$  there are corresponding values of  $\tau_2$  and  $y_2$ . Furthermore, as  $\tau_2 - \tau_1$  is the duration of the exposure to light in mean lives, the value of the mean life can be calculated from the known rate of rotation of the disc.

#### EXPERIMENTAL.

The composition of the solution was potassium oxalate  $N/2$ , iodine  $0.00625N$ , and potassium iodide  $0.00931N$ . The reaction vessel was a glass cylinder of 4 cm. diameter, and it contained 80 c.c. of the above solution. The cylinder was closed with a ground glass stopper in order to prevent loss of iodine by evaporation, and during an experiment it was maintained at a temperature of  $20^\circ$

in a thermostat filled with water and having sides of plane glass. A black screen was placed behind the reaction tube and the thermostat was covered so that no light could enter it except that which had passed through a sector of the disc and a window of the same shape as the sector in one of the glass sides of the thermostat. The reaction tube was placed near to the window in such a position that the whole of the solution it contained was equally illuminated. The source of light was a thousand-watt incandescent lamp placed at a horizontal distance of 38 cm. from the reaction vessel. The light from the lamp passed through an aperture of an appropriate shape in a large piece of cardboard which was placed immediately in front of the lamp, the aperture being of such a size that its penumbra was outside the window of the thermostat. The rotating disc was as near as possible to the thermostat and the reaction vessel. The shadow cast by the edge of the sector was quite sharp, but there was some error which could neither be avoided nor estimated, occasioned by reflexion from the inner wall of the glass bulb of the lamp. The lamp itself was, of course, placed in such a position that its incandescent wire subtended in a plane at right angles to the top edge of the window the minimum angle at a point in the solution. The disc was kept in rotation by means of a geared motor, and in some of the experiments in which the rotation was slow by a clock. The rates of chemical change were determined by finding the times required to bring about the same amount of chemical change as estimated by titration of the iodine with a standard solution of sodium thiosulphate. The mean life of the catalyst was in the first place determined when the solution was illuminated with white light. The results are recorded below :

A.	B.	C.	D.
20	71.75		
20	71.44		
Very fast	62.21	0.0303	0.000688
"	62.20		
24	71.12		
24	70.68	0.0299	0.000678
Very fast	62.21		

In column A is recorded the number of revolutions per minute of the disc; in column B the time of exposure in minutes needed to effect the same amount of chemical change; in column C the calculated mean life, in seconds; and in column D the quotient of the mean life and the time required to effect the given amount of chemical change when the solution was exposed without interruption to the light. This quotient should be a constant.

In a third determination light which had been filtered through a solution of iodine was used. The light passed through 5.5 cm. of an aqueous solution of iodine and potassium iodide of such a

strength that the concentration of each of the dissolved substances was twice as great as the corresponding concentration in the solution contained in the reaction vessel. The effect of using such filtered light would, of course, be to render the velocity of chemical change much more uniform throughout the solution. The results are recorded below :

A.	B.	C.	D.
21	293.2		
5	327.8		
5	324.7		
Very fast	282.8	0.1212	0.000605

From any of the above results the mean life of the catalyst in the dark at the temperature of the experiment can be calculated, provided that the rate of the chemical change in the dark is known, and similar assumptions are made concerning the mechanism of the change. The time required to effect the specified amount of change in the dark was found by experiment to be 10,430 minutes. Using the constant determined in the last experiment, we have the mean life of the catalyst in the dark =  $10430 \times 0.000605 = 6.31$  seconds.

Although we are unable without conducting further research to estimate the errors of the methods described for determining the constant, we believe that the accuracy of the determination is sufficient for present needs, namely, for the purpose of testing a hypothesis.

## LXXVIII.—*The Action of Alkaline Arsenites on Some Halogenated Organic Compounds.*

By ISIDORE ELKANAH BALABAN.

It is well known that sulphonic acids, both aliphatic and aromatic, may be obtained by the action of alkali sulphites on some halogenated organic compounds. In view of the chemotherapeutic importance of arsinic acids, it was thought worth while to investigate the action of alkali arsenites on a series of halogenated organic compounds of varying degrees of reactivity, in order, if possible, to delimit the applicability of the method. Meyer (*Ber.*, 1883, 16, 1440) first employed the method to prepare methyl- and ethyl-arsinic acids, and it was extended to *n*-propyl-, isoamyl-, and benzyl-arsinic acids by Dehn and McGrath (*J. Amer. Chem. Soc.*, 1906, 28, 351). Quick and Adams (*ibid.*, 1922, 44, 809) applied it successfully

to butyl bromide and allyl bromide, whilst Palmer (*ibid.*, 1923, 45, 3023) applied it to chloroacetic acid. In the aromatic series, Rosenmund (*Ber.*, 1921, 54, 438) obtained *o*-benzarsinic acid by the action of potassium arsenite on *o*-bromobenzoic acid.

Two glyoxaline derivatives have now been examined containing highly reactive halogen atoms, 4(5)-methyl-5(4)-chloromethylglyoxaline (I) and 5-chloro-1-methyl-2-chloromethylglyoxaline (II), but only the corresponding alcohols could be isolated in poor yield.

A less reactive glyoxaline compound, 5-chloro-4-nitro-1-methylglyoxaline (III), which had previously been shown to give a sulphonic acid (Balaban and Pyman, J., 1924, 125, 1564), when heated with potassium arsenite in absolute alcohol gave 4-nitro-5-hydroxy-1-methylglyoxaline (IV), a very unstable nitroamide resembling in general properties the nitroacetone and nitroacetophenone of Lucas (*Ber.*, 1899, 32, 600) and Henry (*ibid.*, 1899, 32, 865).

The nitroamide is, however, stable as its *potassium* and *sodium* salts. 2:4-Dinitrobenzene, which resembles the foregoing in containing a halogen atom activated by a nitro-group, yielded 2:4-dinitrophenol, whereas by the action of sodium sulphite in aqueous alcoholic solution it is known to yield 1:3-dinitrobenzene-4-sulphonic acid (D.R.-P. 65240). When 8-chlorocaffeine is heated with potassium arsenite in alcohol at 140–180°, a mixture of 8-hydroxy- and 8-ethoxy-caffeine is obtained. Under somewhat parallel conditions (D.R.-P. 74045), 8-chlorocaffeine is known to yield a sulphonic acid when treated with aqueous sodium sulphite. In the foregoing cases where reaction had taken place, the halogen atom was replaced by hydroxyl or ethoxyl. An unexpected result was, however, obtained on examining the action of alkali arsenite on phthalbromomethylimide in acetone solution, as ethylenediphthalimide was isolated.

When it was boiled with 20% aqueous sodium sulphite, *phthalimido-methanesulphonic acid* was obtained in a yield of 13.2% of the theoretical, the main product being phthalic acid (yield 62%), together with a small amount of phthalimide. An attempt to hydrolyse the sulphonic acid to the unknown aminomethanesulphonic

acid proved unsuccessful. Delépine and Demars also failed to obtain this compound by the action of ammonia on chloromethane-sulphonic acid (*Bull. Soc. Pharmacol.*, 1922, 29, 14).

In none of the above cases, although special search was made, was any organic arsenic acid found. If this result be contrasted with the much more general formation of sulphonic acids by the action of alkali sulphite, one is compelled to attribute it to the difference in alkalinity of sulphite and arsenite.

#### EXPERIMENTAL.

The action of alkali arsenites was examined on the following halogenated organic compounds: 4(5)-*Methyl-5(4)-chloromethylglyoxaline* (I). To a mechanically stirred solution of potassium arsenite (24 g.; 10 mols.) in water (30 c.c.) below 0°, 4(5)-methyl-5(4)-chloromethylglyoxaline hydrochloride (2 g.) in absolute alcohol (50 c.c.) was run in during  $\frac{1}{2}$  hour. After removal of much arsenic trioxide the mother-liquor was evaporated to dryness in a vacuum, the residue extracted with absolute alcohol, and the extract added to aqueous picric acid; 4(5)-methyl-5(4)-hydroxymethylglyoxaline picrate (1.1 g.; yield, 27.5%) was the sole product obtained. It melted at 180°, alone or mixed with an authentic specimen.

The experiment was repeated in absolute alcohol, but no definite organic products could be isolated.

5-*Chloro-1-methyl-2-chloromethylglyoxaline* (II), treated as in the above two experiments, yielded 5-chloro-1-methyl-2-hydroxymethylglyoxaline picrate (3 g.; yield, 64%), m. p. 148–149°, and 0.8 g., m. p. 148°, respectively, but no trace of other organic material.

5-*Chloro-4-nitro-1-methylglyoxaline* (III). The nitro-compound (2 g.) was boiled under reflux with potassium arsenite (5 g.) in absolute alcohol (50 c.c.) for 8 hours, together with a crystal of potassium iodide. On keeping, clusters of yellow needles crystallised (4.2 g.). This product was extracted with water (20 c.c.), and after removal of arsenic trioxide the filtrate was acidified (Congo-paper); 1.07 g. of solid crystallising in fine, colourless needles and decomposing at 106° were then obtained.

4-*Nitro-5-hydroxy-1-methylglyoxaline* (IV) is soluble in water, alcohol, dilute acids and alkalis, and the usual organic solvents. It cannot be recrystallised, as the solution rapidly becomes dark red, and acquires a strong odour of oxides of nitrogen. It was unsuitable for combustion, as it decomposed very rapidly. In alcoholic solution, the nitroamide gives with ferric chloride an intense brown coloration. It also gives the Liebermann nitroso-reaction. The *potassium* salt, prepared by carefully neutralising the nitro-amide

with dilute potassium hydroxide and evaporating the solution to dryness over sulphuric acid, crystallised in fine, long, yellow needles, decomp.  $292^{\circ}$ , containing  $\frac{1}{2}\text{H}_2\text{O}$ , which was very gradually lost at  $95^{\circ}$  (Found in air-dried substance:  $\text{H}_2\text{O}$ , 4.7; K, 20.4, 20.6.  $\text{C}_4\text{H}_4\text{O}_3\text{N}_3\text{K}, \frac{1}{2}\text{H}_2\text{O}$  requires  $\text{H}_2\text{O}$ , 4.7; K, 20.5%). The sodium salt, obtained in a similar manner, crystallised in minute, yellow, anhydrous prisms, decomp.  $320^{\circ}$  (Found: Na, 13.6.  $\text{C}_4\text{H}_4\text{O}_3\text{N}_3\text{Na}$  requires Na, 13.9%).

**2 : 4-Dinitrobromobenzene.** The nitro-compound (2.5 g.), potassium arsenite (8 g.), and absolute alcohol (50 c.c.) were heated under reflux on the water-bath for 8 hours. The product having been worked up as in the previous experiments, 2 : 4-dinitrophenol (1 g.), m. p.  $113-114^{\circ}$ , alone or mixed with an authentic specimen, was isolated. A further crop (0.5 g.), m. p.  $110^{\circ}$ , was also obtained.

**8-Chlorocaffeine.** Potassium arsenite (5 g.), 8-chlorocaffeine (2.3 g.), and absolute alcohol (50 c.c.) were similarly heated for 7 hours. The alcoholic mother-liquor gave 0.75 g., m. p.  $160^{\circ}$ , which after recrystallisation proved to be unchanged material; no products were isolated. The experiment was repeated in aqueous solution, ammonia or methylamine being evolved. After keeping, 0.85 g. of a substance, m. p.  $186^{\circ}$  alone or mixed with 8-chlorocaffeine, was collected, no other organic matter being obtained. A third experiment was carried out with absolute alcohol in a sealed tube at  $140-180^{\circ}$  for 8 hours. The alcohol-insoluble portion (0.4 g.) was hydroxycaffeine (m. p. ca.  $335^{\circ}$ ), and later crops (0.55 g.), which did not melt at  $340^{\circ}$ , were hydroxycaffeine contaminated with arsenic trioxide. The residual alcohol-soluble extract (0.45 g.), m. p.  $140-142^{\circ}$ , was identical with a prepared specimen of 8-ethoxycaffeine, the melting point of the mixture not being depressed.

**8-Hydroxycaffeine,** m. p.  $335^{\circ}$ , was readily prepared by heating 8-ethoxycaffeine with 16% hydrochloric acid for 10 minutes in the boiling-water bath. It was not obtainable directly from 8-chlorocaffeine by Fischer's process (*Ber.*, 1885, 28, 2486).

**8-Ethoxycaffeine** was prepared by heating 8-chlorocaffeine (1.5 g.) with potassium hydroxide (1 g.) and absolute alcohol (15 c.c.) under reflux on the water-bath for 6 hours. After removal of the solvent and extraction with water, 8-ethoxycaffeine (0.93 g.; yield, 62%), m. p.  $140-142^{\circ}$ , was collected; it crystallised in dense, colourless, waxy prisms.

**Phthalbromomethylimide.** When phthalbromomethylimide (2.4 g.) was heated with potassium arsenite (5 g.) in absolute alcohol (50 c.c.) under reflux for 7 hours, 0.9 g., m. p. ca.  $210^{\circ}$  (alone or mixed with phthalic acid), was collected, no other products being obtained. The experiment was repeated in acetone solution (50 c.c.) from

which 0.95 g. of product, m. p.  $230^{\circ}$ , was collected. This crystallised in colourless, rectangular prisms from glacial acetic acid, was very sparingly soluble in boiling water, and insoluble in ether (Gabriel, *Ber.*, 1887, **20**, 2225, gives m. p.  $232^{\circ}$  for ethylenediphtalimide) (Found: N, 8.8 by the Kjeldahl method.  $C_{13}H_{12}O_4N_2$  requires N, 8.7%).

*Action of Sodium Sulphite on Phthalbromomethylimide.*—The bromo-compound (9.1 g.) was boiled under reflux with sodium sulphite (75 c.c. of 20% aqueous solution; 2 mols.) until complete solution was effected ( $1\frac{1}{2}$  hours) and kept, when phthalimide (0.35 g., m. p.  $232^{\circ}$ ) was collected. The mother-liquor, on being acidified (Congo-paper), deposited phthalic acid (3.15 g., m. p.  $200^{\circ}$ ), whilst on concentration a further crop (0.85 g., m. p.  $200^{\circ}$ ; total yield 62%) was obtained. From the mother-liquors, by further concentration, phthalimidomethanesulphonic acid was obtained (1.2 g., m. p.  $270^{\circ}$  with decomp.; yield, 13.2%).

*Phthalimidomethanesulphonic acid* crystallises from water in long, fine, colourless, rectangular prisms, m. p. ca.  $295^{\circ}$  with decomposition according to the rate of heating; these contain  $2.5H_2O$ . After being dried at  $120^{\circ}$ , it does not melt even at  $320^{\circ}$ . It is very soluble in water, but almost insoluble in absolute alcohol (Found in air-dried substance: loss at  $120^{\circ}$ , 15.8.  $C_9H_7O_5NS \cdot 2.5H_2O$  requires  $H_2O$ , 15.7%. Found in substance dried at  $120^{\circ}$ : N, 5.9 by the Kjeldahl method.  $C_9H_7O_5NS$  requires N, 5.8%). The barium salt crystallises in long, fine needles which are sparingly soluble in water.

*Hydrolysis of the Sulphonic Acid.*—The sulphonic acid (0.5 g.) was heated with 20% hydrochloric acid (10 c.c.) for  $2\frac{1}{2}$  hours under reflux. On keeping, phthalic acid (0.3 g., m. p.  $214^{\circ}$ ; yield 91%) was obtained, whilst the mother-liquor on concentration gave less than 0.1 g. of ammonium chloride.

The author is greatly indebted to Dr. King for much helpful advice and criticism, and desires to thank Mr. W. Anslow for assistance in this investigation.

## LXXIX.—*The Crystal Structure of Catechol.*

By WILLIAM AUGUSTUS CASPARI.

THE crystal morphology of catechol is known from the measurements of Beckenkamp (*Z. Kryst. Min.* 1900, **33**, 599), who assigned catechol to the monoclinic-prismatic class, axial ratios

$U^*$

$1.6086 : 1 : 1.0229, \beta = 94^\circ 15'$ . In the present investigation, the rotating-crystal method has been used, and has led to definite data for the crystal cell and the space-group of catechol.

Perfectly developed crystals were obtained without difficulty by the slow evaporation of an aqueous solution. They were in most cases bounded by the three pinacoids; occasionally the prism  $\{110\}$  also appeared; swallow-tail twins about  $\{100\}$  were observed in a few instances.

X-Ray photographs were taken on glass plates through crystals set with the three crystallographic axes as rotation axes. The apparatus was of a simple character with a pinhole beam and requires no description; a Shearer tube with copper anticathode was used.

FIG. 1.

Catechol. Rotation axis  $a$ .

Figs. 1, 2, and 3 show the diagrams obtained by projecting the photographs on paper and marking the spots. As a rough guide to intensity, the size of the spots has been proportioned to the intensity of the photographic spots as far as possible. Spots due to  $K\beta$  radiation are omitted. The scale of the diagrams corresponds to a distance of 4.8 cm. between the plate and the crystal.

The dimensions of the unit cell follow directly from these photographs. Each spot represents the reflexion from a definite crystal plane, and the spots arrange themselves in layer lines upon which all planes have one index in common; these lines in the case of a flat plate take the form of hyperbolas. The spacing corresponding to the distance of the apex of the first hyperbola from the straight centre line is the length of the unit cell along the axis in question,

and those of further hyperbolas are consecutive multiples. Calculations are based on the formula

$$a(\text{or } b \text{ or } c) = n \times 1.54 / \cos \mu \text{ \AA.},$$

where  $n$  is the series number of the layer line, and  $1.54 \text{ \AA.}$  the wavelength of copper  $K\alpha$  radiation. The following cell dimensions were thus obtained:

$$\begin{array}{llll} \text{along } a \text{ axis, mean of 5 layer lines, } a = 17.46 \text{ \AA.} \\ \text{,, } b \text{ ,, ,, } 4 \text{ ,, ,, } b = 10.74 \text{ \AA.} \\ \text{,, } c \text{ ,, ,, } 2 \text{ ,, ,, } c = 5.48 \text{ \AA.} \end{array}$$

The ratios of these dimensions, *viz.*,  $1.62 : 1 : 0.51$ , agree with the goniometric axial ratios except that  $c$  has been stated at double its

FIG. 2.

Catechol. Rotation axis  $b$ .

FIG. 3.

Catechol. Rotation axis  $c$ .

proper length by Beckenkamp. The axial ratios of catechol should be written  $1.6086 : 1 : 0.5114$ .

To find the number of molecules in the unit cell, we have as the weight of the cell, the density of catechol being  $1.375$ ,

$$17.46 \times 10.74 \times 5.48 \times \sin 94^\circ 15' \times 1.375 = 1403 \times 10^{-24} \text{ g.}$$

The weight of the molecule being  $110 \times 1.65 \times 10^{-24} \text{ g.}$ , the quotient is  $7.8$ . That is, there are eight molecules in the unit cell. Indices can now be assigned to the various photographic spots by calculating the spacing  $d$  of each and applying the stereometric formula proper to the monoclinic system, which in the present case takes the form

$$1/d^2 = 0.0033h^2 + 0.0087k^2 + 0.0331l^2 - 0.0016hl.$$

U\* 2

The indices of all the planes observed are tabulated below.

FIG. 4.

The table shows that in all cases the sum of the indices  $h$  and  $k$  is an even number, and that there are no other regularities connecting the various indices. From this it follows that if the cell be represented by four equal molecules at the corners of a parallelepiped, there must be molecules of the same orientation in the centres of the {001} faces (Fig. 4). Hence the space-lattice is  $\Gamma_m'$  and, further, the space-group is narrowed down to  $C_{2h}^3$ . For this space-group, eight asymmetric molecules is the full number permissible; the catechol molecule, therefore, is without any intrinsic symmetry in the crystalline state. Each primary molecule, as shown in Fig. 4, must have three other differently oriented molecules near it.

As regards the actual disposition of the molecules in the crystal, we have as arguments the above symmetry data, the crystal

habit, and the size and shape of the catechol molecule. The evidence at hand points to a simple parallelipipedic arrangement, such that all the molecules are as it were skewered along the  $b$  axis, with the plane of the benzene rings lying parallel to  $a$  and  $c$  and the hydroxyl groups pointing pairwise alternately backward and forward along the  $a$  axis. Detailed discussion may, however, be deferred pending the examination of 2:3-dihydroxynaphthalene and 2:3-dihydroxyanthracene, which is now in progress. The above arrangement is in harmony with the reticular densities of the crystal faces; these would work out as follows:

{100}	face,	1 molecule in	14.7 Å <sup>2</sup> .
{001}	„	„	23.5 „
{010}	„	„	48.0 „
{110}	„	„	57.0 „

In the majority of the crystals, {100} is decidedly the most developed and {010} the least developed face, whilst {110} occurs only sporadically; the order of the reticular densities is thus the same.

The author desires to express his indebtedness to Sir William Bragg, F.R.S., and to his fellow-workers at the Davy Faraday Laboratory for the helpful interest taken by them in this investigation; also to the authorities of the Royal Institution for apparatus and laboratory facilities.

# LXXX.—*Unsymmetrically Substituted Dinitro- and Diamino-derivatives in the Stilbene and Tolane Series. Part I. The Elimination of Hydrogen Chloride from 3:4'-Dinitrostilbene Dichloride.*

By HAROLD AINSWORTH HARRISON and HAROLD WOOD.

FLÜRSCHHEIM was the first to point out the important principle that the alternate effects produced by substituents in aromatic nuclei can be rendered conspicuous by comparing the properties of isomeric  $m$ - and  $p$ -disubstituted derivatives. With groups in these two positions the possibility of ring closure is almost eliminated and anomalies caused by steric hindrance are largely curtailed, whilst the general polar effects are approximately equal. The present research was undertaken with the idea of testing the accuracy of

certain apparently unequivocal forecasts derived by application of the alternate polarity rule to the diphenylethane series. The theory of non-polar alternating affinity, on the contrary, does not appear to afford any trustworthy *a priori* guidance in the types of reaction selected for investigation.

The dichlorides and dibromides of  $\alpha\beta$ -unsaturated acids, when deprived of one molecule of halogen hydride, invariably lose the  $\beta$ -halogen atom. It seemed desirable, therefore, to ascertain whether similarly unidirectional influences could be discovered in the dihalides of unsymmetrically substituted stilbene derivatives. The effect of two nitro-groups in the 3- and 4'-positions is cumulative and a strong difference in the reactivity of the two halogen atoms should accrue. The removal of one molecule of halogen hydride should therefore result in the preferential formation of one or other of the two possible monochlorostilbenes. As a matter of fact,  $\alpha$ -chloro-4 : 3'-dinitrostilbene was the sole product of reaction, and this is in entire agreement with polarity principles.

3 : 4'-Dinitrostilbene had previously been prepared by Cullinane (J., 1923, 123, 2060) by the condensation of *p*-nitrophenylacetic acid and *m*-nitrobenzaldehyde in presence of piperidine at 100° for 1 hour. Exact repetition of his method by the present authors resulted, however, in the isolation of a totally different product. Cullinane's supposed dinitrostilbene consisted of yellow needles, m. p. 155° (yield not stated), which gave green solutions in various organic solvents. The dinitrostilbene obtained by us, having been washed many times with boiling alcohol and recrystallised from glacial acetic acid, melted at 217°, and was sparingly soluble in most solvents, forming only pale yellow solutions.

From the alcoholic washings three other products were isolated in small quantity: *p*-nitrotoluene, formed by the partial decomposition of *p*-nitrophenylacetic acid by piperidine, and the piperidine salts of the two stereoisomeric forms of 3 : 4'-dinitro- $\alpha$ -phenylcinnamic acid, resulting from loss of water without carbon dioxide. Both of these acids were subsequently synthesised. They could be decarboxylated to give the same dinitrostilbene by heating with piperidine. Their properties will be described in a future paper.

Preliminary investigation showed that 3 : 4'-dinitrostilbene dibromide\* on heating with pyridine lost both atoms of bromine; the stilbene was therefore converted into a mixture of dichlorides, from each of which (although with much greater facility in the case of the low-melting  $\beta$ -variety), by prolonged heating with pyridine, one

\* A detailed description of this dibromide will be given in a subsequent paper.

molecule of hydrogen chloride was eliminated, with the formation of only one monochlorodinitrostilbene, having one of the configurations I and II.

The chlorostilbene was eventually\* decomposed by warm concentrated sulphuric acid, with the formation of a coloured intermediate compound (not isolated). This on decomposition with water passed through the transitory enol form to produce 4-nitrophenyl 3-nitrobenzyl ketone (III).

That this ketone had the structure shown was proved by oxidising the intermediate aldol, 3:4'-dinitro- $\alpha\beta$ -diphenylethyl alcohol, isolated as a by-product from the stilbene condensation and therefore possessing the configuration (V), with chromic acid in acetic acid solution, when the isomeric 3-nitrophenyl 4-nitrobenzyl ketone (IV) was obtained.† Another proof of the constitution of (III), by its synthesis from 3:4'-dinitro- $\alpha$ -phenylcinnamamide, will be described shortly.

Each of these ketones (III and IV) was converted into the corresponding monochlorodinitrostilbene by treatment with phosphorus pentachloride, and although these two products melted at approximately the same temperature, a mixed melting point determination showed a depression of 20°, and further, each chlorodinitrostilbene, on treatment with sulphuric acid as before, was reconverted into the corresponding ketone.

Without doubt the monochlorodinitrostilbene formed by loss of the elements of hydrogen chloride from 3:4'-dinitrostilbene dichloride is I and not II.

\* Prolonged boiling with silver acetate in acetic acid, with potassium acetate, or with formic acid was ineffectual. An attempt to prepare the ozonide met with no greater success.

† Finzi had shown (*Monatsh.*, 1905, 26, 1128) that oxidation of a substituted deoxybenzoin to the benzil cannot be carried out with chromic acid in acetic acid.

## EXPERIMENTAL.

**3:4'-Dinitrostilbene.**—A mixture of *p*-nitrophenylacetic acid (76 g.) and *m*-nitrobenzaldehyde (63.5 g.) was heated with piperidine (13 g.) at 110° for 1 hour (carbon dioxide and water were expelled; the liquid then set to a semi-solid mass); thereafter the temperature was raised to 150°\* during 2 hours. The product was boiled with alcohol (200 c.c.) until the solid cake had disintegrated, and the dinitrostilbene was then filtered off, pulverised, and repeatedly washed with boiling alcohol (about 300 c.c.) until it was bright yellow. It crystallised from acetic acid, nitrobenzene or pyridine in yellow needles, m. p. 217° (Found: C, 62.35; H, 3.75.  $C_{14}H_{10}O_4N_2$  requires C, 62.2; H, 3.7%). It is slightly soluble in hot benzene, acetone, ethyl acetate, or chloroform, but very sparingly soluble in boiling alcohol. The yield was 30%. On standing, the mother-liquor and washings deposited a dark brown, viscous oil which could not be purified; treatment of this with cold strong sulphuric acid increased the total yield of dinitrostilbene to 55%.

**3:4'-Dinitro- $\alpha\beta$ -diphenylethyl Alcohol (V).**—After removal of this oil, addition of water precipitated a light yellow solid which, after crystallisation from acetic acid and then from alcohol, melted at 147–148° (Found: C, 58.1; H, 4.3.  $C_{14}H_{12}O_5N_2$  requires C, 58.3; H, 4.2%). This substance is soluble in alcohol, acetic acid, ethyl acetate, or acetone, and sparingly soluble in ether or benzene. Heating with piperidine or treatment with cold strong sulphuric acid produces the dinitrostilbene. Slow evaporation of the solution after removal of the aldol compound caused the separation of a little *p*-nitrotoluene, and on long standing the residual liquors deposited thin leaflets which crystallised from alcohol in straw-coloured needles, m. p. 168–169° (Found: C, 59.7; H, 5.2.  $C_{20}H_{21}O_6N_3$  requires C, 60.15; H, 5.3%). This compound is therefore the *piperidine* salt of one of the two stereoisomeric 3:4'-dinitro- $\alpha$ -phenylcinnamic acids, m. p. 221°.† If the temperature of condensation is allowed to rise to 160° after 1 hour, the yield of dinitrostilbene is even less than usual, much more *p*-nitrotoluene being formed. After removal of the normal reaction products (no pure aldol can be isolated) a crop of crystals separates, which after crystallisation from alcohol consists of bright yellow needles, m. p. 204–205° (decomp.) (Found: C, 59.85; H, 5.5.  $C_{20}H_{21}O_6N_3$  requires C, 60.15; H, 5.3%). This is the *piperidine* salt of the other stereoisomeric substituted cinnamic acid, m. p. 205.5°.†

\* Above this temperature much decomposition takes place.

† The free acids were obtained by treatment of the piperidine salts with warm sodium carbonate solution, and subsequent acidification; the melting points were not depressed by admixture with authentic samples.

*α- and β-Forms of 3:4'-Dinitrostilbene Dichloride.*—Finely divided 3:4'-dinitrostilbene (20 g.) was suspended in chloroform (750 c.c.),\* and dry chlorine passed in during 4 hours. After standing for 4 days, the excess of chlorine was removed from the filtered solution by shaking carefully with dilute sodium bisulphite, and then with sodium hydroxide. After having been washed and dried, the chloroform solution was evaporated to a small bulk until deposition of the dichloride commenced (concentration beyond this stage tends to blacken the product). When cold, the white crystals were filtered off, washed with a little chloroform, and dried (15 g.; 60% yield). They consisted of a mixture of the *α*- and *β*-forms, and melted at 188—196°. By two crystallisations from acetic acid the pure *α*-form could be obtained in thin plates, m. p. 207° (Found: Cl, 20.9.  $C_{14}H_{10}O_4N_2Cl_2$  requires Cl, 20.8%). The more soluble *β*-form, m. p. 132—138°, was never obtained quite pure (Found: Cl, 21.1%). Both forms are appreciably soluble in alcohol.

*α-Chloro-4:3'-dinitrostilbene (I).*—Preliminary investigation having shown that the *α*-modification of the dichloride is much more stable to pyridine than the *β*-, the crude mixture of dichlorides (75 g.) was heated (water-bath) with pyridine (160 g.) for 90 hours. On cooling, bright yellow, glistening needles of the monochloro-dinitrostilbene crystallised out, which after recrystallisation from acetic acid melted at 161° (Found: C, 54.9; H, 3.1; Cl, 11.5.  $C_{14}H_9O_4N_2Cl$  requires C, 55.2; H, 2.95; Cl, 11.6%). Precipitation of the mother-liquors with alcohol resulted in a further small quantity (total yield = 77%). No other product was isolated.† This compound crystallises well from pyridine, acetic or formic acid, benzene, chloroform, or acetone. It is but sparingly soluble in alcohol, ether, or carbon tetrachloride.

*4-Nitrophenyl 3-Nitrobenzyl Ketone (III).*—Finely powdered *α*-chloro-4:3'-dinitrostilbene (I) (5 g.) was gently warmed with strong sulphuric acid (20 c.c.) during 1 hour (above 60°, charring takes place). When the evolution of hydrogen chloride had ceased, the deep red solution was cooled and poured on to ice. The almost white precipitate was crystallised from alcohol, and then from acetic acid; clusters of white needles, m. p. 134°, were thus obtained

\* A smaller quantity of solvent is inadvisable, owing to the slow speed of absorption of chlorine by the stilbene.

† The liquors were concentrated almost to dryness on the water-bath and warmed with strong sulphuric acid. After the vigorous evolution of hydrogen chloride (chiefly from the pyridine hydrochloride) had ceased, the product was poured into water, and the lustrous deposit crystallised from alcohol (charcoal). It melted at 129° and did not depress the melting point of III. It had therefore been formed from the same chlorodinitrostilbene.

(Found: C, 58.5; H, 3.6.  $C_{14}H_{10}O_5N_2$  requires C, 58.7; H, 3.5%). This ketone is easily soluble in all the usual solvents except ether, light petroleum, or carbon tetrachloride. It gives a *semicarbazone* which crystallises from alcohol in pale yellow needles, m. p. 219°. Treatment of the ketone at its melting point with phosphorus pentachloride reconverted it into the monochlorodinitrostilbene.

**3-Nitrophenyl 4-Nitrobenzyl Ketone (IV).**—A solution of the aldol compound (V) (4.5 g.) in hot glacial acetic acid (45 c.c.) was cooled to 50° without allowing deposition of solid, treated with a 10% solution of chromic acid [prepared from crystalline sodium dichromate (7.5 g.), sulphuric acid (10 g.), and water (35 g.)] during 1 hour, and then, while still warm, with water (10 c.c.). The ketone which separated crystallised from 95% alcohol in pearly plates (yield 75%), m. p. 102° (Found: C, 58.65; H, 3.45.  $C_{14}H_{10}O_5N_2$  requires C, 58.7; H, 3.5%). The solubilities of this ketone approximate very closely to those of the isomeric ketone (III), m. p. 134°. It gives a *semicarbazone* which crystallises from alcohol in bright yellow rhombs, m. p. 230°.

**$\alpha$ -Chloro-3 : 4'-Dinitrostilbene (II).**—Treatment of the ketone (IV) at its melting point (brine-bath) with phosphorus pentachloride furnished the corresponding monochlorodinitrostilbene in fair yield; on crystallisation from acetic acid, it formed small clumps of light brown needles, m. p. 162° (Found: C, 55.0; H, 3.0; Cl, 11.8.  $C_{14}H_9O_4N_2Cl$  requires C, 55.2; H, 2.95; Cl, 11.6%). A mixture of the two isomeric monochlorostilbenes melted at 142–145°. The solubilities of this isomeride (m. p. 162°) are almost identical with those of the other (m. p. 161°). The degrees of stability, too, are comparable, since prolonged boiling with formic acid or with silver acetate in acetic acid does not remove the chlorine atom. Pyridine is also without action. Concentrated sulphuric acid at 60° converts it into the ketone (IV) from which it was derived, but so far as could be ascertained there was no difference in the rate of decomposition of the two monochlorodinitrostilbenes.

**Action of Concentrated Sulphuric Acid.**—The dinitrostilbene furnishes a bright red solution, from which the unchanged product is recovered on dilution with water: both monochlorodinitrostilbenes (I and II) give deep red solutions on warming and evolve hydrogen chloride vigorously; they char considerably at 80°: the dinitrostilbene dichloride yields a faintly pink solution, with very slight evolution of gas; it chars somewhat at about 80°: the dinitrostilbene dibromide gives a pink colour and evolves hydrogen bromide at 70–80°; there is no sign of charring, and the product after dilution with water and crystallisation from alcohol still contains bromine.

One of us (H. W.) desires to express his gratitude to the Department of Scientific and Industrial Research for a maintenance grant, and the other (H. A. H.) to the Chemical Society Research Fund for a grant which has defrayed the cost of materials. We are also indebted to Professor Lapworth for suggesting the line of research.

THE UNIVERSITY, MANCHESTER.

[Received, November 27th, 1925.]

## LXXXI.—*The Budde Effect in Bromine. Part I. The Photoactive Constituent of Wet Bromine.*

By BERNARD LEWIS and ERIC KEIGHTLEY RIDEAL.

THE experiments of Dixon and of Baker (*Rep. Brit. Assoc.*, 1894, p. 493; *J.*, 1884, 45, 611) on the influence of small traces of water on physical and chemical changes have led to the theory of internal equilibrium of Smits ("The Theory of Allotropy," Longmans and Co.) in which it is assumed that water acts as a catalyst in accelerating the attainment of equilibrium between various polymeric or allotropic forms of simple molecules in homogeneous systems which were originally in metastable states. To exert this catalytic activity it must be assumed that the water makes a temporary complex with the reactant, which complex must be capable of excitation or activation more readily than the reactant molecules themselves.

The earlier experiments of Budde (*Pogg. Ann.*, 1871, 144, 213; *Wied. Ann.*, 1879, 6, 477), Mellor (*J.*, 1902, 81, 1280), and Bevan (*Phil. Trans.*, 1903, 202, A, 71) as well as those of Pringsheim (*Wied. Ann.*, 1887, 32, 385), Richardson (*Rep. Brit. Assoc.*, 1888, p. 89), Shenstone (*J.*, 1897, 71, 471), and Cordier (*Monatsh.*, 1900, 21, 660) revealed the fact that dry chlorine differed from moist chlorine in that on exposure to radiation, especially in the blue and violet portion of the spectrum, moist chlorine underwent expansion, but dry chlorine, although absorbing the radiation, showed no such expansion. This "Budde" effect has likewise been noted by Budde (*loc. cit.*) and by Ludlam (*Proc. Roy. Soc. Edinburgh*, 1924, 44, 197) in the case of bromine.

The early experiments made it clear that the expansion in the moist halogen was due to the conversion of absorbed radiation into thermal energy of molecular agitation and it was assumed from this fact that, since the Budde effect is still obtainable in a region of the spectrum in which the quantum is small (in the case of bromine a Budde expansion is still noticeable at  $\lambda = 5800 \text{ \AA.}$ , whilst according to Franck [Photochemical meeting, Oxford, 1925], from a consideration of the distribution of the absorbed energy between

rotational, oscillatory, and electronic quantum states of the molecule, dissociation of the molecule cannot be effected with a wavelength greater than  $\lambda = 5000 \text{ \AA.}$ ), the thermal effects are not produced by a primary activation of a bromine molecule followed by a splitting into atoms with their subsequent recombination. It has also been shown by Sir J. J. Thomson (*Proc. Camb. Phil. Soc.*, 1901, 11, 90) that the formation of charged ions according to the reaction  $\text{Br}_2 \rightleftharpoons \text{Br}^+ + \text{Br}^-$  does not occur, a view which can likewise be demonstrated to be improbable from a comparison of the magnitudes of the energies required for dissociation into atoms and ions respectively. How the moisture caused the conversion of radiant into kinetic energy was not elucidated. We may note, however, that Bevan (*loc. cit.*) postulated the existence of complexes such as  $(\text{Cl}_2)_x(\text{H}_2\text{O})_y(\text{H}_2)_z$  in the water-sensitised hydrogen-chlorine mixture, and on analogy with this conception it might be argued that a hydrate  $(\text{Br}_2)_x(\text{H}_2\text{O})_y$  was the photoactive constituent responsible for the Budde effect. Alternatively it might be suggested that in the metastable, freshly distilled, dry halogen a photosensitive polymeride of bromine is absent, but is present when the inner equilibrium is attained with the aid of the catalytic water. With the exception of the work of Coehn and Jung (*Z. physikal. Chem.*, 1924, 110, 705) on the hydrogen-chlorine reaction, no quantitative work on the influence of water on such reactions has been accomplished and it appeared of interest to examine the Budde effect in bromine in more detail.

It may be stated at the outset that the experimental data support the hypothesis that the Budde effect is due to a photosensitive bromine hydrate of composition  $\text{Br}_2 \cdot \text{H}_2\text{O}$  and that the water does not function as a catalyst in the formation of a photosensitive polymeride of bromine. Having established this point, it was necessary to investigate the properties of this hydrate in more detail such as its heat of formation, the value of the equilibrium constant of the reaction  $\text{Br}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{O} \cdot \text{Br}_2$  and the distribution of the hydrate, *i.e.*, the partition of the hydrate between the surface and bulk phases in the reaction vessel.

Finally, it was decided to investigate how far the absorption spectrum of the hydrate differed from that of bromine vapour, to evaluate its absorption coefficient, and to suggest a hypothesis as to the mechanism of operation of the Budde effect.

The importance of these points would appear not to be confined to the Budde effect alone, for if hydrates do exist in the gas or liquid phases of non-polar, or feebly polar substances, it is to be anticipated that the walls of the containing vessel which adsorb water readily will likewise adsorb the hydrate. Thus the partition

of the hydrate between the bulk and surface phases will obey an equation of the type found to hold in the isothermal adsorption of vapours and will prove an important factor in the relative rates at which reactions, which are *ex hypothesi* due to this hydrate, occur in the two phases.

Again, whilst dry bromine does absorb light within a large portion of the spectral region which causes the Budde effect in wet bromine, no thermal effects are to be noted. It follows that the apparent absorption is fictitious, for the light must be re-emitted as fluorescent light or scattered from the molecules. The hydrate molecules, on the other hand, absorb the light which is subsequently converted into thermal energy. The data from absorption spectra clearly do not distinguish between these two phenomena. The influence of water in cutting down the fluorescence of dry hydrogen and oxygen exposed to illumination of a quartz mercury vapour light recently noted by Baker\* (J., 1925, **127**, 1990) and the fluorescence of dry active hydrogen yielding the line  $\lambda = 3064 \text{ \AA.}$ , a water vapour line (Bonhoeffer, *Z. physikal. Chem.*, 1925, **116**, 39), would appear to be a phenomenon similar to that occurring in bromine.

#### EXPERIMENTAL.

Two forms of apparatus were employed for determination of the effect of alteration in the partial pressures of the bromine and

FIG. 1.

water on the magnitude of the Budde effect. For low partial pressures of water, the following method was devised. The reaction vessel, *A*, of 20 c.c. capacity, consisted of a bulb with plane-parallel sides, 2.35 cm. apart, connected on one side by capillary glass tubing to the phosphoric oxide tube, *X*, and the glass gauge, *B*. On the other side capillary connexions were made to the bromine and water reservoirs *D* and *E*, the drying train, *F*, the McLeod gauge, *H*, and mercury vapour pump line, *G*.

During evacuation of the reaction vessel the gauges and reactant

\* Communicated at a meeting of the Society.

reservoirs were temporarily disconnected by capillary glass inner seals 1, 2, 3, 4, which were provided with iron rods enclosed in glass permitting of fracture of the seals with the aid of an electromagnet. Between the diffusion pumps, *G*, and the apparatus a liquid air-trap was placed to prevent back-diffusion of mercury vapour. The gauge, *B*, consisted of a well-annealed (5 months), collapsed elliptical glass bulb forming a Bourdon indicator, attached to a 30 cm. glass pointer, to the end of which one arm of a quartz bifilar suspension for a mirror, *C*, was attached. The mirror was steadied by means of a mica vane dipping in water, the surface tension of which was lowered by the addition of a drop of oleic acid, thus permitting unhindered movement of the mirror. A spot of light from the mirror on a scale one metre away was followed. The sensitivity of the gauge could be varied by alteration, with the aid of a micrometer screw, of the position of the left arm, *H*, of the bifilar suspension; pressure changes of 1/120 mm. of mercury could be registered when it was in most sensitive adjustment. The gauge was calibrated with the aid of a mercury manometer and eye-piece, frequent calibration showing but little change in the characteristics.

The apparatus employed for the higher vapour pressures of water was similar to that described above, but in place of internal seals, stopcocks, lubricated by two rims of chlorinated odourless wax, were employed. In place of the water reservoir, a bulb containing sodium sulphate decahydrate was employed as source of water vapour, which was connected to the reaction vessel and pump through a small dosing apparatus of 0.3 c.c. capacity permitting of admission of small quantities of water vapour to the dry bromine. The source of light was a 1000 c.p. point light, parallel rays being obtained with a collimator, the reaction vessel being mounted in a plane-sided trough through which water was circulated from a thermostat. Between the collimator and the trough was placed a smaller trough in which the requisite colour filters could be placed.

*Materials.*—The bromine was prepared by distillation of the purest obtainable bromine, twice over zinc oxide and once over freshly prepared phosphoric oxide in a closed system which had originally been baked out. The bromine was stored over phosphoric oxide in a sealed vessel and was not used for the dry experiments until 9 months later. The data of Ramsay and Young (1886, 49, 453) were employed for the vapour pressure at various temperatures.

The sodium sulphate decahydrate was prepared by triple crystallisation and partial desiccation. The dissociation vapour pressure

at 0° employed was 2.77 mm., from the value given by Baxter and Lansing in the Landolt-Bornstein tables.

The water employed was pure conductivity water, and the vapour pressures were calculated with the aid of the equation of Nernst (*Verh. deut. physikal. Ges.*, 1907, **11**, 313):  $\log_{10} P_{\text{mm.}} = -\frac{2611}{T} + 1.75 \log T - 0.00210T + 6.5343$ , substantiated experimentally to 100° K. by S. Weber (*Communication Lab. Leyden*, 1915, **14**, 150A).

Three different vapour pressures were employed at temperatures corresponding to the freezing points of toluene, ethyl acetate and chloroform. The values are in the following table:

Substance.	Temperature.	V. p. above the ice in mm. Hg.
Melting toluene .....	-93°	$3.9 \times 10^{-5}$
„ ethyl acetate .....	-83	$2.3 \times 10^{-4}$
„ chloroform .....	-63	$5.3 \times 10^{-3}$

*Method of Operation.*—The method of operation employed was as follows. The reaction vessel was placed in an electric furnace and the capillaries and connexions up to the seals were wound with nichrome wire and thoroughly lagged with asbestos. One or two small parts were heated frequently with a Bunsen flame. A vacuum (less than  $10^{-6}$  mm. Hg) was maintained in the system at 400° for 5 days. The seal connecting the system to the ice maintained in liquid air was first broken with the connexion still open to the pumps. The high vacuum was rapidly reached again, the pumps were disconnected, the liquid air was replaced by melting toluene, and the water vapour allowed to pass into the reaction bulb. When equilibrium was attained (over an hour), the capillary tube leading to the water-vapour container was sealed under the blow-pipe, and the reservoir removed. Dry bromine at the required partial pressure (the bromine reservoir had been previously evacuated and maintained at a desired temperature) was admitted, and the bromine reservoir removed in a similar manner. Finally, dry air was admitted to atmospheric pressure, and the connexion sealed. The phosphoric oxide tube, X, was sealed and the connexion to the gauge established by breaking the capillary seal (1). Finally, the tube containing the iron rod at seal (1) was sealed and removed.

The reaction vessel was brought to a uniform temperature by the circulating water, and the deflection on the gauge observed for various distances of the lamp and with various colour filters (Wratten light filters). Finally, the gauge setting was calibrated. Four separate experiments were carried out in this manner, one with dry bromine-air mixture, in which no Budde effect was noted under the most intense illumination, and three with water vapour at the partial pressures given above.

For determination of the Budde effect at higher water-vapour pressures, taps instead of internal seals were employed and evacuation was effected with a Toepler pump instead of the diffusion pumps. On admission of dry bromine and air to the reaction vessel a small Budde effect was always noticeable under strong illumination, indicating that traces of water vapour (0.001 mm.) could not be eliminated entirely by this procedure.

To admit definite quantities of water to the evacuated system, the sodium sulphate reservoir at 0° was opened to the 0.3 c.c. capillary doser, thus filling it with water vapour at a partial pressure of 2.77 mm. Bromine was admitted to the reaction vessel, and then dry air passed through the doser into the 20 c.c. bulb,

FIG. 2.

thus sweeping the water vapour into the reaction system. Any number of doses could be admitted in this manner.

Neither with air nor with dry bromine on illumination was the slightest change in pressure observed, but in the presence of moisture a rapid rise in pressure, approaching an equilibrium value within 20 to 30 seconds, was always obtained. On cutting off the illumination, the light spot of the gauge indicator returned to its initial position.

An investigation of the magnitude of the Budde effect with various light filters showed (the Wratten filters 15, 16, 21, 25 as well as various combinations were permeable to photochemically active light) that light of wave-length longer than  $\lambda = 5800 \text{ \AA}$ . produced no detectable effect; light within a region  $5600 \text{ \AA}$ . to  $5500 \text{ \AA}$ . was particularly effective. Accordingly, a filter combination transmitting red light and light from  $5400 \text{ \AA}$ . to  $5700 \text{ \AA}$ .

with a maximum permeability near 5500 Å. was employed for all quantitative experiments.

An investigation revealed that the energy distribution in the various wave-lengths between 5000 Å. and 6000 Å. of the point light as measured with a thermopile and galvanometer was uniform, thus a mean of the effective extremes of the light filter could be assumed.

*Results.*—In the curve (Fig. 2) is given the relationship between the Budde effect in bars (dynes per sq. cm.) as a function of the partial pressure of the water vapour at a constant bromine pressure of 158 mm. and a temperature of 40°. Some of the values obtained, from which the curve was plotted on a very large scale so as to permit of accurate analysis, are in the following table :

Partial press. of Br, 158 mm. Temp. of bath, 40°. Distance of lamp, 15 cm.

Press. of H <sub>2</sub> O in mm. Hg.	Deflection in bars.	Press. of H <sub>2</sub> O in mm. Hg.	Deflection in bars.
0	0	$8.3 \times 10^{-2}$	1830
$3.9 \times 10^{-5}$	66	$1.245 \times 10^{-1}$	1950
$2.3 \times 10^{-4}$	226	$1.66 \times 10^{-1}$	2020
$5.0 \times 10^{-3}$	958.8	$3.32 \times 10^{-1}$	2140
$4.15 \times 10^{-2}$	1640	$5.395 \times 10^{-1}$	2140

It will be noted that the curve may be divided into three portions; for low partial pressures of water up to 0.005 mm. the Budde effect rises rapidly; this is followed by an almost linear portion of the curve (0.03 mm. to 0.16 mm.) in which the Budde effect increases proportionally to the increase in the water-vapour pressure; finally, at high water concentrations, the Budde effect increases less rapidly, attaining a maximum of *ca.* 2140 bars at a partial pressure of 0.3320 mm., which is not affected even when the water-vapour pressure is increased to 0.5810 mm. It was suspected that this apparent maximum as well as that shown in Fig. 3 was due to complete absorption of the active radiation. Proof of the correctness of this view was obtained in the following ways. The Budde effect for these high water concentrations was found to be dependent on the distance of the source of illumination from the bulb as shown by the following data, *a* being the distance (cm.) of the lamp from the reaction vessel, and *b* the deflection in scale-divisions :

<i>a</i> .....	72	62	52	42	32	22	15.5	11
<i>b</i> .....	5	7	10	16	25.5	44—45	82	160

It might indeed be argued that the flattening of the curve is caused by increased heat radiation outward, as the Budde effect increases. In the following manner this view was found to be incorrect, within the magnitudes of the Budde effect, and our first view more directly confirmed. A very fine platinum filament,

terminating in thick platinum wires, was sealed in the reaction vessel, which was filled with bromine and water vapour to the desired partial pressures. Several partial pressures of bromine were employed. An electric current was passed through the spiral filament and from a knowledge of the current passing and the potential difference across the spiral the heat evolution in calories per second to give various expansions measured on the gauge could readily be determined. Fig. 4 shows the curve, average values of deflections for different bromine concentrations (these varied only a little) being plotted as ordinates against calories per second developed by the spiral as calculated from  $H = 0.24RI^2$ . It will be observed that the curve bends only slightly within the limits employed. If, now, one takes two deflections on curve A (Fig. 3) and plots as abscissa the heat corresponding, as obtained from Fig. 4, and then from this interval one obtains the scale plotting in place of bromine pressure as abscissa, the calories per sec. (Curve C), one observes that the two curves coincide along the rectilinear portion. It is clear that if the falling off of the Budde effect were due to increased heat radiation, the two curves should coincide throughout. But the Budde effect falls off much more rapidly, supporting the view that the maximum is due to complete absorption of the actinic rays.

The following furnishes additional proof for the total extinction of the actinic rays at the maximum. When the surface is practically saturated, the course of the curve is governed by the absorption of light in accordance with Beer's law.

$$I_e = I_0 e^{-k(dc+K)}$$

where  $K$  is the constant concentration of hydrate on the surface (see later, p. 593).

Hence  $\log(I_e/I_0) = -k(dc + K)$  or  $\log(I_0/I_e) = k'c + K'$ .

$C$ , the concentration of the hydrate, is proportional to the water concentration in the bulk phase. Curve A (Fig. 2) shows that from 0.03 mm., where the surface concentration is practically up to saturation, this proportionality holds true until complete absorption of the light.

Over a certain pressure range the Budde effect increases proportionally to the increase in the partial pressure of the water vapour.

In Fig. 3 are plotted the Budde effects as functions of the partial pressures of bromine at the constant water-vapour pressures of 77 mm. (A) and 0.20 mm. (B), respectively, and at 40°, the distances of the lamp from the bulb being 21 and 32 cm., respectively. Above partial pressures of bromine of ca. 20 and 40 mm., respec-

tively, the curves follow the same course as those noted for the constant bromine-variable water-vapour pressure curves, *viz.*, the Budde effect is proportional to both the partial pressure of the bromine and of the water vapour. Such a relationship is most readily interpreted on the assumption that the photoactive constituent responsible for the Budde effect is a bromine hydrate of composition  $\text{Br}_2 \cdot \text{H}_2\text{O}$  in mass equilibrium with the reactants according to the equation

FIG. 3.

In the light of this hypothesis the convex form of the curve for low water-vapour pressure (Fig. 2) and the concave form of the constant water-vapour pressure curves at low bromine pressures (Fig. 3) are significant.

It is clear that when the partial pressures of water are low (below 0.005 mm.) the Budde effect rises more rapidly than we should be led to expect from application of the law of mass action to the bulk phase. If bromine hydrate were strongly adsorbed by the walls of the glass vessel, the surface concentration increasing with the partial pressure until a saturation maximum was attained at about 0.10 mm., the reason for this increase of the Budde effect at low partial pressures of water vapour and the convex form of the curve when the walls are dry would be clear. Again, if in the

presence of high pressures of water and low partial pressures of bromine the walls of the vessel are covered with water, the Budde effect will consequently be proportional to the bromine hydrate in the gas phase at the commencement, but will rise more rapidly as the pressure of the hydrate increases and displacement of the adsorbed water by the latter commences, thus explaining the initial concave form of the curves for low bromine and high water-vapour pressures. With low partial pressures of water (Fig. 3, curve B) it will be seen that the displacement of water from the surface by the hydrate commences at a lower partial pressure. After this initial curvature the curve rises in a linear manner proportional

FIG. 4.

to the quantity of bromine hydrate present both in the surface and the gas phases.

Such a view, which is advanced from a knowledge of the hygroscopic nature of glass and the convex and concave forms of the bromine-water-vapour pressure curves at low partial pressures, is greatly strengthened by careful analysis of the convex curve. The Budde effect is, according to this view, due to absorption of light by bromine hydrate which is present both in the bulk phase and on the surface of the glass. The curve at low partial pressures of water is thus the effect of both the bulk and the surface concentrations. The bulk concentration increases in a linear manner with increase in water-vapour pressure until the light absorption becomes great, and this portion contributes a Budde effect given

by the line *oa* (Fig. 2). The surface concentration at various partial pressures contributes a Budde effect given by the curve *oB—oa*. If this be the case, it should be capable of expression in the form of an adsorption isotherm. Since it is probable that the water vapour and hydrate layer is but one molecule thick, the partial pressures being far lower than those employed by McHaffie and Lenher (J., 1925, 127, 1559), where multimolecular layers were formed, the Langmuir isotherm should be applicable:

$$x = ap/(1 + bp),$$

where  $x$  = the surface concentration of the hydrate or is proportional to the Budde effect in the surface,  $p$  = the partial pressure of the hydrate in the gas phase or is proportional to the concentration of water, and  $a$  and  $b$  are constants.

The prolongation of the rectilinear portion of the curve, where the surface is hydrate-saturated, intersects the ordinate at 1610 bars. This, then, is the limit to the Budde effect produced by the surface phase.

Hence when  $p$  is large,  $x = a/b = 1610$ ,  
 for  $p = 0.0005$ ,  $300 = 0.0005a/(1 + 0.0005b)$ .  
 From which we obtain  $b = 458$ ,  $a = 7.38 \times 10^5$ .

The following table shows the calculated and the observed values (in bars) of the Budde effect in the surface phase for increasing water-vapour pressures.

Partial press. of H <sub>2</sub> O (mm.).	$x$ calc.	$x$ obs.	Partial press. of H <sub>2</sub> O (mm.).	$x$ calc.	$x$ obs.
$3.9 \times 10^{-5}$	28.4	66	0.01	1320	1200
$2.3 \times 10^{-4}$	154	226	0.03	1500	1500
$5.0 \times 10^{-4}$	300	300	0.08	1573	1590
$5.0 \times 10^{-3}$	1100	950			

Taking into consideration the difficulties of evaluating the actual values of the Budde effect for the initial portion of the curve, which is extremely steep, the agreement between the observed and the calculated values does not exceed the experimental error.

The bromine hydrate which is the photoactive constituent responsible for the Budde effect is thus present in the reacting system both on the walls of the containing vessel and in the homogeneous gas phase, the distribution between surface and bulk phases obeying the usual adsorption isotherm equation.

In order to confirm the view that even at low partial pressures of water vapour there was adsorbed on the walls of the containing vessel a relatively large quantity of hydrate even when the bulk concentration was low, the following experiment was devised.

A small horizontal cell 4 cm. long and 1.25 cm. in diameter with

plane glass ends was constructed. Inside the cell a round coverslip was placed in a vertical plane so that the light passed through the ends of the cell and through the coverslip; a gentle shaking of the cell permitted the coverslip to fall down so that the narrow circular beam of light now passed only through the ends of the cell and the gas phase. Behind the cell a small Moll thermopile was placed so as to obtain a measure of the radiation absorbed by the cell. In addition, the cell was connected to the glass gauge and bromine reservoir in the usual manner.

The following data were obtained on illumination with light passing the colour filters employed in the previous investigation.

<i>Expt. 1.</i>	Cell.	Gas in cell.	Thermopile galvo. deflection.	Budde effect.
Coverslip up.	Air.		22.27	nil
" "		Bromine at 104 mm.	20.23	7—8 av. 7.5
Coverslip down.	" "	" "	21.15	4
" "	Air.	" "	22.27	nil

It will be noted that with air, the position of the coverslip did not affect the amount of light falling on the thermopile, indicating absence of scattering, reflection or absorption of the light due to the glass. When the coverslip was up, the light passed through four glass-gas interfaces and when down through but two such interfaces, the former producing a larger Budde effect and a larger light absorption. If the amount of hydrate in the homogeneous gas phase be denoted by  $x$ , producing a Budde effect,  $kx$ , and a light absorption,  $lx$ , and that on each glass-gas interface be denoted by  $y$ , producing effects  $ky$  and  $ly$ , respectively, we obtain the following relationships:

(a) From the Budde effect.

$$4y + x = 7.5k \quad \text{and} \quad 2y + x = 4k,$$

whence  $2y = 3.5k$  and  $x = 0.5k$ ,

or 12.5% of the Budde effect is produced by hydrate in the gas phase and 87.5% produced by hydrate on the two flat ends of the cylinder.

(b) From the absorption of light.

$$4y + x = 2.04l \quad \text{and} \quad 2y + x = 1.12l,$$

whence  $2y = 0.92l$  and  $x = 0.20l$ ,

or 17.8% of the Budde effect is produced by hydrate in the gas phase and 82.2% produced by hydrate on the two flat ends of the cylinder.

A repetition of this experiment with a bromine pressure of 140 mm. with the same water-vapour pressure gave the following values:

	Coverslip up.	Coverslip down.
Absorption .....	3.06	1.75
Budde effect .....	12	7

whence we obtain the following percentages for the distribution of the hydrate :

	% In bulk phase.	% On surface phase.
From Budde effect .....	28	72
From absorption of light .....	25.3	74.7

As the concentration of hydrate is increased by elevation of the bromine pressure, the bulk concentration of hydrate increases more rapidly than the surface concentration, which, as shown in the previous experiments, finally approaches a surface saturation maximum. From Fig. 2 the percentage of the maximum Budde effect caused by the surface phase is 75, and that of the volume 25 under the experimental conditions.

In Fig. 3 the initial concave portion of the curve was attributed to the effect of the surface adsorption of water vapour which when present in large quantities could displace bromine hydrate when present in but small quantities, *i.e.*, at low partial pressures of bromine.

To confirm this view, both the light absorption and the Budde effect for the bromine in the small cell were determined for low and high partial pressures of water. If excess of water displaces the adsorbed bromine hydrate from the glass surfaces, we should anticipate that, in spite of the increase of the bromine hydrate in the bulk phase due to the addition of water, the removal of the bromine hydrate by displacement from the walls will cause a diminution in the total Budde effect. The following data were obtained :

Cell containing	Deflection for thermopile.	Budde effect.	Absorption.
Air .....	25.49	0	—
Bromine at 144 mm. ....	22.49	11	3.00
Bromine at 144 mm. and H <sub>2</sub> O vapour at 18° .....	23.12	9	2.37

The diminution in the Budde effect on a very large increase in the partial pressure of water is clearly brought out.

#### *Summary.*

The Budde effect in bromine is shown to be proportional to both the partial pressure of bromine and of water vapour and is probably due to a photoactive bromine hydrate of composition Br<sub>2</sub>.H<sub>2</sub>O. This hydrate is strongly adsorbed by glass surfaces and the relationship between the concentration in the bulk and the surface phases can be expressed in the form of an adsorption iso-

therm. The hydrate may be displaced from glass surfaces by water. The Budde effect was not observed on illumination of moist bromine with light of wave-length longer than  $\lambda = 5800 \text{ \AA}$ .

CAMBRIDGE.

[Received, November 16th, 1925.]

## LXXXII.—*The Budde Effect in Bromine. Part II.* *The Kinetics of the Reaction and the Light Absorption of Wet and of Dry Bromine.*

By BERNARD LEWIS and ERIC KEIGHTLEY RIDEAL.

In Part I evidence was presented for the view that the photo-active constituent responsible for the Budde effect in moist bromine is a bromine hydrate of composition  $\text{Br}_2 \cdot \text{H}_2\text{O}$  which is present both in the homogeneous gas phase and on the walls of the containing vessel. The adsorption isotherm equation was shown to be applicable to the partition of the hydrate between the two phases.

It was considered of interest to examine the properties of this bromine hydrate in more detail.

### *The Equilibrium Constant and Heat of Formation.*

From a determination of the Budde effect at various temperatures the alteration of the equilibrium

can be determined. The determinations were carried out with the apparatus described in the previous communication. A low partial pressure of water was employed so that the Budde effect was due almost entirely to the adsorbed bromine hydrate. The following values were obtained,  $t$  being the temperature of the bath, and  $K/K_p$  the deflection in scale divisions:

$t$ .....	99°	81°	63°	41°	22°
$K/K_p$ .....	86	95	106	122	140

The deflection decreases, or the equilibrium constant,  $K_p$ , where

$$K_p = [\text{Br}_2][\text{H}_2\text{O}]/[\text{Br}_2 \cdot \text{H}_2\text{O}],$$

increases, with elevation of the temperature.

Since an intense light was employed and the bromine hydrate concentration was low, the deflection is proportional to the concentration of the hydrate on the surface and may be employed in the van 't Hoff isochore to calculate the heat of formation.

Inserting the above values in the equation

$$2.3 \log_{10} \frac{K_1}{K_2} = \frac{Q}{R} \left( \frac{1}{T_2} - \frac{1}{T_1} \right),$$

we obtain the following values (in calories) for  $Q$ :  $Q_{81^\circ} = 1440$ ,  $Q_{63^\circ} = 1425$ ,  $Q_{41^\circ} = 1340$ ,  $Q_{22^\circ} = 1336$ .

Since  $Q_t = Q_0 + \beta T^2$ , where  $2\beta$  = the difference in specific heat of reactants and products, we obtain

$$\beta = 0.0028 \text{ and } Q_0 = 1090 \text{ cal.}$$

Thus the heat change in the formation of the hydrate in the surface phase can be expressed as follows:

The magnitude of  $Q_0$  is in agreement with expectations regarding the heat of formation of such an unstable compound; it is practically identical with the heat change on solution of bromine in water:

From a knowledge of the heat of reaction it is possible, with the aid of the approximation equation of the Nernst heat theorem, to calculate the value of the equilibrium constant.

Inserting the values  $Q_0 = 1090$  (if there is a difference in the heat of formation in the surface phase and the bulk phase it cannot be very large, for the heat of formation is already so small. We may therefore without serious error assume 1090 cal. as the heat of formation in the bulk phase),  $T = 313^\circ \text{ K}$ ,  $\Sigma \nu = 1$ , and  $\Sigma \nu C = 3$  in the equation

$$\log_{10} K_p = \frac{-Q_0}{4.571T} + 1.75 \Sigma \nu \log T + \Sigma \nu C,$$

we obtain  $\log_{10} K_p = 6.61$  or  $K_p = 4.10 \times 10^6$  in atmospheres =  $3.10 \times 10^9$  in mm.

From this value we find that with a partial pressure of bromine of 200 mm. and of water vapour of 10 mm. the partial pressure of the hydrate will be  $0.65 \times 10^{-6}$  mm., equivalent to a concentration of  $3.86 \times 10^{-11}$  g.-mol. per litre in the bulk phase.

The increase of pressure on illumination has been taken as a measure of the equilibrium constant at various temperatures. Such a procedure is justified, since the Budde effect has already been shown to be proportional to the concentration of the hydrate and the large value of  $K_p$  for the equilibrium constant indicates that the equilibrium concentration of the hydrate is always so small that even large alterations in its concentration due to alteration in the temperature cannot affect the concentration of bromine or water, which may be regarded as constant.

*The Absorption Spectrum.*

If this small quantity of bromine hydrate is the photoactive constituent, it must possess properties different from those of dry bromine. An examination of the absorption spectra of wet and of dry bromine revealed interesting differences.

In Fig. 1 are plotted the absorption curves for wet and for dry bromine determined with the aid of a Nutting spectrophotometer (zero = 0.173), the dry bromine being retained in a clear quartz polarimeter tube which, previously to the admission of bromine,

FIG. 1.

I. Wet bromine. II. Dry bromine.

stored over phosphoric oxide for 9 to 10 months, had been thoroughly ignited whilst a high vacuum was maintained in the system.

The curves indicate that whilst ordinary bromine in wet vessels commences to show a definite absorption at  $\lambda = 6100$  Å., the dry bromine shows no marked absorption before  $\lambda = 5700$  Å. If light absorption is taken as a criterion of molecular excitation, the complex bromine-water requires an energy of excitation 3200 calories per g.-mol. less than that of dry bromine (2.05 volts compared with 2.20 volts) and it might be suggested that the catalytic effect of water vapour in many reactions may in part be due to the lower critical energy increment required for excitation of the complex hydrate.

Whilst the absorption of radiation by the hydrate results in the degradation of the radiant energy, dry bromine absorbs radiation of light of  $\lambda = 5700 \text{ \AA}$ . This light, however, does not reappear as thermal energy, for dry bromine shows no Budde effect. It must be concluded that such light which does not pass through the tube and is not degraded to heat must be either reflected or absorbed and re-emitted by the dry bromine molecules in the direction of the sides of the tube, *i.e.*, must be emitted as resonance radiation or fluorescence. In the presence of water vapour more light is absorbed and fluorescence would be reduced. The possible extinction of such fluorescence in dry bromine by water vapour would appear to have its counterpart in the extinction of fluorescent mercury by gases such as hydrogen and water vapour noted by Stuart (*Z. Physik*, 1925, 32, 262) and the extinction of fluorescence by water vapour in hydrogen and oxygen mixtures noted by Baker. It would further suggest the emission and absorption of light from molecule to molecule in a dry gas until absorption by a hydrate molecule occurred as a mechanism for chain reactions. Several experiments were devised to detect the difference between the nature of the light emitted from the sides of narrow tubes containing wet and dry bromine respectively, down the axes of which narrow pencils of yellow light were passed. Whilst no quantitative data could be obtained, the light emitted from the dry bromine appeared somewhat yellower, *i.e.*, richer in the rays absorbed by bromine, than the reddish light from the wet tube.

*The Stark-Einstein Law of Photoequivalence.*

An attempt was made to establish the validity of the Stark-Einstein law of photochemical equivalence in the case of the Budde effect. The measurements of the absorption of energy by the reaction vessel containing bromine were made with a black-body radiation meter. The meter consisted of a flat black receiving bulb with compensator and aniline gauge and was calibrated by the method of internal electric heating with the aid of a small platinum spiral in the interior; the whole system being carefully lagged and preserved from any slight air currents which might affect either the steadiness or accuracy of reading. Due corrections were made for the resistance of the circuit and leading-in wires. The following calibration values were obtained :

Room temperature 20.2°.		Ergs per sec. per 10 div. $\times 10^{-4}$ .
Reading in scale div.	Cal./sec.	
3.5	$5.36 \times 10^{-4}$	6.42
4.7	$7.73 \times 10^{-4}$	6.83
6.8	$1.29 \times 10^{-3}$	7.93
10.7	$2.55 \times 10^{-3}$	10

x 2

In a typical experiment with light between 5300—5700 Å. it was found that the bromine absorbed energy, as measured by the radiation meter, of  $1.53 \times 10^4$  ergs per second, yielding a Budde effect of 184.8 bars.

As has already been indicated, part of the light apparently absorbed by the bromine, *i.e.*, not transmitted to the radiation meter, is emitted from the sides of the tube in the form of fluorescence. It was necessary to find out how much of the energy of  $1.53 \times 10^4$  ergs per second was emitted as fluorescence, *i.e.*, apparently absorbed by dry bromine, and how much contributed to the Budde effect by absorption by the bromine hydrate. The following arrangement (Fig. 2) was accordingly devised to evaluate this fraction:

A. Moll thermopile.

B. A reaction vessel similar to C containing moist bromine at the same partial pressure, or air.

FIG. 2.

C. Reaction vessel containing either dry bromine in contact with phosphoric oxide, or air.

The two reaction vessels were of similar size and shape, both with plane and parallel sides immersed in a trough through which water from a thermostat was circulated. The point light lamp, water trough, collimator, and screens were used as heretofore. After the lamp had been so adjusted that a constant deflection was obtained on the Moll thermopile with the bulbs containing dry air, dry bromine was first admitted to bulb C at a partial pressure of 120 mm. The deflection on the thermopile was noted and moist bromine (saturated at 17°) admitted to B until the partial pressures of the bromine in the two bulbs were identical. The deflection was again noted and the bromine in the bulb C was replaced by dry air; the final determination of the radiation transmitted to the thermopile was then made. These operations were repeated, reversing the procedure in each case, and the following average readings were obtained:

B containing air	bromine } 24.80	B containing dry air	} 25.43
C containing dry		C containing dry air	
	B containing moist bromine		} 23.97.
	C containing dry air		

These results indicate that the apparent absorption by dry bromine is represented by 0.63 division on the Moll thermopile, that by wet bromine by 1.46 divisions; or about 43.2% of the light apparently absorbed by the moist bromine is emitted again in the form of radiation, as it does not contribute to the thermal energy to which the Budde effect is due.

The areas under the absorption curves between wave-lengths 5400 Å. and 6100 Å. will give the percentage absorptions due to wet and to dry bromine (wet bromine absorbs up to 6100 Å.; the filter transmitted the red rays):

Area under dry curve = 3130. Area under wet curve = 6530.

% absorbed by dry  $\text{Br}_2$  = 48. % absorbed by wet  $\text{Br}_2$  = 52.

All the light absorbed by the unhydrated bromine in the wet bromine is not emitted as fluorescence from the sides of the vessel. A part of it is reabsorbed by the hydrated molecules and degraded into heat energy. What proportion is reabsorbed we have no means of determining from our data. It must be borne in mind that as far as the absorption spectra curves are concerned it makes no difference how much of the emitted light is reabsorbed, since only a small portion of this light, even if not reabsorbed, would find its way through the spectrophotometer.

Accordingly, of the  $1.63 \times 10^4$  ergs per second apparently absorbed, or not transmitted by the wet bromine, in the previous experiment, 56.8% is actually absorbed and 43.2% emitted as radiation, or  $0.926 \times 10^4$  ergs per second are absorbed. The mean wave-length of light employed was 5550 Å., for the energy distribution curve of the radiation passing through the filter was flat within the region 5300 Å.—5800 Å. or the mean quantum was  $3.53 \times 10^{-12}$  erg; the number of quanta actually absorbed by the bromine hydrate per second is accordingly  $0.926 \times 10^4 / 3.53 \times 10^{-12}$  or  $2.62 \times 10^{15}$  quanta per second.

The Budde effect was 184.8 bars, corresponding to a heat evolution, as determined from the curve given in Part I, of  $1.26 \times 10^4$  ergs per second. If this heat is evolved by the conversion of quanta of magnitude  $3.53 \times 10^{-12}$  erg into kinetic energy in the decomposition or deactivation of the excited bromine hydrate molecules, we obtain as the number of molecules undergoing such a process of deactivation or decomposition per second  $1.26 \times 10^4 / 3.53 \times 10^{-12}$  or  $3.57 \times 10^{15}$ .

In the following table are the results of three different experi-

ments performed in the above manner. Figures in the third column are obtained by multiplying the calibration value in the previous table by 1.11 to allow for diffusive reflection of lampblack.

Exp. Temp.	Mano- meter diff.	Total ergs per sec. not trans- mitted $\times 10^{-4}$ .	Quanta per sec. absorbed by the hydrate $\times 10^{-15}$ .	Budde effect in bars.	Ergs per sec. equiv- alent $\times 10^{-4}$ .	Mols. per sec. decom- posing $\times 10^{-15}$ .	Mols. per quanta.
2 20.8°	2.28	1.63	2.62	184.8	1.26	3.57	1.36
3 20.9	2.43	1.73	2.78	186	1.30	3.68	1.32
4 20.2	1.73	1.24	2.00	149	1.01	2.82	1.41

These calculations were made under extreme conditions allowing for no absorption by the hydrate molecules of the re-emitted radiation from dry bromine. Taking this into account would bring the figures in the last column close to unity.

However, it will be noted from the data in the last column that the agreement between the number of quanta absorbed per second by the hydrate and the number of such molecules decomposing per second with the liberation of the energy of activation in the kinetic form is sufficiently close to show the validity of the Stark-Einstein law of photoequivalence in the case of the Budde reaction.

#### *The Absorption Coefficient of the Hydrate.*

On the hypothesis that the photoactive constituent is a bromine hydrate it is possible from a consideration of its concentration and the magnitude of the Budde effect, which is a measure of the light actually absorbed by the hydrate, to effect a determination of the absorption coefficient. The actual bulk concentration of hydrate for definite partial pressures of bromine and water can be determined only on the assumption that the concentration equilibrium of the reaction

is not sensibly affected whether the water vapour and the hydrate are in the surface or bulk phases, an assumption which is only valid if the activity coefficients of the reactants do not change sensibly during adsorption, or that the change in the activity coefficient of the water on adsorption is the same as the change effected in this function of the bromine hydrate. Since the heat of formation of bromine hydrate is small, some measure of support is given to the latter hypothesis. We will therefore employ the value for  $K_p$  determined above as  $3.10 \times 10^9$  when expressed in mm. of mercury.

From the curves given in Fig. 2 (Part I of this investigation), in which the increase in Budde effect with increasing water-vapour pressure at a constant bromine pressure is plotted, it is seen that at a pressure of 0.0415 mm. of water and a pressure of 158 mm.

of bromine, a Budde effect of 115 bars was caused by the bromine hydrate in the gas phase, out of a total of 2140 bars (maximum deflection under the intensity of illumination employed).

Thus 5.4% of the light was absorbed by the bromine hydrate present in the gas phase, which was 2.35 cm. deep, or 94.6% would have been transmitted if no surface phase existed. The partial pressure of the hydrate in the gas phase can with the proviso indicated above be determined with the aid of the equilibrium constant or

$$[\text{Br}_2][\text{H}_2\text{O}]/[\text{Hydrate}] = 3.10 \times 10^9 = 158 \times 0.0415/[\text{Hydrate}],$$

whence the partial pressure of the hydrate is  $2.1 \times 10^{-9}$  mm. From Beer's law,  $I_t = I_0 e^{-kcd}$ , where  $I_0$  is the entering light,  $I_t$  the transmitted light,  $c$  the concentration,  $d$  the thickness, and  $k$  the absorption coefficient of the hydrate, we obtain :

$$\log_e (I_t/I_0) = -kcd,$$

$$\text{or} \quad 2.3 \log_{10} 0.946 = -kcd = -k(2.1 \times 10^{-9}) \times 2.35,$$

$$\text{whence} \quad k = 10.7 \times 10^6.$$

In a similar manner, for a point where  $P_{\text{H}_2\text{O}} = 0.083$  mm. we find a Budde effect, in the gas phase, of 230 bars or 10.75% light absorption, whence  $I_t/I_0 = 0.8925$  and  $k = 11.4 \times 10^6$ . For the low partial pressure of  $P_{\text{H}_2\text{O}} = 0.02$  mm. we find a Budde effect in the gas phase of 55 bars, equivalent to 2.57% light absorption or 97.43% light transmitted, whence  $k = 9.6 \times 10^6$ . The mean value of the absorption coefficient is thus  $10.5 \times 10^6$ .

It is interesting to compare this value with that obtained by Wood (*Physikal. Z.*, 1912, **13**, 353) for the absorption of the light ( $\lambda = 2537 \text{ \AA.}$ ) by mercury vapour. He found that the intensity of this light was reduced by one-half by passage through a layer of mercury vapour 5 mm. thick and at a partial pressure of  $10^{-4}$  mm. Inserting these values in the equation, we obtain

$$2.3 \log_{10} 0.50 = -k \times 10^{-4} \times 0.5, \text{ whence } k = 0.14 \times 10^6.$$

Thus the absorption coefficient of bromine hydrate in the spectral region which produces excitation is comparable in value with that of mercury vapour for its resonance line. On the hypothesis of Ornstein that the range of influence of a quantum of light is proportional to the square of the wave-length, the absorption coefficient of bromine hydrate for light of  $\lambda = 5550 \text{ \AA.}$  should be some four times that of mercury vapour.

#### *Mechanism of the Budde Effect.*

The first elementary process in a photochemical action is, as Stern and Volmer (*Z. Wiss. Photographie*, 1920, **19**, 275) were the

first to show, not the primary reaction but the excitation of the molecule by absorption of radiation. On the hypothesis that there exist in moist bromine both bromine and bromine hydrate molecules, the primary processes of light absorption are the conversion of these into active molecules:

We have seen that in the case of dry bromine no Budde expansion occurs, although light absorption undoubtedly takes place. The excited bromine molecules must thus lose their energy of excitation in the form of radiation. Whether the radiation emitted from an excited bromine molecule in the interior of the gas passes through the gas to the outer walls or undergoes a series of absorptions and emissions from numerous molecules in the operation of transfer of a quantum from the interior to the surface, or, again, whether the energy of the excited molecule is handed on by collision within the life of the excited molecule, *viz.*,  $10^{-7}$  second, thus forming a chain, cannot be established with certainty. As in the case of the resonance line of mercury vapour, if the light is emitted from the bromine molecules as light of the same wave-length as the absorbed light, the course of the fluorescent light is interrupted in its path to the surface by its absorption by hydrate molecules, thus materially reducing the strength of the fluorescent light.

We have seen that only when a bromine molecule is moist, *viz.*, a bromine hydrate, do we obtain a Budde effect or conversion of the light energy into thermal energy. The frequency,  $\nu$ , of any line may be considered as the sum  $\nu = \nu^e + \nu^n + \nu^m$ , where  $e$  is the electronic,  $n$  the oscillatory, and  $m$  the rotational quantum number (Mulliken, *Physical Review*, 1925). In absorbing a quantum, not only may the quantum level of the electron be changed, but also the oscillatory and rotational quantum energy levels. In the case of iodine at low pressures (Oldenberg, *Z. Physik*, 1923, 18, 1), the molecule, without dissociating, can absorb and re-emit as a resonance spectrum an amount of energy five times the work of dissociation when it is illuminated by light of wave-length  $\lambda = 1849 \text{ \AA}$ . The explanation advanced is that the excitation energy is primarily employed in raising the electron system to a higher quantum state, whilst the oscillation and rotation energies are only altered by the coupling of their periods with those of the electron system. But we may have, in the case of the halogens, marked changes in the oscillation energy where the absorption of light alters the potential energy of the nuclei, thus altering the strength of chemical binding of the molecule. In the excited electronic state, the energy required for dissociation is less than in the normal state, and if the alteration

in the oscillation quanta is sufficient to cause the potential energy of the nuclei to become greater than the dissociation energy for the excited state the molecule will fly apart. There is indeed a correlation between a large change in oscillation quantum number and a considerable alteration of the strength of binding on excitation. As a measure of the strength of binding we can utilise, for qualitative estimates, the direction of the shading of the bands, which is an indication of change in the moment of inertia of the molecule. The band spectra of iodine investigated by Mecke (*Ann. Physik*, 1924, **71**, 104) show a convergence limit of the oscillation quantum states at 5000 Å. Wave-lengths, therefore, of 5000 Å. or less will dissociate iodine under certain conditions. The convergence limit for bromine has been placed by Franck (see Part I, *loc. cit.*) at about the same wave-length from the position of the long wave-length limits of the continuous spectra which are known.

The light used in this investigation being of considerably greater wave-length, dry bromine would not be expected to dissociate. That dissociation does not occur is proved further by the work of Ludlam (see Part I, *loc. cit.*), who found no Budde effect with dry bromine illuminated with ultra-violet light containing energy many times that necessary for dissociation.

It would appear that in the case of bromine hydrate the lowering of the critical energy increment for dissociation into atoms is very great. Dissociation may occur thus :

where 51,500 calories is the energy of the radiation of wave-length employed in these experiments, some 4410 calories greater than the threshold value, as is confirmed by the commencement of absorption at 6100 Å. The recombination of the bromine and water to re-establish equilibrium gives rise also to the evolution of the heats of combination :

The same type of mechanism is given by the calculations of Christiansen (*Dansk Vid. Math. Phys. Medd.*, 1919, **1**, 14) for the reactions

Thus 47,090 calories appears to be close to the critical energy that must be absorbed by bromine hydrate before any Budde effect can be expected. The absorption of light of greater frequencies, for a given constant quanta absorption, merely increases

the heat effect on the right-hand side of the equation (1) and thus the Budde effect.

*Summary.*

The heat of formation of bromine hydrate is 1090 calories, comparable with the heat of solution of liquid bromine in water, whilst the equilibrium constant for the dissociation of bromine hydrate at 313° K is of the order of  $3 \cdot 10 \times 10^9$ . The absorption curves of wet and of dry bromine have been compared; marked absorption commences at  $\lambda = 6100 \text{ \AA.}$  for the wet and at  $\lambda = 5700 \text{ \AA.}$  for the dry gas; this corresponds to a lowering of the critical energy increment of excitation of 3200 calories. When corrected for the absorption and probable fluorescence of dry bromine, it is found that the Stark-Einstein law of photoequivalence is obeyed, a maximum of 1.41 molecules per quantum being obtained. The absorption coefficient of bromine hydrate for the spectral region employed is  $10 \cdot 5 \times 10^6$ , comparable with that obtained by Wood,  $0 \cdot 14 \times 10^6$ , for mercury vapour for the line  $\lambda = 2537 \text{ \AA.}$  A mechanism of excitation and decomposition of bromine hydrate molecules is advanced in explanation of the Budde effect.

Our thanks are due to Messrs. Brunner Mond for a grant which enabled us to purchase the apparatus necessary for this research.

LXXXIII.—*Studies of Valency. Part V. Absorption Spectra of Halogen and Sulphonic Derivatives of Camphor: Origin of the Ketonic Absorption Band.*

By THOMAS MARTIN LOWRY and GLYN OWEN.

1. *Scope of the Work.*

THE preceding paper on absorption spectra (Lowry and French, "Studies of Valency," Part IV, J., 1924, 125, 1921) dealt with the selective absorption of camphor and of some of its conjugated derivatives. Its principal feature was an experimental proof of the existence in camphorquinone and in methylenecamphor of two different types of conjugation, corresponding perhaps with the presence of "crossed" and of "concordant" polarities in these two compounds. In the present paper, these experiments have been extended to a series of halogen derivatives of camphor, for which data were required in connexion with measurements of rotatory

dispersion (J., 1925, 127, 1260). The absorption spectra of some of these compounds had been plotted previously by one of us (Lowry and Desch, J., 1909, 95, 807), but only by the old qualitative method of recording the last line transmitted through a given thickness of solution in sufficient intensity to leave a record on the photographic plate. These observations were therefore not sufficiently exact for a quantitative comparison, the ultimate result of which was to reveal the existence of a small discrepancy between the characteristic frequencies deduced from measurements of rotatory dispersion and those obtained by recording directly the maximum value of the molecular extinction coefficient.

The original purpose of the experiments demanded only a knowledge of the characteristic frequency of the band of selective absorption; but the data in Table I have an interest of their own, which exceeds that of the approximate coincidence of the frequencies deduced by the two methods referred to above. Thus, not only have we been able to draw more exact conclusions as to the effect of halogens on the familiar absorption band of the ketone, but the "general absorption" of the compounds, which can now be investigated just as accurately as their "selective absorption," has been found to present striking characteristics, especially with regard to the mutual influence of negative radicals (compare Part VII, following paper). In this way the observations have provided important clues as to the origin and significance of selective and general absorption in carbon compounds generally.

## 2. *Experimental Methods.*

Camphor- $\beta$ -sulphonic acid, and four camphorsulphonates containing a halogen atom, were examined in aqueous solutions. The fifteen other halogen derivatives were all examined in *cyclohexane*. This solvent was selected in order to conform as closely as possible to the conditions under which the rotatory dispersions of many of these compounds had been measured in benzene (J., 1925, 127, 807). The choice of *cyclohexane* as an alternative to benzene (which was not sufficiently transparent for measurements of absorption) was justified by the fact that some of its physical properties approximate very closely to those of benzene (Gifford and Lowry, *Proc. Roy. Soc.*, 1923, A, 104, 430) and in particular that the wave-length of maximum absorption for a solution of camphor in *cyclohexane* had been found to be the same as for a thin film of camphor in benzene (Lowry and French, J., 1924, 125, 1924). Apart from these considerations, however, *cyclohexane* has proved to be a good solvent for measurements of absorption, since, although unpurified specimens are not very transparent, and may even exhibit an absorption band,

the material can be purified readily by repeated shaking with 100% sulphuric acid on a mechanical shaker. When washed with water and distilled, it was then found to be transparent to about 2200 Å.U., which is approximately the limit of transmission of the calcite of the ultra-violet spectrophotometer.

The fifteen halogen derivatives of camphor and the five sulphonates had all been purified by crystallisation, and in most cases the samples had already been used for measurements of rotatory dispersion.

The methods of measurement were the same as in Part IV of this series of papers, absolute values being recorded for the "molecular extinction coefficients" at different wave-lengths up to the limit of transparency of the solution. As a rule, about 60 measurements were made with each compound, at concentrations ranging from  $M/4$  to  $M/400$ ; but the experimental points were too numerous to be inserted in the figures, except in one case (Fig. 7), where the range of wave-lengths and intensities made it possible to plot the data on a larger scale.

### 3. *Summary of Experimental Results.*

The present series of observations has proved that, whilst the presence of a halogen influences both the selective and the general absorption of the compounds, and affects these two properties in a somewhat similar manner, the two influences are sufficiently independent to produce large variations in the "persistence" of the band,\* *i.e.*, in the relative separation of the accessible band of "selective" absorption and the inaccessible band of "general absorption" as measured by the depth of the trough between them. The experimental results, which are summarised in Table I, may therefore be discussed most conveniently under these two headings.

(a) *Selective Absorption.*—The principal results are as follows:

(i) The general proposition, that the position of the ketonic band is largely independent of the nature of the ketone, is confirmed, since the wave-length of maximum absorption ranges only from 2880 Å.U. in camphor to 3230 in  $\alpha'$ -dibromocamphor. The intensities also cover only a small range from  $\log \epsilon = 1.4$  to 2.0. This is in marked contrast with the conjugated systems examined in Part IV, where the value of  $\log \epsilon$  rose from 1.4 in camphor to 4.3 in benzylidene-camphor.

(ii) A halogen in the  $\alpha$ -position produces a marked "intensification" of the selective absorption, since it increases both the wave-length and the maximum extinction coefficient of the ultra-

\* It is therefore unlikely that the general absorption of these compounds is a mere harmonic of the selective absorption.

\* In these compounds, the general absorption is very weak and log  $\epsilon$  does not rise to 1.5 within the limits of our experiments; the value of  $\lambda$  corresponding to log  $\epsilon$  = 1.5 could therefore only be deduced by extrapolation.

† In these two compounds, where the general absorption is very strong, the molecular extinction coefficient falls to a minimum (at log  $\epsilon$  = 1.6 and 1.75 respectively), and then begins to rise again towards the crest of the band of selective absorption, but it never falls as low as log  $\epsilon$  = 1.5.

‡ In this compound, where the general absorption is very weak, the band of selective absorption extends to a minimum at about 2400 Å.U.; the general absorption does not begin, therefore, until the wave-length is already less than 2500 Å.U.

violet band (Fig. 1). The influence of an atom of bromine in the  $\beta$ -position is, however, almost negligible, since an insignificant increase of wave-length is balanced by an equally unimportant diminution in the maximum extinction coefficient (Fig. 7). The conclusion reached in an earlier paper (J., 1909, 95, 817) that, whilst a halogen atom in a  $\alpha$ -position produces an "intensification" of the band, an atom of bromine in the  $\beta$ - or  $\pi$ -position, has a "repressive action," is therefore no longer valid when applied to the selective absorption alone instead of to the "persistence" of the band.

(iii) The data for the  $\alpha\beta$ - and  $\alpha\pi$ -derivatives (Figs. 3 and 4)

confirm the conclusion that an atom of bromine in the  $\beta$ - or  $\pi$ -position produces only negligible changes in the wave-length and penetration of the band, and certainly has no "repressive" action.

(iv) The most striking intensification of the selective absorption is seen in the  $\alpha\alpha'$ -dihalogen derivatives (Fig. 2). In this group of

FIG. 1.

Molecular extinction coefficients of I camphor, II(a)  $\alpha$ -chlorocamphor, II(b)  $\alpha'$ -chlorocamphor, III(a)  $\alpha$ -bromocamphor, III(b)  $\alpha'$ -bromocamphor in cyclohexane.

compounds the progressive replacement of chlorine by bromine is accompanied by a progressive increase in the wave-length of the band, whilst the maximum extinction coefficient remains practically constant at a value midway between those recorded for a single atom of chlorine or bromine in the  $\alpha$ -position. On the other hand, a similar replacement of chlorine by bromine in the  $\alpha\beta$ -series (Fig. 3) produces a progressive increase in the value of the maximum

extinction coefficient, which is not accompanied by any marked change of wave-length. These two figures therefore recall, but in a much less striking form, the contrast between the optical effect of the two types of conjugation recorded in Part IV. In the  $\alpha\pi$ -series (Fig. 4), the principal contrast is between the  $\alpha$ -chloro- and the  $\alpha$ -bromo-compounds. Thus  $\alpha\pi$ -dichlorocamphor gives a band in

FIG. 2.

Molecular extinction coefficients of I camphor, V  $\alpha\alpha'$ -dichlorocamphor, VI  $\alpha\alpha'$ -chlorobromocamphor, VII  $\alpha\alpha'$ -dibromocamphor in cyclohexane.

very much the same position as in  $\alpha$ -chlorocamphor itself; and in the same way  $\alpha\pi$ - and  $\alpha'\pi$ -dibromocamphor (which give almost identical curves) and  $\pi$ -chloro- $\alpha$ -bromocamphor resemble  $\alpha$ -bromocamphor very closely, although the introduction of a halogen atom in the  $\pi$ -position appears to produce a minute increase both in the wave-length and in the maximum value of the extinction coefficient of the bromo-compounds.

(v) The influence of a sulphonic group in the  $\beta$ - or  $\pi$ -position is almost negligible, like that of a halogen atom in either of these positions. Thus in Reyckler's camphor- $\beta$ -sulphonic acid (Fig. 5) a small increase of intensity is balanced by a small decrease of wave-length, just as in  $\beta$ -bromocamphor (Fig. 7) a small decrease of intensity was balanced by a small increase of wave-length. Similar

statements apply to the  $\alpha$ - $\beta$ - and  $\alpha$ - $\pi$ -chloro- and bromo-sulphonates, where the introduction of the sulphonic group produces only small changes in the wave-length and intensity of the band of  $\alpha$ -chloro- and  $\alpha$ -bromocamphor.

(b) *General Absorption.* For the purpose of comparing general absorptions, we have chosen, quite arbitrarily, a standard wave-length,  $\lambda = 2500$  Å.U., and a standard absorptive power,  $\log \epsilon =$

1.5, and have recorded in Table I the wave-length at which the standard absorptive power is attained, and the absorptive power at the standard wave-length. The principal experimental results are as follows :—

(i) We have obtained complete confirmation of the recent observation of Lowry and French (J., 1924, 125, 1924) that a solution of

FIG. 4.

camphor in *cyclohexane* shows no general absorption up to the limits of our present methods of measurement. It is therefore impossible to record the persistence of the band, except by stating that it must be greater than 1.7.\* It is indeed a noteworthy fact that, whereas

\* In the same way, V. Henri found (Ber., 1913, 36, 3627) that acetone shows no general absorption up to 2144 Å.U., although the band had already persisted through a range of 2.0 in log  $\epsilon$ , i.e., over a range of intensities of 100 : 1.

the earlier methods of measurement always indicated the existence of a real or fictitious general absorption in every solution that was examined, we have failed completely in our attempts to detect by the quantitative method any trace of a general absorption in camphor itself when dissolved in *cyclohexane*, although we have been able to

FIG. 5.

Molecular extinction coefficients of I camphor (in *cyclohexane*), XIV camphor- $\beta$ -sulphonic acid (in water), XV potassium  $\alpha$ -chlorocamphor- $\beta$ -sulphonate (in water), XVI potassium  $\alpha$ -bromocamphor- $\beta$ -sulphonate (in water).

reach the end of the band of selective absorption in all the twenty derivatives which were examined in the course of the present research, as well as in camphor itself when dissolved in alcohol (Lowry and French, *loc. cit.*). From the experimental point of view, it is a remarkable experience to find that a relatively strong solution of camphor, containing about 8 grams in 100 c.c., which extinguishes almost the whole of the ultra-violet spectrum from

3400 Å.U. onwards, becomes transparent again at about 2400 Å.U., and transmits with equal intensity all the remaining lines of the iron arc to 2327 Å.U.\*

(ii) After camphor, the smallest general absorption was observed in camphor- $\beta$ -sulphonic acid (Curve XIV), but, as the acid was examined in aqueous solution, the general absorption was easily observed, by reason of the exceptional transparency of the solvent. The minimum lies just beyond 2400 Å.U., but is followed by a very rapid increase, so that the general absorption was already almost level with the maximum of selective absorption (at  $\log \epsilon = 1.54$ ) when the last readings were taken at about 2327 Å.U., in the clear aqueous solution. Apart from camphor, this compound was the only one in which the standard wave-length,  $\lambda = 2500$  Å.U., selected for the comparison of general absorptions, fell within the limits of the band of selective absorption.

(iii) Although chlorine is not greatly inferior to bromine in its ability to intensify the selective absorption of camphor, it is relatively impotent in producing general absorption. Thus, apart from camphor and camphor- $\beta$ -sulphonic acid, the only compounds in which the absorptive power did not reach the standard value of 1.5 within the limits of our experiments were the  $\alpha$ - and  $\alpha'$ -chloro-camphors (Curves II, *a* and *b*). Again,  $\alpha\alpha'$ -dichlorocamphor (Curve V), where the growth of general absorption is much more rapid than in the monochlorocamphors, has an exceptionally deep minimum at  $\log \epsilon = 0.22$ ; and the persistence of the band,  $\log \epsilon (\text{max.}) - \log \epsilon (\text{min.}) = 1.60$ , is greater than in any compound of the series except camphor itself, where it exceeds 1.72 (Lowry and French, *loc. cit.*, p. 1925), and  $\alpha\pi$ -dichlorocamphor (Curve XI), where the general absorption only begins to be perceptible at a wave-length of about 2600 Å.U., after the band has attained a persistence of 1.68.

(iv) Bromine, on the other hand, which produces a strong general absorption even in  $\alpha$ -bromocamphor, becomes extremely efficient in this respect when reinforced by an atom of chlorine or bromine in the other  $\alpha$ -position. Thus, the general absorption at the standard wave-length of 2500 Å.U. *increases* from  $\log \epsilon = 1.83$  in  $\alpha$ -bromocamphor to 2.45 in  $\alpha\alpha'$ -chlorobromocamphor and to 2.86 in  $\alpha\alpha'$ -dibromocamphor. At the same time, as a result of the increase of general absorption, the persistence of the band *decreases* from 0.75 in  $\alpha$ -bromocamphor to 0.3 in  $\alpha\alpha'$ -chlorobromocamphor and to 0.1 in  $\alpha\alpha'$ -dibromocamphor (Fig. 2). The general absorption in  $\alpha\alpha'$ -di-

\* The fact that even this very "clean" band attains a width of 1000 Å.U. in solutions of only moderate concentration will explain why accurate measurements of rotatory dispersion can only be made for wave-lengths much greater than that of the crest of the band.

bromocamphor is indeed so great that at 2900 Å.U. it is already twice as strong as that corresponding with the maximum of the camphor band at the same wave-length. It is, therefore, only because the camphor band has been displaced by about 350 Å.U. in the direction of longer wave-lengths that the dibromo-derivative is able to exhibit a selective absorption at all: apart from this, nothing but a "step-out" would be observed in the curve.

(v) The reinforcement of the general absorption of  $\alpha$ -bromocamphor by a second halogen in the  $\beta$ -position is comparatively small. Thus the general absorption remains practically stationary on passing from  $\alpha$ -bromocamphor, where  $\log \epsilon = 1.83$  at 2500 Å.U., to  $\alpha\beta$ -bromochlorocamphor, where  $\log \epsilon = 1.90$ , although this number rises to 2.5 in  $\alpha\beta$ -dibromocamphor. In the case of the  $\pi$ -compounds,\* the general absorption actually *falls* from  $\log \epsilon = 1.83$  at 2500 Å.U. in  $\alpha$ -bromocamphor to 1.45 in  $\alpha\pi$ -bromochlorocamphor, and remains stationary at 1.83 in  $\alpha\pi$ -dibromocamphor. A sulphonic group in the  $\beta$  or  $\pi$ -position is also practically without influence in augmenting the general absorption of  $\alpha$ -bromocamphor, since the value of  $\log \epsilon$  is only increased from 1.83 at 2500 Å.U. in  $\alpha$ -bromocamphor to 1.90 in the two bromocamphorsulphonates.

#### 4. *Superposition of Selective and General Absorption.*

In accordance with the usual behaviour of negative radicals, halogens in the contiguous  $\alpha$ -position have been found to augment the selective absorption of the ketonic group. Conversely, one must suppose that the ketonic group augments the power of the contiguous  $\alpha$ -halogen atom to develop a general absorption, just as it increases the readiness with which reduction or reverse substitution takes place. In these cases, therefore, any superposition of general and selective absorption by mere addition would be out of the question, since it would ignore the known mutual influence of the negative atoms. This mutual influence diminishes, however, as the distance between the negative atoms is increased; and in  $\beta$ -bromocamphor the band of selective absorption is very similar to that of camphor itself, showing that one of the two mutual influences (namely, that of the halogen upon the ketonic group, but not necessarily that of the ketonic group upon the halogen) has become almost negligible. We have therefore attempted to reproduce the absorption curve of  $\beta$ -bromocamphor by superposing the general absorption of a compound containing the group  $-\text{CH}_2\text{Br}$  (see Part VII) on the selective absorption of camphor itself. The general absorption of *one* molecular proportion of methyl bromide was found

\* Anomalies in the optical properties of the  $\pi$ -derivatives have already been noted and discussed (J. 1925, 127, 1504).

to be too small, whilst that of *half* a molecular proportion of methylene bromide or of ethylene bromide was too great, on account of the excessive mutual influence of the two halogens. Finally, by using a mixture of one molecular proportion of camphor with half a molecular proportion of trimethylene bromide (in which the two negative

FIG. 6.

*Molecular extinction coefficients of I camphor in cyclohexane, XVII ammonium  $\alpha$ -chlorocamphor- $\pi$ -sulphonate, XVIII ammonium  $\alpha$ -bromocamphor- $\pi$ -sulphonate in water.*

atoms are separated by three intermediate atoms of carbon, just as in  $\beta$ -bromocamphor), we have obtained an absorption curve (Fig. 7) which pursues very much the same course as that of  $\beta$ -bromocamphor, although it is not identical with it. In this way the validity of the principle of superposition of general and selective absorptions appears to be sufficiently established, whilst the theory which assigns the selective absorption to the  $>\text{CO}$  group and the

general absorption to the  $\geq\text{C Br}$  group (see following paper) receives a direct experimental confirmation.

In addition to the absorption curve for  $\beta$ -bromocamphor, and the

FIG. 7.

Molecular extinction coefficients of IV  $\beta$ -bromocamphor in cyclohexane. Also of methyl, methylene, ethylene, and trimethylene bromide and of a solution of camphor with half a molecular proportion of trimethylene bromide in cyclohexane.

curve for a mixture of camphor and trimethylene bromide, Fig. 7 shows the curves of general absorption for solutions of methyl, methylene, ethylene and trimethylene bromides in cyclohexane, the curves plotted in Part VII being for solutions in alcohol. On account

of the narrower range of wave-lengths and intensities which it covers, this diagram was plotted on twice the scale of Figs. 1 to 6; it was therefore possible to insert, without overcrowding, all the experimental points on which the curves were based.

### 5. Auxochromic Influence of Alkyl Radicals and of Halogens.

Bielicki and Henri (*Ber.*, 1913, **46**, 3627) and Rice (*Proc. Roy. Soc.*, 1915, *A*, **91**, 76) have shown that the absorption band of acetone is displaced towards the visible region when the hydrogen atoms are replaced by alkyl groups. Thus according to Rice "the shifts obtained in the successive substitution of the three  $\alpha$ -hydrogen atoms are 23, 50, and 30 Å.U." for the first methyl, and the total shift of 103 units is doubled ( $\lambda = 2747 \rightarrow 2850 \rightarrow 2950$  Å.U.) when the three hydrogens of the second methyl group are also replaced. On the other hand, Henri finds that a shift in the same direction occurs when the whole methyl group is replaced by hydrogen, since aldehydes give a band of longer wave-length and smaller intensity than ketones, in addition to showing a much stronger general absorption.

In order to determine the influence of halogens (and of negative radicals generally) on the absorption spectra of the ketones, it is convenient to take camphor instead of acetone as the parent compound, since the liquid halogen derivatives of acetone are less easy to prepare and purify than the alkyl derivatives (which are easily synthesised) and are in every respect inferior to the analogous compounds of the camphor series, where crystalline products are available in large numbers, and with the substituent in four different positions, namely,  $\alpha$  or  $\alpha'$ ,  $\beta$  and  $\pi$ . It is a mere accident of nomenclature that in the  $\alpha$ - and  $\alpha'$ -derivatives of camphor the substituent is attached to a carbon atom in the " $\alpha$ " position relative to the ketonic group, and that in the case of the  $\beta$ -derivatives we can now assign the substituent to a methyl group of which the carbon atom is in a " $\beta$ " position relative to the ketonic group (Lowry and Burgess, *J.*, 1925, **127**, 279). In the  $\pi$ -compounds, the substituent is attached to a carbon atom in a " $\gamma$ " position relative to the ketonic group, although it can also be reached by a longer route which would make it a " $\delta$ " carbon atom. It is therefore possible, by working in the camphor series, to compare the effect on the selective absorption of the ketonic group of introducing a negative substituent in an  $\alpha$ -,  $\beta$ - or  $\gamma$ -position. The fact that the camphor nucleus is relatively complex is not a matter of great importance, since we have no reason for supposing that the influence of a negative group depends on the *shape* of the chain of atoms through which it is transmitted. It is, however, important to remember that there is

already evidence to show that the optical properties of the  $\pi$ -derivatives are sometimes abnormal (Richards and Lowry, J., 1925, 127, 1504).

With these facts in mind, the experimental data given above can be summarised by saying that, whilst the general absorption is influenced profoundly by the introduction of a negative group *in any position in the molecule*, the selective absorption is influenced strongly by a halogen atom only when this occupies a contiguous  $\alpha$ -position, the effect of a halogen or of a sulphonic group in the more distant  $\beta$ - and  $\gamma$  ( $\pi$ )-positions being negligible. Thus the increment for a single atom of bromine in the  $\alpha$ - or  $\alpha'$ -position is about 200 Å.U. (mean of 220, 240, 180, 150), and for a single atom of chlorine about 160 Å.U. (mean of 170, 180, 150, 130), when the other  $\alpha$ -position is occupied by hydrogen; and it is about 120 Å.U. for bromine and 50 Å.U., for chlorine, when the other  $\alpha$ -position is already occupied by a halogen. For a halogen in the  $\beta$ -position, the increments are -20, +50, +10, -20 Å.U. and for a halogen in the  $\pi$ -position, +30, +50, +20, -30 Å.U. A comparison with Rice's observations shows that the increments for two  $\alpha$ -atoms of chlorine, or for a single  $\alpha$ -atom of bromine, in camphor is already larger than for six  $\alpha$ -methyls in acetone.

### 6. Origin of the Ketonic Band.

At the time when the earlier observations of absorption spectra were made (J., 1909, 95, 807, 1340; 1910, 97, 899, 905) it was thought that selective absorption was due to an oscillation in the molecule of the same period as that of the absorbed light. The experiments then described showed, however, that the ketonic band could not be due to the "isorropesis" or intramolecular oscillation of a mobile hydrogen atom, since bands were developed by many compounds which were incapable of undergoing isomeric change in the manner suggested. The conclusion was therefore drawn that "the camphor band is evidently in some way a function of the ketonic group," but that "it is not at all easy to say in what way the group acts in promoting the formation of the band."

This problem has, however, been simplified considerably by recent developments in physical optics, which lead us to ascribe the absorption, not to an intramolecular vibration, but to the presence of a system which when activated by light can take up energy quanta of suitable magnitude. On inquiry amongst physicists, we find that the ultra-violet ketonic band cannot be attributed to activation of the nuclei of the carbon and oxygen atoms relatively to one another, since this would give bands in the infra-red region; nor can it be due to the ionisation of the unshared electrons of the oxygen

atom (*all* the carbon electrons are shared), since the ionisation potential for oxygen corresponds with a wave-length far out in the Schumann region. The ketonic band can therefore only be attributed to an activation of the valency electrons of the double bond which forms the link between carbon and oxygen.

These valency electrons differ from the others in being simultaneously under the control of two nuclei, A and B. They can therefore be raised to a higher energy level relatively to A, or to B, or to A and B simultaneously. If A is carbon and B is oxygen (or in general if A is a less "negative" element than B), it will be easier to activate the valency electrons relatively to A than relatively to B. The effect will be to produce a "polar activation" of the double bond, since the valency electrons which absorb the light will be displaced from carbon towards oxygen, a process which (if continued far enough) would culminate in the ionisation of one link of the bond, and the conversion of the "non-polar" into a "semi-polar" double bond, as indicated by the scheme  $>C=O \rightleftharpoons >\overset{+}{C}-\bar{O}$ .

The theory of polar activation, now used to explain the absorption of light by the unsaturated carbonyl radical, corresponds closely with the explanation given by Norrish (in Part III of this series of papers, J., 1923, 123, 3006) of the arrest of the interaction of ethylene with bromine or chlorine, when enclosed in a vessel lined with paraffin wax, *i.e.*, that the interaction depends on a "polar activation" of the olefine and halogen, which can only be brought about at a polar surface. It should also be noted that, whilst semi-polar double bonds are permanent in the systems  $>SO$ ,  $\geq NO$ , and  $\geq PO$ , they are not stable in  $>C=C<$  or  $>C=O$  (Sugden, J., 1925, 127, 1525); they are, therefore, available as unstable or activated forms of the molecule in order to account for phenomena such as those discussed above.

The views now set out in reference to the utilisation of the energy absorbed by double bonds in unsaturated compounds could obviously be extended to single bonds; but since these are usually much more stable than double bonds, the quanta of energy required to activate them must be much larger, and the wave-lengths much smaller, than in the case of the ketonic band, corresponding, for instance, with a frequency in the Schumann region of the spectrum. Since this region is still inaccessible to our present methods of investigation of absorption spectra, saturated compounds generally give rise only to "general absorption."

## 7. Summary.

(a) Quantitative data are given for the general and selective absorption of twenty halogen and sulphonic derivatives of camphor.

(b) Halogen atoms in the  $\alpha$ -position intensify both the general and the selective absorption of camphor; but halogen atoms and sulphonic groups in the  $\beta$ - or  $\pi$ -position are relatively impotent in increasing the selective absorption of the ketone, although they may contribute substantially to its general absorption.

(c) The origin of the ketonic band is discussed.

We wish to acknowledge our indebtedness to the University of Wales for a Fellowship Grant which has enabled one of us (G.O.) to take part in this work.

### LXXXIV.—*Studies of Valency. Part VI. General and Selective Absorption of Halogen Derivatives of Methane. The Origin of General Absorption.*

By THOMAS MARTIN LOWRY and ROSE RACHEL SASS.

#### 1. *Purpose of the Experiments.*

(a) THE observations described in the preceding paper created the impression that, just as the selective absorption of the ketones can be attributed to some form of polar activation or incipient ionisation of the *double* bond of the carbonyl group, so their general absorption might be attributed to the activation or incipient ionisation of a *single* bond, e.g., between carbon and hydrogen or between carbon and a halogen. In camphor itself, the single bonds appear to be so strong that they can only be activated by, and can therefore only absorb, light of very high frequency; the corresponding maximum of "general" absorption is therefore so remote that even the foot of the band cannot be detected at a wave-length of 2400 Å.U. On the other hand, in  $\alpha\alpha'$ -dibromocamphor (where the bonds between carbon and bromine are so weak that the compound acts as an oxidising agent) the general absorption is so strong that it almost covers up the selective absorption. The increase of absorptive power is indeed so rapid as to indicate that it must reach a maximum at a wave-length not far beyond the limits of our experiments. We therefore formed the opinion that, just as the double bond of the carbonyl group produces a characteristic absorption at about 2700 Å.U., so the single bond between carbon and bromine might have a characteristic absorption at some shorter wave-length; and that just as the maximum of the ketonic band of camphor can be shifted to the extent of some 350 Å.U. under the influence of contigu-

ous negative atoms, so the band of general absorption might be shifted through some hundreds of Ångström units in the direction of longer wave-lengths, as a result of the weakening of the single bond under the influence of contiguous negative atoms. This view, which served to explain the close analogy between the influence of the halogens on the selective and on the general absorption of the halogen derivatives of camphor, had the advantage that it could be tested by direct experiments on a much simpler series of compounds, and in this way it led to the experiments on the general and selective absorption of the halogen derivatives of methane, which form the subject of the present paper.

(b) In the experiments on general absorption advantage was taken of the fact that the introduction, first of the sector-photometer and then of the ultra-violet spectrophotometer, has made it possible to measure the molecular extinction coefficients of a solution in the ultra-violet region, and so to make an exact quantitative comparison of the general absorptions of a series of substances. Previous observations, in which the older qualitative methods were used (Crymble, Stewart, and Wright, *Ber.*, 1910, 43, 1183; Massol and Faucon, *Compt. rend.*, 1917, 164, 813), had given numerical values only for the characteristic wave-lengths of the iodo-compounds, which are the only ones to show a selective absorption in the accessible ultra-violet region.

(c) On the supposition that a marked general absorption could be produced by the incipient ionisation of a weak single bond between carbon and a halogen we anticipated :

(i) That the general absorption would increase progressively in the series  $\text{CH}_3\text{F}$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{Br}$ ,  $\text{CH}_3\text{I}$ , since the bond between carbon and fluorine is known to be extremely strong, whilst the bond between carbon and iodine is so weak that it can be ionised quite readily, *e.g.*, in the formation of a methiodide from an alkyl iodide and a nitrogenous base, or in the interaction between methyl iodide and silver nitrate in the Zeisel method of estimating methoxyl groups.

(ii) That the general absorption would increase in series such as :

since the accumulation of negative atoms would tend to weaken the bond between the carbon and the halogen, and so bring the crest of the band nearer to the accessible ultra-violet region. These anticipations have been fulfilled, as can be seen from the following summary of the experimental results.

## 2. Summary of Experimental Results.

The experimental data in reference to the halogen derivatives of methane are shown in Fig. 1, and are summarised in Table I.

TABLE I.

*Absorption Spectra of Alcoholic Solutions of Halogen Derivatives of Methane.*

Cl <sub>2</sub>						— 3450 2880 —
KI <sub>3</sub>	log $\epsilon$ = 3.9 at 3550, 2900	—	3570	3030	—	

(i) The data recorded above show that the absorptive power of the chlorine compounds is very slight. Thus even chloroform only produces a measurable absorption at high concentrations and short wave-lengths, *e.g.*, the value of log  $\epsilon$  at 2400 Å.U. is only -1.0. Carbon tetrachloride, however, develops a marked absorptive power at 2700 Å.U., where log  $\epsilon$  = 0.0, and gives rise to a well-defined curve of general absorption (Fig. 1, c).

(ii) Just as  $\alpha\alpha'$ -dibromocamphor gives rise to a much greater general absorption than  $\alpha\alpha'$ -dichlorocamphor, so the bromoderivatives of methane are much more absorptive than the corresponding chloro-compounds. Thus methyl bromide is nearly as absorptive as carbon tetrachloride; and the general absorption becomes increasingly strong in the series CH<sub>3</sub>Br, CH<sub>2</sub>Br<sub>2</sub>, CHBr<sub>3</sub>, CBr<sub>4</sub> (Fig. 1, b), until in the last compound the foot of the band begins to approach the violet end of the visible spectrum. It is noteworthy that the general absorption of  $\beta$ -bromocamphor, where the distance between the bromine atom and the oxygen of the ketonic group is sufficiently great to prevent the two negative radicals from influencing each other to any large extent, is very similar to that of methyl

bromide; thus the molecular extinction coefficient, which rises to  $\log \epsilon = 1.1$  at 2500 Å.U. in  $\beta$ -bromocamphor, reaches the same value at 2400 Å.U. in methyl bromide. This result is in harmony with the view that in both cases the weak bond which gives rise to the general absorption is the bond between carbon and bromine.

(iii) Conclusive evidence that the general absorption of the halogen derivatives of methane is due to a band of short wave-length, and that this wave-length can be increased by weakening the bond which links the halogen to the carbon, was obtained from the study of the iodides of the series  $\text{CH}_3\text{I}$ ,  $\text{CH}_2\text{I}_2$ ,  $\text{CHI}_3$ . In this series, although we only expected to find an enhanced "general absorption,"

FIG. 1.

definite bands are in fact developed (Crymble, Stewart, and Wright, *Ber.*, 1910, **43**, 1183; Massol and Faucon, *Compt. rend.*, 1917, **164**, 813). Up to a certain point the extinction coefficients of methyl iodide are almost identical with those of bromoform, *viz.*,  $\log \epsilon = 1.0$  at 3000 Å.U. and 2.0 at 2800 Å.U.; but the curve for the iodide, instead of rising progressively to  $\log \epsilon = 3.0$  at 2400 Å.U., reaches a maximum,  $\log \epsilon = 2.6$  at 2600 Å.U., and then falls again to  $\log \epsilon = 2.0$  at 2327 Å.U. (Fig. 1, a).

(iv) The absorption band, which thus makes its appearance for the first time in methyl iodide, develops progressively in the series  $\text{CH}_3\text{I}$ ,  $\text{CH}_2\text{I}_2$ ,  $\text{CHI}_3$ , until, in the case of iodoform, the foot of the band extends half-way across the visible spectrum. The visible colour of this compound, however, unlike that of *p*-benzo-

quinone, is still due to a selective absorption in the ultra-violet. The appearance of a general absorption beyond the band is a novel feature, which was seen for the first time in iodoform; but no great significance appears to attach to it, since it merely suggests the existence of a reserve of bands of shorter wave-length, which can be shifted towards the accessible ultra violet region by the accumulation of negative atoms.

(v) The most interesting feature of the iodoform curve is the division of the crest of the band into two maxima,  $\log \epsilon = 3.5$  at 3450 and 2940 Å.U., separated by a shallow minimum. It is not certain, however, whether even this should be regarded as an entirely abrupt development, since the band becomes progressively wider on passing from methyl iodide to methylene iodide and then to iodoform, although a careful examination failed to reveal any similar subdivision of the crest of the band in methylene iodide. The general form and position of the curves certainly suggest that we are dealing with the same band throughout, and that, although the second and third atoms of iodine may reinforce and develop the band, they are not needed in order to initiate it. It is, however, equally clear that the striking development of the band in methylene iodide and in iodoform reveals the influence of certain novel factors, which are not present in the simple alkyl iodides and are sufficiently important to form the subject of a separate discussion.

### 3. *Absorption Spectra of Iodine, Potassium Iodide, and Potassium Tri-iodide.*

In view of the qualitative comparisons which earlier workers have made between the absorption spectra of the iodo-derivatives of methane and those of solutions of iodine in alcohol and in aqueous potassium iodide, we have thought it desirable to include these solutions in our series of quantitative measurements. The results are shown in Fig. 1, *a*, together with a curve of general absorption of potassium iodide. They have also been included in Table I. The general conclusions are as follows:

(a) Although visible colour is developed more readily in compounds of iodine than in those of the other halogens, so many colourless compounds of iodine are known that one must suppose its chromophoric properties to be like those of oxygen, which depend on the mode of combination of the element, rather than like those of chromium or cobalt, where the elements seem to be almost incapable of yielding colourless derivatives. It is, therefore, very doubtful whether Massol and Faucon were justified, after recording the existence of three bands at 4700, 3500, and 2880 Å.U. in an alcoholic solution of iodine, in identifying these same bands in the

absorption spectra of the iodo-derivatives of methane. A theoretical objection to this method of treatment is found in the fact that, according to the conventional view, the atoms of iodine in an alcoholic solution are linked only by iodine-iodine bonds, whilst in the iodo-derivatives of methane all the atoms of iodine are held by carbon-iodine bonds. There is, therefore, no obvious basis for an identity of characteristic frequency, unless it arises from the inherent properties of the iodine atom or molecule; and the former alternative at least is ruled out by the fact that the frequency of the band in methyl iodide (2600 Å.U.) is so far different from that of the iodine bands that Massol and Faucon did not attempt any identification in this case. On the experimental side, this identification is limited by the fact that the band at 4800 Å.U., which imparts a visible colour to the alcoholic solution of iodine, is not reproduced in any of the derivatives, the colour of which is invariably due to the extension into the visible spectrum of the foot of an ultra-violet band. The second band at 3500 Å.U. can also be omitted from the discussion, since it is not recorded by Crymble, Stewart, and Wright, and no trace of it can be found on the quantitative curves which we have plotted in Fig. 1, *a*. It is therefore only the third band, at 2900 Å.U., that is available for the purpose of identification.

A band at 2900 Å.U. occurs in the absorption spectrum of iodine in aqueous potassium iodide, as well as of iodine in alcohol; but it is accompanied by a second band at 3500 Å.U., which is of much shorter wave-length than the visible band at 4770 Å.U. of the alcoholic solution. It is, therefore, impossible to attribute the selective absorption at 2900 Å.U. to the presence of free iodine in the aqueous iodide solution. If, therefore, the band is really the same in the two cases, it must be ascribed to some identical type of bond between the atoms of iodine, a conclusion against which no theoretical objection can be urged.

We have already seen that the wave-length of the band in methyl iodide is less than in elementary iodine; but in methylene iodide it is approximately equal to it. Since ethylene iodide gives a band of the same frequency as methyl iodide, although of rather greater intensity, Crymble, Stewart, and Wright attribute the methylene iodide band to the juxtaposition of two atoms of iodine in the same molecule, *i.e.*, they suggest that  $\text{I}-\overset{\text{I}}{\underset{\text{I}}{\text{C}}}-\text{I}$  gives the same band as  $\text{I}-\text{I}$ , but that  $\text{I}-\overset{\text{I}}{\underset{\text{I}}{\text{C}}}-\overset{\text{I}}{\underset{\text{I}}{\text{C}}}-\text{I}$  behaves like  $-\overset{\text{I}}{\underset{\text{I}}{\text{C}}}-\text{I}$ . Our own measurements indicate, however, that the band in methylene iodide reaches a maximum at 2960 Å.U., and is definitely of lower frequency than the iodine band at 2900 Å.U. It is, moreover, quite different in appearance, and could only be identified with the iodine band on the

assumption that it was really a double band, of which one component was identical with one of the bands of elementary iodine. It is therefore only in iodoform that any real identification is possible.\*

(b) Whilst Massol and Faucon attempt (perhaps somewhat unreasonably) to identify the bands of elementary iodine with those of its derivatives, Crymble, Stewart, and Wright associate together the spectra of potassium tri-iodide and iodoform. This identification appeared at first sight to be at least equally unreasonable, since the colour of the tri-iodide is always attributed to the negative ion  $I_3^-$ , which (like iodine itself) can only contain iodine-iodine bonds, whilst in iodoform the three atoms of iodine have always been regarded as linked independently to a central atom of carbon. Before accepting so remote an identification, therefore, we regarded it as essential to plot quantitative absorption curves for the two substances. The result has been to establish a degree of resemblance which is even closer than that shown by the qualitative curves. Thus (i) each spectrum includes two bands, and only two, in the accessible range of the spectrum.

(ii) The foot of the band of longer wave-length extends in each case into the visible spectrum and gives rise to visible colour.

(iii) In the same way, the band of shorter wave-length is followed almost immediately by a strong general absorption.

(iv) The persistence of the band of shorter wave-length is thereby limited to about 0.25 in both compounds.

(v) The two crests are of similar wave-length, namely, 3500 and 2900 Å.U. for potassium tri-iodide and 3450 and 2940 for iodoform.

(vi) In both cases the two crests are of equal intensity.

(vii) They are also separated by a shallow minimum which limits the persistence of the band of longer wave-length to about 0.25 in both cases.

(viii) Finally, the intensities of the bands on the absolute scale, although not identical, are almost the same in the two cases, namely  $\log \epsilon = 3.5$  for iodoform and 3.9 for potassium tri-iodide.

These eight points of agreement, which appear to us to be far beyond the possibilities of a mere coincidence, point to the existence of some definite similarity of structure between the two compounds. No such similarity is indicated, however, by any of the conventional formulæ. Thus, the most plausible formula for the  $I_3^-$  ion is perhaps

\* Carbon tetraiodide is so unstable in alcoholic solution that it was not investigated by Crymble, Stewart, and Wright, nor by ourselves; we cannot therefore say what weight should be attached to the statement of Massol and Faucon that it gives the same bands as iodoform.

one which represents it as the analogue of the  $\text{HF}_2^-$  ion, *e.g.*,  $\overset{+}{\text{K}}[\overset{+}{\text{I}}\overset{+}{\text{I}}\overset{+}{\text{I}}]$  (compare  $\overset{+}{\text{K}}[\overset{+}{\text{F}}\overset{+}{\text{F}}\overset{+}{\text{F}}]$ ); but the formula of iodoform cannot be made to conform to this pattern, since it has always been assumed that the three atoms of iodine are linked directly to carbon and not to one another. The stricter rules of the electronic theory of valency forbid, in an even more emphatic manner than before, any tampering with these formulæ, *e.g.*, by assigning a higher covalency to iodine, and thus superposing a ring structure on the traditional tetrahedron. We can therefore only conclude that our present theories of valency are inadequate to express certain features of molecular structure which may become of predominant importance in cases such as that now under consideration. It appears, indeed, as if both molecules were dominated by a cluster or ring of three contiguous iodine atoms, just as (according to W. L. Bragg's recent determinations) the crystal structure of most of the oxy-salts and of many of the metallic oxides is dominated by clusters of contiguous oxygen atoms, leaving the co-ordinating atom to occupy a mere cavity between the oxygens. This picture, from which all traces of the bonds between the atoms have been erased, is admittedly unconventional, but it appears to be the only one which gives any clue to the origin of the amazing similarity of the two absorption spectra.

#### 4. Summary and Conclusions.

(a) The general absorption of the chloro- and bromo-derivatives of methane increases progressively from chloroform to carbon tetrabromide. Methyl iodide, however, produces a band which becomes more intense and of longer wave-length on passing to methylene iodide and to iodoform, where the crest of the band is finally resolved into two maxima.

(b) The ultra-violet absorption band of methyl iodide cannot be explained by any of the older theories of colour, but finds a simple explanation in the relative weakness of the bond between carbon and iodine, and the consequent smallness of the quanta of energy that are required to activate it. The suggestion is therefore made that the general absorption of the halogen derivatives of camphor and of methane, and the intensification of the general absorption by an accumulation of contiguous negative atoms, is due to the activation or incipient ionisation of a single bond, just as the ketonic band of camphor may be attributed to the activation or incipient ionisation of the double bond of the carbonyl group.

(c) There is a close resemblance between the absorption spectra of iodoform and of potassium tri-iodide, which is not accounted for by the formulæ commonly assigned to these compounds, and appears

to be beyond the scope of our present theories of valency. It may, however, be due to the presence of three contiguous atoms of iodine in the space models of the two compounds.

### LXXXV.—*The Equivalent Conductivity of Solutions of Sodium Hydroxide and the Mobility of the Hydroxyl Ion.*

By HUMPHREY RIVAZ RAIKES, ALBERT FREDERICK YORKE, and  
FREDERICK KENNETH EWART.

THE object of the work detailed in this paper was to make use of the very pure water obtainable from stills of the type described by Bourdillon (J., 1913, 103, 791) for determining the value of the mobility of the hydroxyl ion.

It has long been recognised that the chief impurity in conductivity water is carbon dioxide. Present as it is in extremely small quantities, its effect on the conductivity of solutions of salts and to a less degree of acids may well be regarded as negligible and the true value of the conductivity is obtained from the observed value by subtracting a "water-correction."

With hydroxides, however, the case is quite different, since slow-moving carbonate ions are substituted for mobile hydroxyl ions and in very dilute solution the conductivity is that of a carbonate and not that of a hydroxide. The observed values will thus be less than the true values and if anything a correction should be added instead of subtracted.\* As, however, the determination of the value of this correction is not a simple matter, our method has been to use only water of the highest purity and to regard the whole conductivity as being due to the hydroxide.

The still used was a slightly modified Bourdillon still. It delivered, in quantity, water of specific conductivity 0.06—0.07 gemmho, and in the best experiments this had not increased beyond 0.09 gemmho after the water had been transferred to the conductivity cell.

\* Mr. W. F. K. Wynne-Jones has very kindly examined our figures and in one run where water of 0.599 gemmho purity was used and in which the equivalent conductivity showed a maximum at a concentration of 0.0007 mol. per litre he has shown that the application of a correction based on the assumption that the conductivity of the water was due to carbon dioxide brings the values obtained into close agreement with those found by us in water of a high degree of purity.

## EXPERIMENTAL.

*Preparation of Sodium Hydroxide Solutions.*—The chief methods available for the preparation of pure aqueous sodium hydroxide are (i) the action of water on metallic sodium; (ii) methods involving the precipitation of the carbonate present in ordinary sodium hydroxide by means of a barium or calcium salt; (iii) the electrolysis of an aqueous solution of a sodium salt.

In the first method, the difficulty is to get rid of the scale of carbonate on the surface of the metal before submitting it to the action of water.

FIG. 1.

*Apparatus for the preparation of sodium hydroxide solutions.*

In the second method, it is impossible to avoid the presence in the final product of either barium or calcium. Noyes states (*Pub. Carnegie Inst.*, 1907, No. 63) that his final product contained at least 0.1% of barium sulphate.

A very pure product may be obtained, however, by the third method.

A method somewhat similar to ours for obtaining aqueous sodium hydroxide free from carbonate has been described by Jorissen and Filippo (*Chem. Weekblad*, 1909, 6, 145).

*Description of Apparatus.*—The cell (Fig. 1) consisted of an outer vessel of common glass about a litre in capacity, carrying a wide glass tube of about 200 c.c. capacity which was made the cathode

compartment. The tube was at first of Jena glass and later of Pyrex glass; no difference in the purity of the final product could be detected. All the glass tubing used was boro-silicate and was well steamed before being made up. The bottom of the cell was covered to the depth of about an inch with mercury, previously distilled in a vacuum.

A tightly fitting wooden cap in the outer vessel carried the cathode compartment and other accessories. The lower end of the cathode compartment dipped well below the surface of the mercury, but did not touch the bottom of the outer vessel. A tightly fitting cork in the top of the cathode compartment itself carried the accessories necessary in this compartment.

The anode consisted of a carbon rod, which was rather rapidly attacked by chlorine; it was protected as far as possible by means of a glass tube, and arranged so that its end was about 1 inch above the mercury surface.

The cathode was of iron protected by a sheath of borosilicate glass tubing; its lower end dipped into the mercury and the iron never came into contact with the solution in the cathode compartment.

At first the whole apparatus was arranged so that it could be rocked gently in order to facilitate the passage of the sodium amalgam into the cathode compartment. This rocking was, however, found to be unnecessary and was abandoned.

The current used was about 2.3 amps. when the cell could be watched, but when it had to be left this was reduced to 1.2 amps. in order to avoid the risk of heating.

*Procedure when Working the Cell.*—The mercury having been run into the cell, the cap was placed in position and sealed on. As an additional precaution, the whole of the outside of the cap was covered with a layer of high melting-point paraffin-wax.

The cathode compartment was washed from five to six times with fairly good conductivity water; the water being run in through *D* and syphoned out through *E*.

A normal solution of sodium chloride (Merck) made up with water of about 0.5 gemmho conductivity was run into the anode compartment through the tube *A*, so that the level of the liquid was about an inch below the end of *C*; the tube *A* was then fitted with a soda-lime tube.

A current of dry air, free from carbon dioxide and ammonia, was next passed through the cathode compartment, *via* the tube *F*, the tubes *D* and *E* during this operation carrying soda-lime tubes; after this, the tube *F* was connected to a soda-lime tube.

Finally, about 200 c.c. of pure water (0.3 gemmho conductivity)

were run into the cathode compartment through the tube *D*, which was connected to the flask delivering the water, so that at no time did the latter come into contact with the atmosphere. The tubes *D* and *E* were then closed.

The current was now switched on, the hydrogen evolved at the cathode escaping through the soda-lime tube connected with *F*, and the chlorine being drawn off through *C* by means of a water pump; it was found necessary to connect the tube *A* to the air (through a soda-lime tube) in order to prevent a reduction of pressure taking place in the anode chamber, and consequent passage of the cathode liquid into the anode compartment. The exhausted brine was syphoned off through *B*.

Care was taken to keep the temperature of the cell as low as possible during the reaction, in order to prevent the solution of silica. The temperature at no time rose above 40° and was usually kept between 25° and 30°.

After the current had passed for about 6 hours, some of the sodium hydroxide in the cathode compartment was drawn off, and its strength roughly estimated. The solutions eventually used varied from *N*/10 to *N*. The main quantity of solution was then transferred by suction to a Jena glass flask which had been previously steamed and filled with pure air.

Thus the sodium hydroxide solution never came into contact with the air of the room at any time during its preparation. The solution was stored in this flask until required for a dilution, but was rarely kept for more than 3 days before being so used.

*Purity and Analysis of the Sodium Hydroxide Solutions.*—The sodium hydroxide prepared as above was invariably tested for chlorine and carbon dioxide, the former by the nephelometric method of Richards (*Amer. Chem. J.*, 1904, **31**, 235; 1906, **35**, 99), and the latter by mixing with baryta in the nephelometer by a method which enabled the solutions to be compared without any risk of contamination by carbon dioxide. The solutions never showed a greater cloudiness than a clear solution of baryta which was used as standard. Chlorine was always absent. The analysis of the solutions was carried out by means of weight titrations against hydrochloric acid, with methyl-red as indicator. The analyses were always done in triplicate and never differed by more than 1 part in 10,000. The hydrochloric acid was purified and estimated by Richards's method (*J. Amer. Chem. Soc.*, 1905, **27**, 459). Three analyses of each sample were made and the results agreed to 1 part in 20,000.

The weights used were standardised by Richards's method (*J. Amer. Chem. Soc.*, 1900, **22**, 144) and the appropriate vacuum correction was always applied. The densities of the sodium

hydroxide and hydrochloric acid solutions were taken from Landolt and Bornstein's tables.

*The Conductivity Measurements.*—The cell used was one designed by Hartley and Barrett and will be described in a future publication. It consisted essentially of a 1500 c.c. Jena glass beaker, to the top of which was cemented a brass ring. To this ring was attached by means of screws a silver-plated brass cover which carried the electrodes, a stirrer, and a thermometer, and was provided with two openings through one of which a stream of pure air could be passed, whilst the tip of the weight pipette was inserted through the other. These openings could be closed at will. The electrodes were coated with platinum black.

All the resistances were calibrated against Wolff standards which had been recently restandardised at the National Physical Laboratory.

The cell constant, determined in the manner described by Frazer and Hartley (*Proc. Roy. Soc.*, 1925, A, 109, 355), had the value 0.1367, identical with the value obtained by Hartley and Barrett in 1909.

*The Thermostat.*—The temperature variation of the bath was never more than  $\pm 0.01^\circ$  and for most of the runs it did not exceed  $\pm 0.005^\circ$ .

*The Weight Pipette.*—The weight pipette used for adding the solution to the cell was provided with a filling arrangement which effectually prevented the contamination of the solution by the carbon dioxide of the air.

A run was carried out by adding weighed portions of stock solution to the solvent in the cell.

*Cleaning and Drying the Cell.*—After each run the cell was rinsed out several times with pure water, and the electrodes, thermometer, and stirrer were cleaned by means of a stream of water. The cell was then filled with about a litre of pure water, the top placed in position, and the stirrer set going for several hours. The water was changed at least once a day and stirred. When the cell was required for a run, the beaker was inverted and allowed to drain for about 6 hours; the rest of the cell was also drained. For the first two runs the beaker was finally dried by means of filter-paper; the thermometer and stirrer were dried in a similar manner. The electrodes were dried by just touching their edges with filter-paper.

It was found later that the water was of better quality if the beaker was not wiped, but if, after draining, the top was placed in position and a current of dry air passed through it for several hours, the stirrer being rotated in order to keep the air circulating. This was found to be a very effective method of drying.

*The Results.*—In all, seven runs were carried out at 18° and two at 10°. The figures in Tables I and II show that even in the best water the equivalent conductivity fell off in solutions less concentrated than  $N/1000$ . In some of the earlier runs the values obtained were quite untrustworthy.

All concentrations are given in gram-molecules per litre at the temperature of experiment ( $\text{NaOH} = 40$ ).

TABLE I.

## Equivalent Conductivity of Sodium Hydroxide at 18°.

Uncorrected for solvent conductivity.

Run H. 31/5/1922.  $T = 18^\circ \pm 0.005^\circ$ . Water 0.086 gemmho.

Conc. $\times 10^4$	0.266	0.576	0.889	2.45	7.24	17.87	29.9
A .....	171.8	185.0	189.0	200.7	205.0	208.0	208.0

Run K. 12/6/1922.  $T = 18^\circ \pm 0.005^\circ$ . Water 0.084 gemmho.

Conc. $\times 10^4$	2.54	5.85	11.28	22.5	48.7	99.5	170	319
A .....	208.3	211.4	214.4	213.6	211.4	209.5	207.6	203.8

Run L. 20/6/1922.  $T = 18^\circ \pm 0.005^\circ$ . Water 0.087 gemmho.

Conc. $\times 10^4$	10.5	22.3	41.2	76.4	158	277	545
A .....	215.0	213.7	212.0	210.1	207.9	204.9	198.1

TABLE II.

## Equivalent Conductivity of Sodium Hydroxide at 10°.

Uncorrected for solvent conductivity.

Run D. 29/4/1922.  $T = 10^\circ \pm 0.01^\circ$ . Water 0.082 gemmho.

Conc. $\times 10^4$ ...	0.431	1.26	8.42	17.6	33.1
A .....	152.4	169.1	178.3	178.6	178.0

Run M. 22/6/1922.  $T = 10^\circ \pm 0.01^\circ$ . Water 0.089 gemmho.

Conc. $\times 10^4$ ...	9.74	18.9	36.7	73.5	144	285
A .....	179.2	178.2	177.0	176.6	175.1	173.0

Fig. 2 gives the graph of equivalent conductivity plotted against the square root of the concentration, and it will be seen that for solutions more concentrated than  $N/1000$  the points lie on straight lines up to a concentration of  $N/30$ . The equations to these lines are :

$$\begin{aligned} &\text{at } 18^\circ, \Lambda_{18} = 217 - 75.7\sqrt{c} \\ &\text{and at } 10^\circ, \Lambda_{10} = 180.2 - 44.2\sqrt{c}, \end{aligned}$$

$c$  being the concentration of the solution in gram-molecules per litre at the temperature of experiment.

Noyes (*loc. cit.*), whose sodium hydroxide was estimated by himself to contain 0.1% of barium sulphate, gives four values for the equivalent conductivity which lie about 0.5% below our values (see Fig. 2).

For comparison, the values obtained by Kohlrausch (*Wied. Ann.*, 1885, 26, 197) are also plotted in Fig. 2.

*The Temperature Coefficient of Equivalent Conductivity between 10° and 18°.*—The temperature coefficient calculated from the above figures is 4.60. The value obtained by Noyes (*loc. cit.*) for the range 18–100° was also 4.60.

*The Mobility of the Hydroxyl Ion.*—The mobility of the sodium ion at 18° being taken as 43.4 (Noyes and Falk, *J. Amer. Chem. Soc.*, 1912, 34, 479), the mobility of the hydroxyl ion becomes 173.6 at 18°.

FIG. 2.

The points marked  $\Delta$  are those of Noyes; the concentrations have been recalculated to gram-mols. per litre.

If the mobility of the sodium ion as calculated by Washburn (*J. Amer. Chem. Soc.*, 1918, 40, 158) is taken to be 43.23, the value for the hydroxyl ion becomes 173.8.

On the somewhat untrustworthy assumption that the transport number of the hydroxyl ion in sodium hydroxide has the same value at 18° and 10°, the mobility of the hydroxyl ion at 10° is, using the Noyes and Falk value for the sodium ion, 144.2, and using the Washburn value, 144.3.

#### Summary.

The equivalent conductivity of solutions of sodium hydroxide has been measured at 18° and 10° and the values for infinite dilution found to be 217.0 and 180.2, respectively.

Using Washburn's value for the mobility of the sodium ion, the mobility of the hydroxyl ion is found to be 173.8 and 144.3 at the two temperatures.

The authors wish to express their indebtedness to the Research Fund Committee of the Chemical Society for assistance in purchasing a part of the apparatus used for the still, to the authorities of Balliol and Trinity Colleges for permission to use their laboratory, and in particular to Brigadier-General H. Hartley for his continued interest and advice during the course of the work.

EXETER COLLEGE, OXFORD.

## LXXXVI.—*The Mercuration of Aromatic Substances.* *Part II. o-Nitrotoluene.*

By SAMUEL COFFEY.

THE position taken up by the acetoxymercuri-group in the mercuration of benzenoid compounds is sometimes anomalous; thus in the mercuration of nitrobenzene 50 and 40% of the *o*- and *m*-compounds respectively are formed, whilst with toluene the proportions of the three isomerides are  $o:m:p = 43:13:44$  (J., 1925, 127, 1029).

In the mercuration of the three mononitrotoluenes, which has now been studied, the reaction does not follow the expected course. This paper deals with the results obtained on mercuring *o*-nitrotoluene. When a third substituent is introduced into this compound, the 1:2:6 and 1:2:4-derivatives are generally the chief products. Of the four possible chloromercuri-*o*-nitrotoluenes, the 1:2:4-compound was isolated in quantity, the 1:2:6-compound was proved to be present in relatively large amounts, and the formation of the 1:2:3- or 1:2:5-derivative also was demonstrated. Attempts that were being made to discover which of these two was actually present were abandoned when the author was informed that Dr. Kenner, working at Sheffield, had obtained the 1:2:3-derivative in considerable quantity by mercuring *o*-nitrotoluene.

Although nitrotoluenes react with mercuric oxide and hot caustic soda solution to give compounds containing mercury in the side chain (Reissert, *Ber.*, 1907, 40, 4209), no mercurinitrotoluenes containing mercury directly attached to the nucleus are known. These are readily obtained when *o*-nitrotoluene is heated with mercuric acetate at 140°.

For comparison and in order to see whether the 1:2:3- and  
Y\*

1:2:5-derivatives differed at all in physical properties from the normal substitution products, 4-chloromercuri- and 5-chloromercuri-2-nitrotoluene were made synthetically through the corresponding sulphinic acids (compare Peters, *Ber.*, 1905, 38, 2567).

#### EXPERIMENTAL.

*Mercuration of o-Nitrotoluene.*—From the product of reaction in boiling acetic acid, only mercurous acetate and the internal anhydride of monohydroxymercuri-acetic acid were isolated.

The mercuration was best carried out as follows: Mercuric acetate (1 part) and *o*-nitrotoluene (4 parts) were heated gradually with occasional shaking. At 110–120°, the mercuric salt became orange-red and viscous, the solution frothed slightly, and acetic acid distilled off. As the temperature increased, the red mass gradually disappeared and a pale yellow solution formed. A temperature of 140–150° was attained after an hour's heating and was maintained until the product failed to respond to a test for mercuric ions (4 hours). After 12 hours, a brown, amorphous solid, containing a little free mercury but consisting mainly of mercurous acetate, separated.

The clear nitrotoluene solution was then poured into a large volume of ether and left for 24 hours, when an almost colourless, amorphous solid separated. This had a high mercury content and apparently consisted of polymercuri-compounds; it was free from monoacetoxymmercuri-derivatives. The ether was distilled off, the clear yellow solution treated with an excess of sodium chloride solution to convert the acetoxymmercuri-compounds into the more easily purified chloro-derivatives, and the excess of nitrotoluene removed as quickly as possible in a current of steam. The main product of the reaction remained as a heavy, almost colourless mass. This was broken up and allowed to dry in the air. The yields (in grams) of the various products obtained in different experiments were:

	I.	II.	III.	IV.
Nitrotoluene used .....	210	310	1000	360
Mercuric acetate .....	50	75	200	90
Insoluble in nitrotoluene .....	3	7½	18	5
Insoluble in ether .....	9	15½	35	15
Main product .....	40	55	166	69

This crude main product contained a small amount of nitrotoluene which was retained very tenaciously but was finally removed by extraction with ether in a Soxhlet apparatus. The residue melted at 120–155° and consisted only of monochloromercuri-*o*-nitrotoluenes (Found: N, 3.75.  $C_7H_6O_2NClHg$  requires N, 3.8%).

*Separation and Orientation of 4-Chloromercuri-2-nitrotoluene.*—By crystallising the crude product (160 g.) twice from 500 c.c. of hot

acetone the pure compound was obtained in silky needles, m. p. 220.5—221° (corr.), having, when dry, the appearance of asbestos. By working up the mother-liquors a total yield of 32 g. was obtained (Found: N, 3.7; Hg, 53.9. Calc., N, 3.8; Hg, 53.9%).

4-Chloromercuri-2-nitrotoluene is sparingly soluble in all usual solvents except acetone and hot glacial acetic acid. By treatment with the theoretical quantity of bromine in chloroform it was slowly but quantitatively converted into 4-bromo-2-nitrotoluene, which crystallised from methyl alcohol in slender needles, m. p. 44.5—45°; when it was crystallised very slowly it was obtained in large, pale yellow, brittle prisms (compare Hübner and Roos, *Ber.*, 1873, 6, 799).

Most organic mercury compounds react with iodine very readily, but the reaction of 4-chloromercuri-2-nitrotoluene with an equivalent of iodine in chloroform required 11 or 12 days for completion, theoretical yields being obtained of mercuric chloride, mercuric iodide, and 4-iodo-2-nitrotoluene, which crystallised from methyl alcohol in small, brittle prisms, m. p. 60.5—61°, identical with that obtained by Heynemann (*Annalen*, 1871, 158, 345) and Reverdin (*Ber.*, 1897, 30, 3001).

4-Bromomercuri-2-nitrotoluene was prepared by treating a solution of the chloro-compound in aqueous acetone with potassium bromide; after boiling for a few minutes, it was cooled, filtered, and the solid washed with water, and recrystallised from acetone. It is a heavy, crystalline powder, m. p. 241° (corr.), less soluble than the chloro-compound.

4-Iodomercuri-2-nitrotoluene, prepared in a similar manner, melts at 286° with slight decomposition. It was recrystallised from acetone, in which it was only sparingly soluble.

4-Mercuribis-2-nitrotoluene.—No mercuri-bis-nitro-compounds are known with the exception of mercuribistrinitrobenzene, obtained by heating mercuric trinitrobenzoate. The mercuribisnitrotoluene was obtained by carefully reducing the above chloro-compound with the calculated quantity of sodium sulphide. Under these conditions the chloromercuri-group is attacked before the nitro-group, owing no doubt to the fact that *o*-nitrotolyl mercuric sulphide is first formed and this unstable compound on warming undergoes spontaneous decomposition. In this way, the reducing agent is effectually "fixed" and cannot react with the nitro-group.

4-Chloromercuri-2-nitrotoluene (3.7 g.) was shaken in a solution of crystallised sodium sulphide (1.2 g.) for 3 hours, being thereby converted into the colourless sulphide. The mixture was heated on the water-bath for 2 hours, the black product filtered off, washed, dried, boiled with acetone, and the solution filtered hot. The black,

inky extract, containing colloidal mercuric sulphide, thus obtained was filtered again when cold, the black, colloidal mercuric sulphide passing through the filter and leaving a white, crystalline solid. This spectacular method of purification was repeated until no more solid was obtained. The product was pure 4-mercuribis-2-nitrotoluene, which crystallises from acetone in a woolly mass of needles, m. p.  $291^{\circ}$  (corr.) (Found: Hg, 42.0.  $C_{14}H_{12}O_4N_2Hg$  requires Hg, 42.4%). On boiling for 3 hours with one equivalent of mercuric chloride in alcohol, it gave an almost theoretical yield of pure 4-chloromercuri-2-nitrotoluene, its constitution being thus determined.

*Existence of 6-Chloromercuri-2-nitrotoluene.*—The remainder of the mixed chloromercurinitrotoluenes (see p. 638) was suspended in chloroform and treated with bromine (1 mol.), and the bromonitrotoluenes, which were purified by distillation in steam, were obtained in quantitative yield as a golden-yellow oil, freezing at low temperatures to a buttery mass. Attempts to separate this oil into its constituents by means of freezing, fractional distillation in steam, or a vacuum, or by crystallisation, failed. The nitro-compounds were therefore reduced to the corresponding bromotoluidines by warming for 2 hours with sodium sulphide in aqueous alcoholic solution on the water-bath. The amines were distilled in steam, an excess of hydrochloric acid was added to the distillate, and the mixed hydrochlorides were fractionally crystallised; but no pure compound could thus be isolated. The mixture of bases was therefore acetylated, and 7.2 g. of the product were fractionally crystallised as follows. The solution in 50 c.c. of hot 50% acetic acid was filtered, and cooled very rapidly, when 2.1 g. (A) separated, m. p.  $150-158^{\circ}$ . On standing, the mother-liquor deposited 0.7 g. (B) of pale brown needles, m. p.  $159-161^{\circ}$ . Only solids with low melting points could be obtained from the final mother-liquor.

On recrystallisation from 10 c.c. of 50% acetic acid (A) gave 1.6 g., m. p.  $163-164^{\circ}$ , and further recrystallisation from benzene furnished colourless needles of constant m. p.  $165.5^{\circ}$  (corr.). On hydrolysis this acetyl compound gave a base, m. p.  $32^{\circ}$ , which was converted into a benzoyl derivative, m. p.  $160^{\circ}$  (corr.). The base was compared with 4-bromo-*o*-toluidine; the latter also melted at  $32^{\circ}$ , and its acetyl derivative at  $165.5-166^{\circ}$  (compare Janney, *Annalen*, 1913, 398, 359), as did also a mixture with (A). The benzoyl compounds were also identical. The yield of 4-bromoaceto-*o*-toluidide isolated was 23%, corresponding to 18% of the original mixed mercurated nitrotoluenes. Hence the total amount of 4-chloromercuri-2-nitrotoluene accounted for is 38%.

The product (B) on recrystallisation from benzene gave 0.55 g.

of long needles, m. p. 162—163°; a mixture with (A) melted at 120—130°. Hydrolysis furnished a liquid base, which was proved to be 6-bromo-*o*-toluidine as follows: 2:6-dinitrotoluene was reduced, as described by Noeltig (*Ber.*, 1904, **37**, 1018), to 6-nitro-*o*-toluidine. This was diazotised and converted into 6-bromo-*o*-nitrotoluene, m. p. 38°. The latter was reduced to a liquid base, which gave a theoretical yield of the acetyl compound (B) on treatment with acetic anhydride; it melted at 164.5° (corr.).

Some of the melting points of this acetyl compound given in the literature are erroneous; Friedländer, Bruckner, and Deutsch (*Annalen*, 1912, **388**, 30) give it as 163°.

*Proof of the Presence of 3- or 5-Chloromercuri-2-nitrotoluene.*—Many attempts were made to isolate other derivatives of the bromotoluidines, the bromodinitrotoluenes (obtained by nitrating the mixture of bromonitrotoluenes), or the nitrotoluenesulphonic acids (obtained by sulphonating the original mercuri-compounds), but without success. A small quantity of 3:5-dibromo-*o*-toluidine was isolated, which indicated the presence of one or both of the compounds in question, but a more direct proof was obtained by eliminating the amino-group from the mixed bromotoluidines and showing the presence of *m*-bromotoluene in the product.

A mixture of the dry amines, absolute alcohol (4 parts), and 20% oleum (2 parts) was warmed with an excess of sodium nitrite, and the product distilled in steam. The bromotoluenes, which passed over together with a brown substance, were purified by steam distillation from an alkaline solution and repeated fractional distillation, a colourless liquid, b. p. 179—190°, being finally obtained which only partly solidified at —80°. Hence it was not a mixture of the *o*- and *p*-isomerides only. The mixture was oxidised to the corresponding bromobenzoic acids, and the latter were separated as already described in Part I. In this way pure *m*-bromobenzoic acid, m. p. 154°, was isolated, the presence thus being proved of a substance in the original mixture having the chloromercuri-group in the meta-position with respect to a methyl group and in the ortho- or para-position with respect to a nitro-group; which is abnormal for direct substitution.

*Synthesis of 5-Chloromercuri-2-nitrotoluene. Preparation of 2-Nitrotolyl 2-Nitrotoluene-5-sulphazide.*—Almost all the nitrotoluene-sulphinic acids are unknown. Since the usual methods of preparation failed here, a process devised by Limpricht (*Ber.*, 1887, **20**, 1238) was used.

Sulphur dioxide was passed into a suspension of 6-nitro-*m*-toluidine (10 g.) in 100 c.c. of alcohol at 0° until absorption ceased. The resulting solution was treated at 0° with nitrous fumes or with

a saturated solution of 20 g. of potassium nitrite with constant stirring. The mixture was kept in ice over-night and at room temperature for 2 days and then poured into water. The bright orange precipitate (9 g.) thus obtained was extracted with boiling alcohol, in which it was only sparingly soluble, and crystallised from glacial acetic acid, 2-nitrotolyl 2-nitrotoluene-5-sulphazide separating in deep orange prisms, m. p. 157—158° (violent decomp.) (Found: N, 15.5.  $C_{14}H_{14}O_6N_4S$  requires N, 15.3%).

Fission of a sulphazide by boiling sodium hydroxide solution usually proceeds smoothly:  $R \cdot SO_2 \cdot NH \cdot NHR' + NaOH = R \cdot SO_2Na + R'H + N_2 + H_2O$  (compare Escales, *Ber.*, 1885, 18, 896). From the nitrotoluene compounds, however, much tar was produced and the acids were difficult to obtain pure by the usual methods. In the preparation of 2-nitrotoluene-5-sulphinic acid and other nitrosulphinic acids good use has been made of the fact that they form insoluble ferric salts, which are unchanged by dilute acids (Thomas, J., 1909, 95, 342).

The preceding sulphazide was boiled with a slight excess of baryta until no more nitrotoluene escaped with the steam. The deep reddish-brown solution was filtered hot through a wet filter to remove tar, acidified, well diluted, filtered from a little more tar, and treated with an excess of ferric chloride solution. The copious precipitate of ferric salt obtained was boiled with ammonia, the solution filtered from ferric oxide and evaporated to a small volume. On acidification a pale yellow oil separated. This was extracted with ether, and on removal of the solvent, 2-nitrotoluene-5-sulphinic acid separated in small, colourless needles (Found: equiv., 203.  $C_7H_7O_4NS$  requires equiv., 201.1. Found for the ferric salt: Fe, 8.3.  $C_{21}H_{18}O_{12}N_3S_3Fe$  requires Fe, 8.3%).

The sulphinic acid was boiled with a 50% aqueous alcoholic solution of mercuric chloride for a week, the solid which separated being filtered off periodically. After washing and drying, the crude chloromercuri-compound was extracted with hot acetone; pure 5-chloromercuri-2-nitrotoluene crystallised from the solution in a felted mass of small, shining needles, m. p. 210°. In solubility and general properties it was very similar to the 4-isomeride.

*2-Nitrotoluene-4-sulphinic Acid.*—When a dilute solution of diazotised 6-nitro-*p*-toluidine was treated with sulphur dioxide and copper powder, a tarry mass was produced immediately. Better results were obtained by working in strongly acid solution, but even then the sulphazide was produced and not the free acid. The base (10 g.) was dissolved in sulphuric acid (75 c.c.) and water (75 c.c.), cooled to 0°, and diazotised; the latter reaction took place very slowly. The solution was saturated at 0° with sulphur

physiological effect, and further absorption spectrum study was undertaken to investigate this important phase of the subject.

Acetylthyroxin was prepared by Kendall's method (*loc. cit.*) from 20 mg. of commercial thyroxin. It remained amorphous and gummy,

FIG. 1.

A, keto-Thyroxin. B, Acetylthyroxin. C, Thyroxin in alkaline solution.

despite attempts to purify it by crystallisation from alcohol. Through the courtesy of Dr. Kendall, who specially prepared a specimen of the acetyl derivative from pure thyroxin, measurements of the absorption were made possible. The substance was dissolved

in 75% aqueous alcohol and examined in concentrations of  $M/2,000$ ,  $M/8,000$ ,  $M/20,000$ ,  $M/50,000$ , and  $M/100,000$ .

*keto*-Thyroxin was prepared by dissolving the pure substance in 75% alcohol containing four equivalents of hydrochloric acid, and measurements were made at the same concentrations as the above.

The alcohol-soluble derivative obtained by passing carbon dioxide into a solution containing thyroxin and its equivalent of sodium hydroxide (*loc. cit.*) was dissolved in the minimum of 60% alcohol, and measurements were made as rapidly as possible at concentrations of  $M/4,000$ ,  $M/20,000$ ,  $M/80,000$ , and  $M/100,000$ .

### Discussion.

Allowance must be made for the error in the value of the absorption coefficient likely to arise from the use of such minute quantities of material, but even so the evidence of the wave-lengths of the absorption bands remains. The curves for the acetyl derivative and the *keto*-form of thyroxin are more closely related to each other than to the curve for thyroxin in alkaline solution. The major band in the last lies at 3275 Å.U., whilst in the other two it lies respectively at 2850 Å.U. and 2925 Å.U., the third band at 2750 Å.U. being absent from both. The curve for the so-called open-ring form, prepared by the action of carbon dioxide on an alkaline solution of thyroxin, is almost identical with that for the *keto*-form, except that it tails off suddenly at 2400 Å.U., in the region of  $\log \epsilon = 4$ , into the Schumann region, giving no band as in the other cases. It is possible that during the time taken to make the measurements, even in dilute alcohol, water may be removed, with consequent closure of the ring, and therefore the results obtained may be intermediate values. The change is represented as follows :

Since the original measurements were made on thyroxin, Friedli has confirmed the presence of the band in indole, in the region 2100 Å.U. (*Bull. Soc. chim. Biol.*, 1924, 6, 10, 908).

My thanks are due to Professor Sir F. Gowland Hopkins for his continued interest in the work, and to Dr. E. C. Kendall for the gift of acetylthyroxin. This work was done during the tenure of a Beit Memorial Fellowship for Medical Research.

LXXXVIII.—*N*-Alkylated Amidines.

By MONMOHAN SEN and JÑANENDRA NATH RÂY.

IN connexion with certain investigations relating to glyoxaline alkaloids, it became necessary to prepare and study the behaviour of a number of *N*-alkylated amidines. The methods already available for the preparation of these substances (Wallach, *Ber.*, 1879, 12, 328; 1882, 15, 208; 1883, 16, 357, 1647; Strecker, *Annalen*, 1857, 103, 328) are not entirely satisfactory. Hofmann (*Jahresber. Fort. Chem.*, 1865, 414; *Monatsberichte Berl. Akad.*, 1865, 640) obtained diphenylacetamidine and diphenylbenzamidine by condensing aniline with acetanilide and benzanilide, respectively, in presence of phosphorus trichloride or pentachloride. This rather convenient method seems to have been little investigated and it was deemed desirable to study it systematically. It is of very general applicability and by its means a number of new amidines have been prepared, in good yield in most cases. Phosphorus trichloride is the most suitable condensing agent for the purpose, although phosphoric oxide in boiling xylene may advantageously replace it in some cases.

A mixture of the requisite quantities of an amine and an acylamine in about ten times the weight of phosphorus trichloride is heated at 110–120° for about 3 hours. The completion of the reaction is indicated by a drop of the reaction mixture giving a clear solution in water. The product is dissolved in cold water and basified; the amidine is then precipitated in a crystalline condition.

The method is applicable to a secondary amine like diphenylamine and an acylamine. On the other hand, acetomethylanilide condenses with *m*-toluidine, hence the reaction is represented as taking place as follows :

But no isomeric forms can be isolated, as the amidines show virtual tautomerism (compare von Pechmann, *Ber.*, 1895, 28, 869). By altering the order of combination the same product was isolated (A) from acetanilide and *m*-toluidine and from aceto-*m*-toluidine and aniline, and (B) from acetanilide and *p*-nitroaniline and from *p*-nitroacetanilide and aniline. The result (B) is interesting, as here a strongly negative group in the molecule has not impaired the mobility of the hydrogen atom in any way.

With a view to prepare hydrazidines, we attempted to condense an acylamine with phenylhydrazine by this method. The product

of interaction of acetanilide and phenylhydrazine, on being rendered alkaline, evolved ammonia and diphenylacetamidine was obtained in more than 70% yield.

Next, we attempted to prepare cyclic amidines by using urethane in place of an amine. Phosphoric oxide acting on molar proportions of acetanilide and urethane in boiling xylene solution gave rise to the compound (I), which will be described along with others of the same series in a subsequent communication.

A further point of interest is in connexion with the Beckmann transformation of acetophenoneoxime. The transformation may be represented as taking place through the phases (a) and (b):

Both (a) and (b) represent reactive chloro-compounds capable of condensing with aniline to form acetophenonephenylhydrazone and diphenylacetamidine respectively. The actual amounts of each would depend on the relative reactivity of the two chlorine atoms in (a) and (b). Actually, the amidine was produced and no trace of acetophenonephenylhydrazone could be detected. This result may, of course, be due to the smaller reactivity of the chlorine atom in the group C:NCl as compared with N:Cl, but it may also be taken to indicate that the intermediate phase (a) exists only for a very short period of time.

#### EXPERIMENTAL.

Some properties of the amidines that have been prepared are tabulated below. Unless stated otherwise, the amidines were crystallised from alcohol. The values in brackets in column 3 are the calculated percentages of nitrogen. An amidine X:NY was prepared from the components XO and NH<sub>2</sub>Y; e.g.,

NHPh·CMe:N·C<sub>6</sub>H<sub>4</sub>Me  
from NHPh·COMe and C<sub>6</sub>H<sub>4</sub>Me·NH<sub>2</sub>, and so on.

## LXXXIX.—Substitution in Vicinal Trisubstituted Benzene Derivatives. Part IV.

By LEON RUBENSTEIN.

THE investigation of substitution in dialkylxybenzene derivatives of type (I) in which the group X is meta-directing has been conducted on a large number of compounds and discussed at length (Davies and Rubenstein, J., 1923, 123, 2839; Rubenstein, J., 1925, 127, 2268).\* The continuation of that work is now described.

\* The bromination of these dialkylxyaldehydes has been stated (*loc. cit.*) to give only the 5-bromo-derivative, the argument being based upon (i) the position of substitution of the salicylaldehyde derivatives and (ii) the capacity of the brominated product to give a 6-nitro-compound. The position of the bromine atom in these compounds has now been proved by the direct preparation of 5-bromo-*o*-veratric acid from 5-nitro-*o*-veratric acid (see p. 652).

Substitution processes have been investigated on vicinal substances of type (I) in which X is a weakly ortho-para-orienting group. The first series of compounds examined as fulfilling these requirements were the dialkyloxybenzyl alcohols, and the nitration and bromination of these substances were carried out. In the nitration of *o*-veratryl alcohol, 2:3-diethoxybenzyl alcohol, and 3-methoxy-2-ethoxybenzyl alcohol good yields of the 5-nitro-benzyl alcohol were obtained in each case, the position of the nitro-group being shown by oxidation of the benzyl alcohol derivative to the corresponding benzoic acid. Bromination did not proceed so smoothly, but moderate yields of the 5-bromo-benzyl alcohols were obtained, the place of substitution again being shown by oxidation. The second series of compounds examined were the dialkyloxy-cinnamic acids (III) in which the group X (I) is ortho-para-orienting and unsaturated. In this case again, 5-nitro-derivatives were produced exclusively in the case of 2:3-diethoxycinnamic and 3-methoxy-2-ethoxycinnamic acids. From these substances, the respective benzoic acids were reformed on oxidation. From 2:3-dimethoxycinnamic acid a mixture of isomerides was formed on nitration, and by fractionally separating first the acids and then the esters left in the residual mixture on esterification it was shown that 85% of the nitration mixture consisted of 5-nitro-2:3-dimethoxycinnamic acid, the rest being the 6-nitro-acid.

#### EXPERIMENTAL.

**5-Nitro-2:3-dimethoxybenzyl Alcohol.**—2:3-Dimethoxybenzyl alcohol (5.5 g.; prepared from *o*-veratraldehyde by means of the Cannizzaro reaction) dissolved in glacial acetic acid (20 c.c.) is treated gradually with a solution of nitric acid (5.5 c.c., *d* 1.42) in glacial acetic acid (5.5 c.c.); the temperature rises to 40–50°. After being maintained at 50° for 2 hours and at room temperature over-night, the brown solution is poured into water. The product, an oil which slowly solidifies, crystallises from methyl alcohol in colourless needles, m. p. 67° (yield 90%) (Found: N, 6.6.  $\text{C}_9\text{H}_{11}\text{O}_5\text{N}$  requires N, 6.6%). On oxidation with alkaline permanganate solution and subsequent acidification with dilute hydrochloric acid 5-nitro-*o*-veratric acid is obtained, m. p. 176°, identical with the acid obtained by the nitration of *o*-veratric acid.

**3-Methoxy-2-ethoxybenzyl Alcohol.**—3-Methoxy-2-ethoxybenzaldehyde (12 g.) dissolved in methyl alcohol (16 c.c.) is treated with

a solution of potassium hydroxide (17.6 g.) in methyl alcohol (45 c.c.). After 24 hours, the greater portion of the methyl alcohol is distilled off, the residue shaken with benzene, the extract washed a few times with concentrated sodium bisulphite solution and dried over potassium carbonate, and the benzene evaporated. The residual oil almost wholly distills at reduced pressure as a colourless liquid, b. p.  $148^{\circ}/13$  mm. (yield, almost theoretical).

*5-Nitro-3-methoxy-2-ethoxybenzyl Alcohol.*—3-Methoxy-2-ethoxybenzyl alcohol (2 g.) dissolved in glacial acetic acid (2 c.c.) is treated with a solution of nitric acid (2 c.c.) in glacial acetic acid (2 c.c.), and the reddish-brown solution kept over-night. The 5-nitro-3-methoxy-2-ethoxybenzyl alcohol which separates in pale yellow, prismatic crystals is filtered off; more is obtained on pouring the filtrate into water and crystallising the oily product, which hardens, from alcohol; m. p.  $132^{\circ}$  (yield 65%) (Found: N, 6.4.  $C_{10}H_{13}O_5N$  requires N, 6.2%). On oxidation with an alkaline solution of potassium permanganate 5-nitro-3-methoxy-2-ethoxybenzoic acid, m. p.  $169^{\circ}$ , is obtained.

*2:3-Diethoxybenzyl Alcohol.*—This is obtained from 2:3-diethoxybenzaldehyde and purified substantially by the process described under 3-methoxy-2-ethoxybenzyl alcohol. It is a colourless oil, b. p.  $163^{\circ}/11$  mm.,  $167^{\circ}/19$  mm., which solidifies on cooling and can be crystallised from light petroleum (b. p.  $60-80^{\circ}$ ), separating in colourless needles, m. p.  $35^{\circ}$  (Found: C, 67.6; H, 8.0.  $C_{11}H_{16}O_3$  requires C, 67.4; H, 8.2%).

*5-Nitro-2:3-diethoxybenzyl Alcohol.*—This is obtained from 2:3-diethoxybenzyl alcohol (1.5 g. in glacial acetic acid, 2 c.c.) and nitric acid (1.5 c.c. in glacial acetic acid, 1.5 c.c.) by the method described under 5-nitro-2:3-dimethoxybenzyl alcohol. It crystallises from alcohol in colourless needles, m. p.  $75^{\circ}$  (yield 1.7 g. or 90%) (Found: N, 7.2.  $C_{11}H_{15}O_5N$  requires N, 7.1%), and on oxidation with 1% alkaline permanganate yields 5-nitro-2:3-diethoxybenzoic acid, m. p.  $118^{\circ}$ , identical with the nitration product of 2:3-diethoxybenzoic acid.

*5-Bromo-2:3-dimethoxybenzyl Alcohol.*—*o*-Veratryl alcohol (5 g.), dissolved in glacial acetic acid (25 c.c.) containing sodium acetate (7.5 g.), is treated with bromine (5 g.) in glacial acetic acid (20 c.c.). After 2 days, the mixture is poured into water. The oil that separates, and hardens slowly, is removed (3.5 g.), and the filtrate treated with solid sodium bicarbonate; a further 3.7 g. of solid are then obtained. The combined products, crystallised from light petroleum a few times, yield 5-bromo-2:3-dimethoxybenzyl alcohol in colourless needles, m. p.  $82^{\circ}$  (Found: Br, 31.8.  $C_9H_{11}O_3Br$  requires Br, 32.1%). The acid produced by its oxidation with

1% alkaline potassium permanganate at 60—70°, after crystallisation from light petroleum, melts at 120° and does not depress the m. p. of 5-bromo-*o*-veratric acid obtained by oxidation of 5-bromo-*o*-veratraldehyde.

*5-Bromo-3-methoxy-2-ethoxybenzyl Alcohol*.—3-Methoxy-2-ethoxybenzyl alcohol (2 g.) is brominated by the foregoing method. The oil produced on dilution, after hardening, is isolated by means of benzene and crystallised twice from light petroleum (b. p. 60—80°); 5-bromo-3-methoxy-2-ethoxybenzyl alcohol is thus obtained in white prisms, m. p. 55—56° (Found: Br, 30.3.  $C_{10}H_{13}O_3Br$  requires Br, 30.6%).

*5-Bromo-2 : 3-diethoxybenzyl Alcohol*.—2 : 3-Diethoxybenzyl alcohol (2.5 g.) dissolved in glacial acetic acid (13 c.c.) containing sodium acetate (4 g.) is treated at 20—25° with bromine (2 g.) in glacial acetic acid (7 c.c.). After remaining in sunlight for a few days, the mixture is poured into water; the oil obtained partly solidifies after several days. The oily portion is removed as completely as possible, and the residue crystallised three times from light petroleum; 5-bromo-2 : 3-diethoxybenzyl alcohol is thus obtained in colourless, prismatic crystals, m. p. 60° (Found: Br, 28.6.  $C_{11}H_{15}O_3Br$  requires Br, 29.1%).

*Nitration of 2 : 3-Dimethoxycinnamic Acid*.—The finely powdered acid (5 g.) is added in small portions and with stirring to nitric acid (25 c.c.; *d* 1.42). After 3 hours, the mixture is poured over ice. The cream-coloured precipitate (6 g.) is dried and dissolved in boiling alcohol. By careful fractional separation 3.3 g. of a substance, m. p. 205—227°, are obtained. The alcoholic filtrate is evaporated to small bulk, saturated with hydrogen chloride, and heated on a water-bath for 1 hour. Fractional separation of the mixture of esters thus produced yields first *ethyl 5-nitro-2 : 3-dimethoxycinnamate*, which crystallises from alcohol in cream, prismatic needles, m. p. 111° (Found: N, 5.2.  $C_{13}H_{15}O_6N$  requires N, 5.0%). [*5-Nitro-2 : 3-dimethoxycinnamic acid* is obtained, by twice crystallising the product, m. p. 205—227°, in pale yellow prisms, m. p. 229° (Found: equiv., 256.  $C_{11}H_{11}O_6N$  requires equiv., 253). Oxidation with potassium permanganate gives 5-nitro-*o*-veratric acid.] *Ethyl 6-nitro-2 : 3-dimethoxycinnamate* is obtained from later fractions and crystallises from aqueous alcohol in long, white needles, m. p. 86°. It is hydrolysed by boiling for a few minutes with equal volumes of water, glacial acetic acid, and sulphuric acid, giving 6-nitro-2 : 3-dimethoxycinnamic acid, which crystallises from aqueous alcohol in brown needles, m. p. 210—215° (decomp.). On oxidation with alkaline potassium permanganate solution at 90° and acidification, it gives a substance of high m. p.

(above 280°) which appears to be identical with the 6-nitro-3-hydroxy-2-methoxybenzoic acid obtained by boiling 6-nitro-2:3-dimethoxybenzoic acid for 15 hours with 2.5 *N*-sodium hydroxide.

**3-Methoxy-2-ethoxycinnamic Acid.**—3-Methoxy-2-ethoxybenzaldehyde (6 g.) is added to pyridine (20 c.c.) containing malonic acid (7.2 g.), 6 drops of piperidine are added, and the solution is heated under reflux on a steam-bath for 1 hour; the evolution of carbon dioxide is then completed by boiling the solution for 5 minutes. The cooled solution is poured into water acidified with concentrated hydrochloric acid, and the precipitate of 3-methoxy-2-ethoxycinnamic acid (yield almost quantitative) collected. It crystallises from alcohol in colourless needles, m. p. 151° (Found: equiv., 220.  $C_{12}H_{14}O_4$  requires equiv., 222).

**5-Nitro-3-methoxy-2-ethoxycinnamic Acid.**—Finely divided 3-methoxy-2-ethoxycinnamic acid (1 g.) is added gradually to nitric acid (10 c.c.; *d* 1.42), and the mixture kept over-night. On dilution with water 5-nitro-3-methoxy-2-ethoxycinnamic acid is obtained in quantitative yield. Crystallised from alcohol, it gives cream needles, m. p. 200–201° (Found: equiv., 269.  $C_{12}H_{13}O_6N$  requires equiv., 267).

**2:3-Diethoxycinnamic Acid.**—This acid, prepared from 2:3-diethoxybenzaldehyde (5 g.) by the pyridine method described above (yield 5.3 g. or 90%), crystallises from alcohol in long, slender, colourless needles, m. p. 161° (Found: equiv., 235.  $C_{13}H_{16}O_4$  requires equiv., 236).

**5-Nitro-2:3-diethoxycinnamic Acid.**—Prepared (at 20–25°) from 2:3-diethoxycinnamic acid (1 g.) and isolated by the method described under 5-nitro-3-methoxy-2-ethoxycinnamic acid, this acid is obtained in quantitative yield. It crystallises in long, cream prisms, m. p. 199° (Found: equiv., 280.5.  $C_{13}H_{15}O_6N$  requires equiv., 281).

The following is an account of the preparation of 5-bromo-*o*-veratric acid from 5-nitro-*o*-veratric acid.

5-Nitro-2:3-dimethoxybenzoic acid (4.5 g.) is heated with concentrated hydrochloric acid (15 c.c.) and tin (4.5 g.) on a steam-bath for a few hours, the solution diluted with water, the tin removed as sulphide, and the colourless filtrate evaporated under reduced pressure; white, prismatic crystals of the hydrochloride of 5-amino-2:3-dimethoxybenzoic acid are deposited (yield 80%).

The hydrochloride is soluble in water or alcohol and in warm concentrated hydrochloric acid, from which it can be crystallised. The solutions turn pink and then red in the air, especially if in presence of an excess of acid. 5-Amino-2:3-dimethoxybenzoic acid is obtained by treating a concentrated solution of the hydrochloride

with solid sodium carbonate until it is just acid to Congo-red. The colourless needles, m. p.  $250^{\circ}$  (decomp.), soon become deep-red owing to oxidation, and are soluble in acids and in alkalis (Found : N, 6.9.  $C_9H_{12}O_4N$  requires N, 7.0%).

The hydrochloride (4 g.) is dissolved in water (17 c.c.), neutralised with solid sodium carbonate, treated with hydrobromic acid (7.5 c.c.;  $d$  1.50), and diazotised at  $0^{\circ}$  with sodium nitrite (1.2 g. in water, 3 c.c.). The black, semi-crystalline solid obtained by heating the diazonium solution with cuprous bromide and concentrated hydrobromic acid is boiled with alcohol and animal charcoal, and the hot filtered solution cooled after addition of a little water. Long, cream needles are deposited, m. p.  $112-113^{\circ}$ , which, after further treatment with animal charcoal and recrystallisation from aqueous alcohol, melt at  $120^{\circ}$  and do not depress the m. p. of 5-bromo-*o*-veratric acid obtained by oxidation of 5-bromo-*o*-veratraldehyde.

### XC.—*The Decomposition of Substituted Carbamyl Chlorides by Hydroxy-compounds. Part II. The Influence of the Hydroxy-compound.*

By TUDOR WILLIAMS PRICE.

IN Part I (J., 1924, 125, 115) an account was given of the reaction between phenylmethylcarbamyl chloride and ethyl alcohol at different temperatures. An account is now given of the reaction between phenylmethylcarbamyl chloride and various hydroxy-compounds at  $100^{\circ}$ .

Norris and Ashdown (*J. Amer. Chem. Soc.*, 1925, 47, 837) studied the reaction between various alcohols and *p*-nitrobenzoyl chloride in ether at  $25^{\circ}$ , but no quantitative work, so far as the author is aware, has hitherto been published on the influence of the constitution of the hydroxy-compound upon the velocity of reaction with a carbamyl chloride.

*Materials.*—The phenylmethylcarbamyl chloride was from the same batch as was used in the previous work, and had been kept over phosphoric oxide in a desiccator.

The various alcohols used were the purest commercial alcohols

and were all treated twice at their respective boiling points with fresh calcium turnings (1.0 and 0.5% by weight) and fractionated. The other hydroxy-compounds, which also were the purest commercial substances, were purified by fractional distillation, some under reduced pressure. Each hydroxy-compound after purification boiled either constantly at one temperature or over a range of less than  $0.2^{\circ}$ .

*Method of Work.*—In each experiment, 0.424 g. of the carbamyl chloride (equivalent to 25 c.c. of *N*/10-solution) and 5 c.c. of the hydroxy-compound were sealed in a test-tube and heated at  $100^{\circ}$  for a definite time. A hydroxy-compound that was solid at the ordinary temperature was first melted and 5 c.c. were placed in the tube, which was then cooled before the carbamyl chloride was introduced. These proportions caused the hydroxy-compound to be present in large excess, thus making the reaction unimolecular with respect to the carbamyl chloride.

In the case of the alcohols the whole reaction is made up of two consecutive reactions:

but the progress of the first reaction can be studied by determining the amount of carbamyl chloride left in the system at any instant. This was done, for those alcohols (methyl, ethyl, and *n*-propyl) which give low-boiling chlorides, in the manner described in Part I (*loc. cit.*). For the other hydroxy-compounds, since aspiration of air through the system would not remove the chloro-compound formed, the following method was used. After being heated at  $100^{\circ}$  for the required time, the mixture was titrated with *N*/10-potassium hydroxide. Excess of ammonia was then added to convert any unchanged carbamyl chloride into ammonium chloride and the corresponding substituted carbamide. The solution, after standing in the cold for 1 hour to complete the conversion, was extracted four times with light petroleum to remove the chloro-derivative of the hydroxy-compound, acidified with pure nitric acid, and titrated with *N*/10-silver nitrate without an indicator. This titre was a measure of both the ammonium chloride and the hydrogen chloride present. The amount of the latter was known from the *N*/10-potassium hydroxide titre, and by subtraction the ammonium chloride titre, which was equivalent to the carbamyl chloride, was obtained.

In the case of *n*-propyl alcohol both methods were employed, and gave almost identical results.

The quantity of phenylmethylcarbamyl chloride present being

known, the velocity coefficient for a unimolecular reaction was calculated from the expression

$$k = \frac{1}{t_2 - t_1} \log_e \frac{a - x_1}{a - x_2},$$

where  $t_1$  is 5 minutes and  $a - x_1$  is the amount of carbamyl chloride present in the system after the tube had been in the water-bath at  $100^\circ$  for 5 minutes. This expression was used to obviate the initial disturbances.

### Results.

In Table I, where the results for methyl and *n*-propyl alcohols are given in detail, the first column gives the duration of heating in minutes ( $t$ ), the second the amount of hydrogen chloride present, expressed as c.c. of *N*/10-solution ( $b$ ), the third the amount of hydrogen chloride plus phenylmethylcarbamyl chloride present, expressed as c.c. of *N*/10-solution ( $c$ ). The fourth column gives the amount of phenylmethylcarbamyl chloride present ( $d$ ), obtained by subtracting the figures in column 2 from those in column 3. The fifth column gives the velocity coefficient for the reaction between phenylmethylcarbamyl chloride and the hydroxy-compound, calculated from the figures in column 4.

The whole of the results are summarised in Table II.

The hydroxy-compound may influence the reaction in two ways : by its constitution and by its solvent action. The influence of a solvent on the velocity of a reaction in which it does not take part has been extensively studied, and no general relation has been traced between the chemical or physical properties of the solvent and its effect on the velocity coefficient.

Menschutkin (*Z. physikal. Chem.*, 1887, 1, 611; 1890, 6, 41) found that the velocity of certain reactions was greatest in those solvents having the highest dielectric constant, but in other reactions this rule did not hold. Patterson and Montgomerie (*J.*, 1912, 101, 26, 2100) state that a given set of solvents may hasten a particular reaction in a certain sequence, whilst it may retard another reaction in the same or nearly the same sequence, and that the properties which bring this about are probably the same throughout.

Another view of the influence of the solvent is that the solvent and the solute form an unstable additive compound, in which case it is probable that the chemical constitution of the solvent, rather than its physical properties, would be most effective in influencing the velocity of the reaction. The work of Cox (*J.*, 1920, 117, 493) supports this view.

In the present work, the hydroxy-compound, which can be regarded as a solvent, reacts with the carbamyl chloride, hence its chemical constitution does influence the velocity of the reaction and the question arises whether, in addition to that, the physical properties of the hydroxy-compound play a part. The physical properties most likely to have some effect upon the velocity of a reaction are the viscosity, the dielectric constant, and the refractive index.

Reformatsky (*Z. physikal. Chem.*, 1891, 7, 34) showed that viscosity did not appear to have any great influence on the velocity coefficient of a reaction. The refractive index of the hydroxy-compounds examined varies between  $n_D^{20}$  1.3290 for methyl alcohol and  $n_D^{20}$  1.576 for cinnamyl alcohol; for most of them it is about 1.4, so that the small differences in refractive index are not sufficient to explain the large differences in velocity coefficient. The dielectric constant shows a greater variation, the highest being 32 for methyl alcohol (20°) and the lowest 9.7 for phenol (48°). These two extremes, however, are the values for the hydroxy-compounds having the greatest velocity coefficients, so that there does not seem to be a connexion between dielectric constant and velocity coefficient. In addition, the differences between the physical properties of the various liquids will tend to become smaller as the temperature is raised and therefore it is probable that at 100° the effect due to the different solvent action of the hydroxy-compounds will be very

small compared with the effect of their differences in chemical constitution.

In considering the effect of chemical constitution upon the velocity of a reaction several factors have to be taken into account: first, the general polar effect, due to substituent atoms or groups affecting the molecule as a whole; secondly, the steric effect; and thirdly, an alternate polarity effect. In many cases two or all three factors may operate simultaneously, and then it is difficult to assess the effect of each factor individually. With regard to the straight-chain aliphatic primary alcohols, the steric factor is not sufficiently strong to influence the velocity, and the results show no trace of an alternate effect, for the velocity coefficients are in the order methyl alcohol > ethyl alcohol > *n*-propyl alcohol > *n*-butyl alcohol. The order is the same as that found by Menshutkin (*Z. physikal. Chem.*, 1887, 1, 611) in the reaction between acetic anhydride and several alcohols in benzene solution at 100°, and different from that found by Norris and Ashdown (*loc. cit.*), where the order was methyl alcohol > ethyl alcohol > *n*-butyl alcohol > *n*-propyl alcohol. The reactivity of the alcohol decreases, *i.e.*, the hydroxyl hydrogen atom becomes more firmly bound, as the length of the straight chain increases. With the primary *iso*-compounds it is again seen that an extra  $-\text{CH}_2-$  group in the straight chain decreases the velocity coefficient. A branched-chain alcohol has a smaller velocity coefficient than a straight-chain alcohol of the same molecular weight; thus *n*-propyl > *isopropyl* and *n*-butyl > *isobutyl*. In the case of *isopropyl* alcohol the velocity coefficient is abnormally small, probably owing to a steric effect superimposed upon the general polar effect of the substituent, since this is a secondary alcohol whilst the others are primary alcohols. A similar effect was found by Ashdown and Norris.

The introduction of a phenyl group at the end of the straight chain decreases considerably the reactivity of the alcohol, as is shown by the following figures: methyl alcohol 0.222, benzyl alcohol 0.0185, allyl alcohol 0.0420, cinnamyl alcohol 0.00744.

The effect of unsaturation is to cause a great increase in the reactivity of the alcohol; thus *n*-propyl alcohol 0.0251, allyl alcohol 0.0420.

Taking methyl alcohol as the standard, and considering the replacement of one of its hydrogen atoms in the methyl group, we find that the general polar effect of the various substituents in decreasing the reactivity of the hydroxyl hydrogen is in the following order:  $\text{CH}_3 < \text{CH}_2\cdot\text{CH} < \text{C}_2\text{H}_5 < \text{C}_6\text{H}_5 < \text{C}_3\text{H}_7 < \text{CH}(\text{CH}_3)_2 < \text{CH}(\text{CH}_3)_2\cdot\text{CH}_2 < \text{C}_6\text{H}_5\cdot\text{CH}\cdot\text{CH}$ .

The introduction of a second hydroxyl group, as in ethylene

glycol, increases the reactivity so greatly that the velocity coefficient cannot be obtained with accuracy by the method employed.

The aromatic compounds show special features. Phenol, as was to be expected, is very reactive, more so than methyl alcohol. The introduction of a methyl group, as in the cresols, diminishes the reactivity of the hydroxyl hydrogen, the extent of the diminution depending on the relative positions of the methyl and hydroxyl groups in the benzene ring. The velocity coefficients are: phenol 0.308, *o*-cresol 0.0541, *m*-cresol 0.146, *p*-cresol 0.175. The low value for *o*-cresol is undoubtedly due to a preponderating steric effect.

Work with other carbamyl chlorides is in progress.

The author wishes to thank the Chemical Society for a grant from the Research Fund which has partly defrayed the cost of this investigation.

THE TECHNICAL COLLEGE, BRADFORD. [Received, December 16th, 1925.]

## XCI.—*Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XXVIII. d-sec.-Butylbenzene.*

By PHILIP WILLIAM BENSON HARRISON, JOSEPH KENYON,  
and JOHN ROBERT SHEPHERD.

OF the compounds which have been examined in the study of the relationship between chemical constitution and optical activity, very few have been hydrocarbons, probably because of the experimental difficulties in preparing this type of compound in an optically active condition.

Mention may be made, however, of *d*-methylethyl-*n*-propylmethane with  $[\alpha]_D^{20} + 9.5^\circ$ , which was prepared by Marckwald (*Ber.*, 1904, 37, 1046) by the action of sodium on a mixture of ethyl iodide and *d*-amyl iodide. Klages and Sautter (*Ber.*, 1904, 37, 649) prepared *d*- $\alpha$ -phenyl- $\gamma$ -methylpentane ( $[\alpha]_D^{18} + 17.2^\circ$ ) by the reduction of *d*- $\alpha$ -phenyl- $\gamma$ -methyl- $\Delta^a$ -pentene ( $[\alpha]_D^{18} + 43^\circ$ ), which was obtained by the interaction of active amyl iodide ( $[\alpha]_D^{18} + 5.78^\circ$ ) and benzaldehyde in presence of magnesium. The same authors (*Ber.*, 1905, 38, 2312), by analogous reactions, prepared *d*- $\gamma$ -*m*-isopropylphenyl- $\gamma$ -methylpentane ( $[\alpha]_D^{18} + 15.91^\circ$ ) and *d*- $\gamma$ -*m*-isopropylphenyl- $\gamma$ -methyl- $\Delta^a$ -pentene ( $[\alpha]_D^{18} + 41.89^\circ$ ).

This communication describes the preparation of *sec*-butylbenzene in what is believed to be an optically pure condition.

The preparation has proved to be so tedious and laborious that the question of preparing other optically active hydrocarbons will be held in abeyance until a more convenient procedure has been devised.

The method of preparing *d*-*sec*.-butylbenzene is briefly as follows : The inactive hydrocarbon was nitrated and the *p*-nitro-*sec*.-butylbenzene, which is the principal product of the reaction, was reduced to *p*-amino-*sec*.-butylbenzene. The latter was then converted into the *hydrogen tartrate*, which was submitted to systematic prolonged fractional crystallisation until a salt of constant rotatory power was obtained. The amino-group of the optically active base obtained by the decomposition of this salt was then eliminated in the usual way, giving optically active *sec*.-butylbenzene.

The resolution of *sec*.-butylbenzene into its optically active isomerides had been attempted previously. Klages (*Ber.*, 1906, 39, 2131) converted the hydrocarbon into its sulphonic acid and obtained therefrom a number of crystalline salts by combining it with several of the commoner alkaloids. Fractional crystallisation of these salts, however, brought about no resolution.

*p*-Amino-*sec*.-butylbenzene was obtained in an optically active condition by Glattfeld and Wertheim (*J. Amer. Chem. Soc.*, 1921, 43, 2682) by the crystallisation of the salt with *d*-camphorsulphonic acid. The rotatory power of the amine quoted by these authors is, however, far too low, being some sixty times smaller than the value obtained in the course of the present work.

Each of the compounds now described exhibits a very high optical rotatory dispersive power:  $\alpha_{4359}/\alpha_{5461} = 1.87$  for the amine and 1.81 for the hydrocarbon, whilst an examination of the rotatory powers shows that in no case do they satisfy the simple dispersion equation  $\alpha = K/(\lambda^2 - \lambda_0^2)$ .

As it is possible that the high optical rotatory dispersive power may be due to these compounds containing a benzene nucleus in the molecule, several attempts were made to reduce *sec*.-butylbenzene to *sec*.-butylcyclohexane to ascertain what effect, if any, the loss of aromatic character would have on the rotatory dispersive power. However, under the conditions employed, namely, agitation of the substance with hydrogen in the presence of colloidal platinum or palladium, little, if any, reduction was effected.

#### EXPERIMENTAL.

*dl*-*sec*.-Butylbenzene was prepared by the method of Klages (*Ber.*, 1902, 35, 2641). The methylethylphenylcarbinol obtained by the interaction of magnesium ethyl chloride and acetophenone was slowly distilled at the ordinary pressure, and the resulting

$\beta$ -phenyl- $\Delta^2$ -butylene (75% yield) reduced rapidly with sodium and absolute alcohol. *sec*-Butylbenzene was collected at 168—173° and obtained in 87% yield.

*p*-Nitro-*sec*-butylbenzene.—To *dl*-*sec*-butylbenzene (200 g.) was added during 3 hours a mixture of nitric acid (128 c.c.; *d* 1.42) and sulphuric acid (160 c.c.; *d* 1.84) at such a rate that the temperature of the reaction was maintained at 15—20°; external cooling was resorted to, and the mixture kept vigorously stirred. The principal product of the reaction was *p*-nitro-*sec*-butylbenzene—shown by the production of *p*-nitrobenzoic acid in good yield on oxidation—accompanied by a relatively small amount of a lower-boiling fraction which was presumably *o*-nitro-*sec*-butylbenzene. Only a rough separation was possible at this stage, owing to the difficulty of obtaining a fraction of constant boiling point. Further purification was, however, easily effected after the next operation by the recrystallisation of the *oxalates* of the mixed amines.

*dl*-*p*-Amino-*sec*-butylbenzene.—The *p*-nitro-compound was very easily reduced to the corresponding amine by tin and concentrated hydrochloric acid. After decomposition of the stannic chloride compound of the base by caustic soda, the amine was isolated by distillation in steam.

The mixture of neutral *oxalates* of the amines was crystallised several times from hot water and it was found by determining the density of the amine recovered that one crystallisation was sufficient to remove almost completely the lower-boiling isomeride of greater density. The amine thus obtained distilled constantly at 118°/15 mm.; its density (*d*<sub>4</sub><sup>25</sup> 0.949), and the melting point (123°) of its acetyl derivative were unaltered after further recrystallisation of the neutral *oxalate*. Reilly and Hickinbottom (J., 1920, 117, 120) give 125—126° as the melting point of *p*-*sec*-butylacetanilide; that prepared by the present authors melts at 123° even after several recrystallisations.

*Resolution of dl-p-Amino-sec-butylbenzene*.—Salts of the *dl*-amino with several optically active acids were prepared—that with *l*-malic acid was excessively soluble and could not be crystallised; those with *d*-camphoric and *d*-camphorsulphonic acids were crystalline, but their separation into enantiomorphous forms by fractional crystallisation was too slow to be of use. The compound with *d*-hydroxymethylenecamphor was also prepared, but fractional crystallisation of this failed to effect any resolution. (This is in agreement with the observation of Glattfeld and Wertheim, *loc. cit.*).

After many preliminary attempts it was found that the *d*-hydrogen

tartrate was the most promising of all the salts tried. *p*-Amino-*sec*.-butylbenzene (285 g.) was added to a hot solution of *d*-tartaric acid (300 g.) in water (1100 c.c.); the clear solution on standing deposited a crop of crystals (which titration showed to be the *hydrogen tartrate*) in very small, prismatic rods. These were systematically recrystallised until the rotatory power of the amine obtained by decomposing successive crops of the crystals became constant. The rate of the resolution is indicated by the following data :

After four recrystallisations of the hydrogen tartrate, the observed rotatory power ( $\alpha_{5461}^{20}$ ;  $l = 100$  mm.) of the liberated base was  $+16^\circ$ , after eight  $+23^\circ$ , after twelve  $+28^\circ$ , after sixteen  $+31^\circ$ , after twenty-two  $+37^\circ$ , after twenty-five  $+38.2^\circ$ , after twenty-seven  $+38.7^\circ$ , after thirty  $+38.7^\circ$ .

This prolonged process of recrystallisation is very wasteful and the *d-p*-amino-*sec*.-butylbenzene obtained by decomposition of the various crops of salt of constant rotatory power amounted to only 10 g. The amine had b. p.  $114^\circ/12$  mm. and  $d_4^{20} 0.945$ .

Various attempts were made to isolate the *l*ævorotatory form of *p*-amino-*sec*.-butylbenzene in an optically pure condition, but without success. By the decomposition of the most soluble fractions of the hydrogen tartrate, portions of amine of rotatory powers lying between  $\alpha_{5461} - 12^\circ$  and  $-20^\circ$  were obtained. The *d*-camphorsulphonate of the base with  $\alpha_{5461} - 20^\circ$  was prepared and recrystallised several times; the *l*ævorotation of the amine obtained from the less soluble fractions of this salt increased, but at so slow a rate as to render the method valueless. Recrystallisation of the hydrochloride and of the oxalate of the partially active amine was also without effect on the rotatory power. Other solvents besides water were tried in all the above bases for recrystallisation of the various salts, but they bring about separation with even greater slowness than does water.

*d-sec*.-Butylbenzene was readily prepared by mixing a solution of *d-sec*.-butylbenzenediazonium chloride (from 6 g. of amine) with a strongly alkaline solution of sodium stannite and distilling the mixture in a current of steam. The hydrocarbon was obtained as a colourless liquid which distilled constantly at  $172^\circ$ ; the yield was 2 g. = 40% of the theoretical (compare Friedländer, *Ber.*, 1889, 22, 587).

Although it was considered unlikely that any racemisation would occur during the elimination of the amino-group situated at the end of the molecule remote from the asymmetric carbon atom, yet the following experiments were carried out to gain some information on this important point. Partially active *d*- and *l-p*-amino-*sec*.-butylbenzenes of various degrees of rotatory power were diazotised

and treated with sodium stannite under different experimental conditions; the ratio of the rotatory power of the original amine to that of the hydrocarbon obtained from it in each of the several cases was quite constant, thus rendering it highly improbable that any racemisation had taken place.

The authors desire to express their thanks to the Government Grant Committee of the Royal Society for a grant with which some of the materials used in this investigation were purchased. Two of them (J. R. S. and P. W. B. H.) wish also to acknowledge their indebtedness to the Department of Scientific and Industrial Research for maintenance grants which enabled them to participate in the work.

## XCII.—*The Chemistry of Polycyclic Structures in Relation to their Homocyclic Unsaturated Isomerides.* *Part VI. Some Reactions of isoPhorone.*

BY JOHN WILLIAM BAKER.

THE chemistry of homocyclic compounds is often complicated by reactions which find no simple explanation in the structure usually assigned to the compound (Farmer and Ingold, J., 1920, **117**, 1362, and subsequent papers), the ambiguity extending in one case even to the synthesis of the substance, syntheses which should yield respectively the acids (I) and (II) yielding the same acid (Farmer, Ingold, and Thorpe, J., 1922, **121**, 128).

Such conflicting evidence was reconciled by the assumption of intra-annular tautomerism between the *bicyclopentene* and the *cyclopentadiene* systems, the two enolic forms being merely valency isomerides in accordance with the scheme :

There is no *a priori* reason why such redistribution of residual affinity within the ring, extending from mere conjugation of affinity across the ring to the establishment of a real bridge bond, should be restricted to the *cyclopentadiene* series: its extension to the

heterocyclic rings thiophen and furan, and to benzene has already been developed (Ingold, J., 1922, 121, 1133, and subsequent papers).

The present paper deals with the extension of such intra-annular tautomerism to the *cyclohexadiene* series in accordance with the general scheme :

On first inspection it may be considered that the structure (IV) is improbable in view of the strain involved, but it must be understood that it is not intended to represent a stable individual substance, but merely a phase in the scheme of valency distribution which, under favourable conditions, may pass into a more stable, true bridged phase. Such favourable conditions may occur when one or both of the potential trimethylene rings are stabilised by the presence of a *gem*-dimethyl group, and, in this case, products containing a *cyclopropane* ring may result from the degradation of the molecule.

An example of this type of intra-annular tautomerism has, in the author's opinion, been established in the case of *isophorone*. The generally accepted formula (V) for *isophorone* has been established both by synthesis and by oxidation. Knoevenagel and Fischer (*Annalen*, 1897, 297, 185) obtained it by the condensation of mesityl oxide and ethyl acetoacetate at 5° and hydrolysis of the *isophorone*carboxylic ester so produced. The structure was confirmed by Crossley and Gilling (J., 1909, 95, 24), who obtained the ketone by the condensation of ethyl sodiomalonate with chloro-dimethyl*cyclohexenone* and hydrolysis of the ethyl dimethyl*cyclohexenone*acetate so obtained.

The oxidation of *isophorone* was investigated by Bredt and Rubel (*Annalen*, 1898, 299, 160), who obtained a whole series of acids intermediate between *isophorone* and its final oxidation product, *as*-dimethylsuccinic acid. Formula (V) is also in good accord with most of the reactions of the ketone, *e.g.*, the formation of monobenzylidene-monopiperonylidene derivatives.

Kerp and Muller (*Annalen*, 1898, 299, 193), however, found that this structure alone was not sufficient to represent all the reactions of *isophorone* (obtained, in this case, by the condensation of acetone). *isoPhorone* condenses with another molecule of acetone to yield a higher condensation product, xylitone, which these investigators found also yields a monobenzylidene derivative, and hence must contain the group  $CMe_2:C \cdot CO \cdot CH_2 \cdot$ ; this necessarily involves the existence of the group  $\cdot CH_2 \cdot CO \cdot CH_2 \cdot$  in the original *isophorone* molecule. Hence, in this reaction at least, *isophorone*

must be represented by the structure (VI) rather than (V), and these authors concluded that *isophorone* obtained from acetone is a static mixture of the two isomerides (V and VI).

The interconversion of these two forms merely involves the well-known  $\alpha\beta$ - $\beta\gamma$  change across a three-carbon system, and the conflicting results would be readily explained if such a tautomeric system were assumed to exist in the *isophorone* molecule. The enolic modification (VII) of the structure (VI) conforms to the *cyclohexadiene* type mentioned above, and hence there is the possibility of a second kind of tautomeric change, *viz.*, intra-annular, a redistribution of affinity across the ring resulting, initially, in the *tricyclohexane* structure (VIII). It is not suggested that this form represents more than a transitory phase in the whole scheme, for only one of the potential three-membered rings is stabilised by the presence of a *gem*-dimethyl group, and it is to be expected that such a structure would immediately ketonise across the ring, thus destroying the unstabilised three-membered ring, to yield a bridged modification of the *isophorone* molecule (IX). Finally, this could change in the usual manner to yield an enolic modification of a bridged form of *isophorone*. The complete scheme is as follows :

Thus in the *isophorone* molecule three types of tautomerism are possible, each being superimposed on the other; (a) three-carbon,  $\alpha\beta$ - $\beta\gamma$ -change, (b) intra-annular, (c) keto-cyclol.

Evidence is submitted in this paper which, in the author's opinion, can be explained only by assuming such a scheme in connexion with the *isophorone* molecule.

Kerp and Muller (*loc. cit.*) found that in ice-cold glacial acetic acid solution *isophorone* forms an unstable dibromo-additive product which spontaneously evolves hydrogen bromide. Their analysis is 5% low for this compound. When, however, *isophorone* in ice-cold carbon tetrachloride solution is treated with a standard

solution of bromine in the same solvent, absorption is rapid and a white, crystalline dibromo-compound (XI) separates, but no trace of hydrogen bromide is evolved until two atoms of bromine have been added. This additive compound is stable in the absence of moisture, but on exposure to air it immediately loses one molecule of hydrogen bromide to form monobromoisophorone (XII). Although the possibility of bromine addition to the enolic double bond and subsequent loss of hydrogen bromide to yield a  $\alpha$ -bromoketone cannot be excluded, it is considered more probable, in view of the degree of stability of the intermediate compound, that the addition of bromine occurs at the double bond in the three-carbon system, thus forming a blocked system, which therefore spontaneously liberates hydrogen bromide to reform a mobile system in accordance with the scheme :

Evidence of the bridged modification of *isophorone* was obtained by a study of its reduction products. When *isophorone* is reduced by the Clemmensen method, a solid hydrocarbon,  $\text{C}_{18}\text{H}_{28}$ , can be isolated in small yield from the product. This hydrocarbon is saturated, and therefore valency considerations necessitate the existence of the bridged structure (XIII). This structure is supported by the oxidation of the hydrocarbon with boiling potassium permanganate in sodium hydrogen carbonate suspension, the main product being *trans*-caronic acid. The formation of this hydrocarbon from the bridged, enolic modification of *isophorone* (X) is represented by the following scheme, additive ring formation preceding the reduction :

A similar constitution has been assigned to  $\alpha$ -dicamphylic acid (XIV) obtained by the action of potash on sulphocamphylic acid (Perkin, J., 1903, 83, 835).

Reduction of *isophorone* with sodium and moist ether yields a

mixture of two isomerides,  $C_{18}H_{30}O_2$ , m. p.  $126^\circ$  and  $162^\circ$ , respectively. The latter is undoubtedly the product obtained by Hess and Munderloh (*Ber.*, 1916, **51**, 383) by the reduction of *isophorone* with 2.5% sodium amalgam and methyl alcohol. These investigators, apparently merely on the analytical data, assigned the pinacol formula (XV) to this product. Such a constitution is, however, quite inconsistent with the properties of this reduction product. Both substances, m. p.  $126^\circ$  and  $162^\circ$ , are saturated and do not decolorise potassium permanganate in sodium hydrogen carbonate solution in the cold, both yield disemicarbazone derivatives, but neither will form an acetyl derivative on heating with acetic anhydride. They are probably derived from the unsaturated ring form of *isophorone* (VII) by a reduction similar to that which occurs in the formation of deoxymesityl oxide and deoxyphorone, respectively, from mesityl oxide and phorone, two stereoisomerides (XVI and XVII) being produced.

Thus the ambiguity of structure which had previously been noted in the *cyclopentadiene* series would seem to be present also in other unsaturated cyclic systems, and may indeed be of much more frequent occurrence than is generally supposed.

#### EXPERIMENTAL.

The *isophorone* employed was prepared by the condensation of mesityl oxide and ethyl acetoacetate (Knoevenagel and Fischer, *loc. cit.*), but at the temperature of the steam-bath for 4 hours, under which conditions the main portion of the *isophorone*carboxylic ester is converted into *isophorone*. The fraction, b. p.  $95\text{--}100^\circ/14$  mm., consisted of nearly pure *isophorone*. In order to determine whether it was a single individual or a mixture of isomerides (compare Kerp and Muller, *loc. cit.*), its semicarbazone was submitted to a rigorous fractional crystallisation from alcohol. No trace of a second semicarbazone could be detected. The pure semicarbazone, crystallised from alcohol, has m. p.  $199.5^\circ$  (decomp.) (Crossley and

Gilling, *loc. cit.*, give  $191^{\circ}$ ), and does not depress the melting point of a specimen prepared by the latter method (Found: C, 61.5; H, 8.8. Calc., C, 61.5; H, 8.8%). The ketone regenerated from the pure semicarbazone by steam distillation with oxalic acid had b. p.  $99^{\circ}/14$  mm.; the oxime had m. p.  $79.5^{\circ}$  (Crossley and Gilling, *loc. cit.*, give  $78^{\circ}$ ).

A *monopiperonylidene* derivative was obtained and after crystallisation from ethyl acetate had m. p.  $145\text{--}146^{\circ}$  (Found: C, 75.2; H, 7.0.  $C_{17}H_{18}O_3$  requires C, 75.4; H, 6.7%).

*Bromination of isoPhorone. Formation of the Unstable Dibromide (X).*—A standard solution of dry bromine in dry carbon tetrachloride (1 c.c. = 0.1 g. Br) was added dropwise to a solution of 1 g. of dry *isophorone*, in a little carbon tetrachloride cooled in ice, moisture being rigorously excluded. Decoloration was instantaneous, and when 2 c.c. had been added the crystalline dibromide began to separate. When 13 c.c. (1.3 g. Br) had been added, the solution became coloured with free bromine and a trace of hydrogen bromide could be detected. Addition of two atoms of bromine requires 1.2 g. of bromine. After traces of bromine and hydrogen bromide had been removed under diminished pressure, the product was broken into a large excess of water, and the liberated hydrobromic acid titrated with potassium hydroxide (Found: 0.56 g. of hydrogen bromide. Liberation of 1 mol. of hydrogen bromide requires 0.60 g.). In another experiment the solvent was removed by evaporation in a vacuum. The dibromide remained as a mass of short, thick prisms, m. p. about  $40^{\circ}$ , which on exposure to air immediately changed to a colourless oil with the evolution of hydrogen bromide.

*Monobromoisophorone (XII).*—The carbon tetrachloride solution of the unstable dibromide having been poured into water, the precipitated, colourless oil was extracted with pure ether and washed with very dilute alkali. The residue from the dried ethereal extract was left in an evacuated desiccator over potash for 24 hours, and since it could not be distilled without decomposition, was analysed in the crude state (Found: C, 50.4; H, 6.2.  $C_9H_{18}OBr$  requires C, 49.8; H, 6.0%).

1 : 3 : 4 : 5 (?) - *Tetrabromo-3 : 3 : 5-trimethylcyclohexan-1-one* is obtained by exhaustive bromination of *isophorone* in carbon tetrachloride solution. After crystallisation from ethyl acetate-ligroin (b. p.  $60\text{--}80^{\circ}$ ), it has m. p.  $135^{\circ}$  (Found: C, 24.0; H, 2.4; Br, 70.7.  $C_9H_{12}OBr_4$  requires C, 23.7; H, 2.6; Br, 70.2%). The same compound is produced when an excess of bromine is added to *isophorone* in ice-cold glacial acetic acid solution, and crystallises on keeping.

Attempts to prepare the tribromo-compound always resulted in the formation of an uncrystallisable gum.

*Reduction of isoPhorone.*—(1) *With sodium and moist ether.* *Formation of 1:1':3:3:3':3':3'-trimethylbicyclohexyl-5:5'-dione*,  $\alpha$  and  $\beta$  forms (XVI and XVII). *isoPhorone* was dissolved in 20–30 times its volume of ether saturated with water, and sodium wire added in small successive portions. It seems to be essential to allow the first reaction to proceed as vigorously as possible. A flocculent solid separated, the liquid turning first yellow and finally deep red. The product was poured into water, acidified with hydrochloric acid, extracted with ether, and any acid fraction removed with sodium hydrogen carbonate solution. The neutral residue was a brown syrup which partly crystallised. The solid crystallised from ethyl acetate–ligroin had m. p.  $162^{\circ}$  (Found: C, 77.6; H, 10.8; *M*, cryoscopic in benzene, 268.  $C_{18}H_{30}O_2$  requires C, 77.6; H, 10.8%; *M*, 280). It does not decolorise potassium permanganate in sodium hydrogen carbonate solution.

A *disemicarbazone* was obtained which after crystallisation from glacial acetic acid had m. p.  $259\text{--}260^{\circ}$  (decomp.) (Found: C, 61.0; H, 9.4.  $C_{20}H_{36}O_2N_6$  requires C, 61.2; H, 9.3%).

The portion of the reduction product which had failed to solidify was fractionally distilled under reduced pressure. Low fractions consisting mainly of unchanged *isophorone* were first obtained, and then a large, exceedingly viscous fraction distilled at  $220\text{--}240^{\circ}/20$  mm., which immediately solidified when rubbed with low-boiling ligroin. The solid was crystallised from ethyl acetate–ligroin. It consists of the second isomeride, m. p.  $126^{\circ}$  (Found: C, 77.4; H, 10.7%). It does not decolorise potassium permanganate in sodium hydrogen carbonate solution in the cold, and only slowly on boiling. Careful fractional crystallisation of this substance failed to indicate the presence of any other product. A further quantity of this isomeride was obtained by a second fractional distillation of the gum obtained from the ligroin mother-liquors.

A *disemicarbazone* was obtained as before, but was precipitated from the alcoholic reaction mixture only on addition of water. After crystallising several times from about 90% methyl alcohol, it had m. p.  $220^{\circ}$  (decomp.) (Found: C, 61.2; H, 9.4%).

The same products were obtained when *isophorone* was reduced with zinc and acetic acid, or with sodium amalgam and a boiling alkaline solution.

(2) *By the Clemmensen method.* *Formation of the hydrocarbon* (XIII). The ketone (10 g.) was refluxed with about 50 g. of amalgamated zinc and an excess of concentrated hydrochloric acid for 3 hours, small quantities of hydrochloric acid being occasionally

added. The reaction mixture was steam distilled. The first portion of the distillate consisted of a very small quantity of a volatile oil, with a camphoraceous odour, which was not obtained in quantity sufficient for identification. The hydrocarbon then distilled and solidified in the receiver, cooled in ice. The yield was small, a large amount of resinous material, non-volatile in steam, being produced. The hydrocarbon was extracted with ether, and the residue from the dried extract rapidly solidified. It crystallised from dilute alcohol in fine needles, m. p.  $112^{\circ}$  (Found : C, 88.5; H, 11.5;  $M$ , cryoscopic in benzene, 231.  $C_{18}H_{28}$  requires C, 88.5; H, 11.5%;  $M$ , 244). It is stable to potassium permanganate in sodium hydrogen carbonate solution in the cold, but decolorises bromine in carbon tetrachloride solution, probably owing to the destruction of two of the bridge bonds.

*Oxidation of the Hydrocarbon XIII.*—The hydrocarbon (0.42 g.), suspended in a solution of potassium permanganate and sodium hydrogen carbonate, was heated under reflux, successive quantities of permanganate being added until the reaction mixture remained pink (48 hours). The product was steam-distilled to remove traces of the hydrocarbon, and the alkaline liquor was worked up in the usual manner, acidified at  $0^{\circ}$  with dilute sulphuric acid, and the product extracted with pure ether. The residue from the dried, ethereal extract immediately solidified. Crystallised from pure ether, it had m. p.  $212-213^{\circ}$ , either alone or mixed with a genuine specimen of *trans*-caronic acid (Found, by micro-combustion : C, 52.6; H, 6.7. Calc., C, 53.1; H, 6.4%). The oxidation was repeated, with the same result, on a fresh quantity of the hydrocarbon obtained by the reduction of a different specimen of isophorone.

The author desires to express his thanks to the Research Fund Committee of the Chemical Society for a grant with which the expenses of this research were met, and to Professor C. K. Ingold, F.R.S., for his continued interest and valuable suggestions during the progress of the investigation.

THE UNIVERSITY, LEEDS.

[Received, December 22nd, 1925.]

XCIH.—*The Molecular Configurations of Polynuclear Aromatic Compounds. Part VI.  $\beta$ -Dinitrodiphenic Acid; its Constitution and Resolution into Optically Active Components.*

By GEORGE HALLATT CHRISTIE, ALBERT HOLDERNESS, and JAMES KENNER.

$\beta$ -DINITRODIPHENIC acid, originally obtained by Schultz (*Annalen*, 1880, 203, 108), is prepared by oxidation of the dinitroquinone produced, with its 2:7-isomeride, when phenanthraquinone is dinitrated. This acid has been regarded as a 6:6'-dinitrodiphenic acid (I) since it was examined by Schmidt and Kämpf (*Ber.*, 1903, 36, 3745), who claimed to have converted it by distillation with dry sand into 2:2'-dinitrodiphenyl (II). "Wir erhielten dabei sehr wenig eines schwer löslichen Körpers vom Schmelzpunkt ca. 240° (wahrscheinlich Dinitrofluorenon) und als Hauptproduct ca. 1 g. einer leichter löslichen Verbindung vom Schmelzpunkt 124–6° Dieselbe wurde genau verglichen mit o-o'-Dinitrodiphenyl, das wir uns nach den Angaben von Ullmann (*Ber.*, 1901, 34, 3803) bereitet hatten. Beide Präparate zeigten in allen Eigenschaften völlige Uebereinstimmung."

The conversion of the corresponding diaminodiphenic acid into carbazole (III) recorded at the same time supplied confirmatory, though obviously less conclusive, evidence in support of the very precise statement quoted, so that Kenner and Stubbings (*J.*, 1921, 119, 593) felt justified in regarding their synthetic 6:6'-dinitrodiphenic acid as a stereoisomeride of Schultz's acid when it was found that the two differed in properties.

The observations recorded by Christie and Kenner (this vol., p. 470) rendered it necessary, however, to re-examine Schultz's acid. The outcome of our experiments, carried out under somewhat different conditions from those used by Schmidt and Kämpf, was that in place of 2:2'-dinitrodiphenyl, m. p. 124°, 2:4'-dinitrodiphenyl (IV), m. p. 93°, was obtained, so that Schultz's acid would be 4:6'-dinitrodiphenic acid (V):

This result in itself is no more definite than that claimed by Schmidt and Kämpf, and perhaps somewhat less so if regard be paid to the considerably lower melting point of our product. Further, we were unable to detect any other product than 2:7-dinitrophenanthraquinone when 2-nitrophenanthraquinone was nitrated under the conditions for converting phenanthraquinone into 2:7- and what the above result would indicate to be 2:5-dinitrophenanthraquinones. The following considerations will, however, probably be held to be decisively in favour of our view rather than that of Schmidt and Kämpf:

(1) The same 2:4:7-trinitrophenanthraquinone is formed from the dinitroquinone in question and 2:7-dinitrophenanthraquinone, and attempts to prepare 2:4:5:7-tetranitrophenanthraquinone by further nitration have been unsuccessful (Christie and Kenner, *loc. cit.*).

(2) It would be expected that if 4:5- and 2:7-dinitroquinones are produced from phenanthraquinone by nitration, some of the 2:5-isomeride also would be formed. But only two products have been observed.

(3) Dinitration of diphenyl furnishes the 2:4'- and 4:4'-derivatives as chief, if not sole products (Fittig, *Annalen*, 1862, 124, 276):

(4) The amino-group in 6-aminodiphenic acid is not diazotisable, but one of those in the diamino-acid, for which the 4:6'-constitution is now advocated, is diazotisable (Schmidt and Schall, *Ber.*, 1905, 38, 3769). In previous papers, it was shown that such 6-aminoacids readily form phenanthridone derivatives. The accounts in the literature of the acids referred to make it not impossible that they may in reality be phenanthridone derivatives, as has been shown to be the case with other compounds similarly derived (compare Christie and Kenner, *loc. cit.*).

Kenner and Stubbings (*loc. cit.*) converted their synthetic 6:6'-dinitrodiphenic acid into a "hydrazide," and suggested that this derivative might furnish a means of converting the new acid into its supposed stereoisomeride:

This idea gained further credence when a "hydrazide" was prepared from the  $\beta$ -acid, and behaved similarly when heated. However, the "hydrazides" from the two sources differed in their behaviour towards acetic anhydride and were readily converted by oxidative hydrolysis with fuming nitric acid according to a procedure very briefly indicated by Curtius and Foersterling (*J. pr. Chem.*, 1895, 51, 371), into acids melting, respectively, at  $300^\circ$  and  $249-253^\circ$ , as compared with  $300^\circ$  and  $258-259^\circ$  recorded for the original acids. Clearly, then, no interconversion of the acids is to be achieved through the hydrolysis of the "hydrazides" as intermediates.

$\beta$ -Dinitrodiphenic acid, if it is the 4:6'-derivative, is closely related in constitution to 4:6:4'-trinitrodiphenic acid (VI), of which the resolution into optically active components through the agency of brucine has been described (Christie and Kenner, *J.*, 1923, 123, 779).

Similar experiments with the  $\beta$ -acid showed that it furnished a uniform brucine salt, but on the other hand two distinct quinine salts were obtained which were easily separable owing to their different solubilities in alcohol. From these salts, solutions of optically active acids and their sodium salts were prepared in the usual manner. A second illustration is therefore provided of an acid capable of existence in an asymmetric form when only three of the four 2, 6, 2', and 6'-positions are occupied by substituents.

Since the stereoisomerism of  $\beta$ - and 6:6'-dinitrodiphenic acids, which originally inspired the experiments on their resolution, would now seem to be non-existent, it is perhaps desirable to record the fact that the resolution of the  $\beta$ -acid has been repeated with freshly prepared materials by Mr. V. M. Trikojus, B.Sc., in the laboratories of the University of Sydney.

#### EXPERIMENTAL.

$\beta$ -Dinitrodiphenic acid, prepared by Schmidt and Kämpf's method (*loc. cit.*), was further characterised by the preparation of its *chloride*, colourless, rectangular plates, m. p.  $120^\circ$ , from benzene-light petroleum (Found: N, 7.9.  $C_{14}H_6O_6N_2Cl_2$  requires N, 7.6%); its *ethyl ester*, colourless, pentagonal prisms, m. p.  $114-115^\circ$  (Found:

N, 7.3.  $C_{18}H_{16}O_8N_2$  requires N, 7.2%); and its *amide*, colourless, hexagonal prisms, m. p. 247.5°, from dilute alcohol (Found: N, 17.2.  $C_{14}H_{10}O_6N_4$  requires N, 16.9%).

*Degradation of  $\beta$ -Dinitrodiphenic Acid to Dinitrodiphenyl.*—A mixture of  $\beta$ -dinitrodiphenic acid with fine dry sand was distilled under the conditions described by Schmidt and Kämpf (*loc. cit.*); the yellow solid distillate, in agreement with their observation, melted at 240—245° after being extracted with alcohol, but the extract, which would have contained any dinitrodiphenyl which had been distilled, left practically no residue on distillation. The following modified procedure was therefore employed. A finely ground mixture of the acid (1 g.) with Naturkupfer C (0.1 g.) (compare Sabatier and Mailhe, *Compt. rend.*, 1914, 159, 217) was distributed by stirring over sufficient glass wool to fill an Anschütz flask of 75 c.c. capacity. This flask was connected through a larger one to a filter-pump. When the mixture was very gradually heated in an oil-bath under a pressure of 30 mm., a reaction of explosive violence occurred at 285°. After the dense white vapours had subsided, both the distillate and the blackened residue were extracted with boiling alcohol. The extract was evaporated, diluted with water, and treated with cold dilute ammonia; a small solid residue was obtained. By solution in benzene of the product (0.45 g.) from eight such experiments, dark, insoluble matter was removed, and fairly homogeneous, transparent crystals closely resembling those of 2:4'-dinitrodiphenyl were obtained. After further purification by solution in light petroleum-benzene to remove a small quantity of less soluble, granular material, the product melted at 93°. A mixture with authentic 2:4'-dinitrodiphenyl melted at the same temperature, even after fusion and resolidification. A mixture with 2:2'-dinitrodiphenyl, m. p. 124°, shrank at 68—70°, was largely molten at 90°, but not completely so until 118°. After resolidification, the opaque mass commenced to clear at 90°, was almost all molten at 100—103°, and entirely liquid at 105°. The product was therefore 2:4'-dinitrodiphenyl.

For the preparation of the compound from diphenyl, light petroleum (b. p. 70—80°) was much more effective in the late stage of purification than the methyl alcohol recommended by Fittig (*Annalen*, 1862, 124, 276).

*Nitration of 2-Nitrophenanthraquinone.*—After 2-nitrophenanthraquinone (10 g.) had been boiled under reflux with nitric acid (135 c.c.; *d* 1.5) and sulphuric acid (17 c.c.) for 30 minutes, the mixture was poured into water. From the solution of the precipitate in glacial acetic acid (1200 c.c.), 2:7-dinitrophenanthraquinone (8.9 g.), m. p. 301°, was deposited, whilst 0.4 g., m. p. 280—290°,

and 0.1 g., m. p. 225–293°, were recovered on concentrating the liquors to 200 c.c. and 50 c.c., respectively.

*Hydrolysis of the "Hydrazides" of  $\beta$ - and 6:6'-Dinitrodiphenic Acids.*—The "hydrazide" of  $\beta$ -dinitrodiphenic acid was prepared from the chloride in the manner already described for the corresponding derivative of 6:6'-dinitrodiphenic acid (Kenner and Stubbings, *loc. cit.*). It separates from acetone–light petroleum in small, colourless prisms, m. p. 294–295° (decomp.) (Found: N, 16.7.  $C_{14}H_8O_6N_4$  requires N, 17.0%), and does not reduce Fehling's solution. Repeated but unsuccessful attempts were made to prepare a well-defined acetyl derivative of the "hydrazide" corresponding to that previously described as having been obtained from the "hydrazide" of 6:6'-dinitrodiphenic acid. The compound (0.25 g.) was heated with nitric acid (4 c.c.; *d* 1.5) for 75 minutes at 100°; the solution then deposited dinitrodiphenic acid, m. p. 300–301°, on dilution with water (15 c.c.).

The "hydrazide" of 6:6'-dinitrodiphenic acid was obtained in colourless prisms, m. p. 310° (decomp.), by crystallisation from acetone–light petroleum. The acid formed by hydrolysis with fuming nitric acid at 100° for 40 minutes was isolated by evaporation of the liquors at the ordinary temperature in an exhausted desiccator over sodium hydroxide. Its melting point, 249–253°, was not depressed when the acid was mixed with 6:6'-dinitrodiphenic acid.

*Resolution of  $\beta$ -Dinitrodiphenic Acid into Optically Active Components.*—A solution of the acid (2 g.) and hydrated brucine (5.61 g.) in boiling water (1050 c.c.) deposited, on cooling, fern-shaped sprays of irregular plates (3.9 g.), m. p. 209° (decomp.). By successive concentration to 575 c.c., 200 c.c., and 50 c.c., further crops of 2.2 g., m. p. 206° (decomp.), 0.3 g., m. p. 209° (decomp.), and 0.4 g., m. p. 207° (decomp.), were respectively obtained. The salt was hydrated [Found:  $H_2O$ , 4.2.  $C_{60}H_{60}O_{16}N_6 \cdot 2\frac{1}{2}H_2O$  requires  $H_2O$ , 3.9%. Found, for the salt dried at 130°: N, 7.8.  $C_{12}H_6(NO_2)_2(CO_2H)_2 \cdot 2C_{23}H_{26}O_4N_2$  requires N, 7.5%]. For 1.5% solutions in 10*N*-acetic acid of the anhydrous salt from each of the first two fractions,  $[\alpha]_D = -13.29^\circ$  and  $-13.31^\circ$ , respectively. It was therefore not surprising that a solution of the sodium salt of the acid prepared from the brucine salt was inactive.

But when boiling solutions of the acid (4 g.) in alcohol (100 c.c.) and of quinine hydrate (9.2 g.) in alcohol (80 c.c.) were mixed, colourless, rectangular plates (5.7 g.), m. p. 178–179° (decomp.), separated on cooling; no further crystallisation occurred on concentration. On evaporating the alcohol, an oil remained, which was obtained in a solid condition by precipitation with light

petroleum from its solution in benzene. The melting point of the plates was unchanged after recrystallisation (Found:  $\text{C}_2\text{H}_6\text{O}$ , 2.45.  $\text{C}_{54}\text{H}_{56}\text{O}_{12}\text{N}_6 \cdot \frac{1}{2}\text{C}_2\text{H}_6\text{O}$  requires  $\text{C}_2\text{H}_6\text{O}$ , 2.4. Found, for the salt dried at  $130^\circ$ : N, 8.6.  $\text{C}_{54}\text{H}_{56}\text{O}_{12}\text{N}_6$  requires N, 8.6%). For a 1.43% solution of the dried salt in chloroform,  $[\alpha]_D^{25} = -218.1^\circ$ .

The more soluble salt melted at first at about  $93^\circ$ , but at  $162$ – $163^\circ$  after being heated to constant weight at  $120^\circ$  (Found: N, 8.55.  $\text{C}_{54}\text{H}_{56}\text{O}_{12}\text{N}_6$  requires N, 8.6%). For a 1.44% solution of the dried salt in chloroform,  $[\alpha]_D^{25} = -62.10^\circ$ .

d- $\beta$ -Dinitrodiphenic acid, obtained from the less soluble quinine salt by treatment with hydrochloric acid, melted at  $296^\circ$ , whilst a mixture of the acid with the racemic acid melted over the range  $285$ – $293^\circ$ .

For a 0.96% solution of the acid in ether,  $[\alpha]_D^{25} = +26.90^\circ$ , whilst for a 0.66% solution of the sodium salt in water,  $[\alpha]_D^{25} = -186.4^\circ$ .

l- $\beta$ -Dinitrodiphenic acid, obtained from the more soluble quinine salt, also melted at  $296^\circ$ . For a 0.92% solution of the acid in ether,  $[\alpha]_D^{25} = -26.46^\circ$ , and for a 1.29% solution of the sodium salt in water,  $[\alpha]_D^{25} = +179.4^\circ$ .

Two of the authors (G. H. C. and A. H.) take this opportunity of expressing their gratitude to the Department of Scientific and Industrial Research for grants which enabled them to take part in this work. The authors are indebted to the Research Fund Committee of the Chemical Society for a grant towards the purchase of materials.

#### XCIV.—Styrylpyrylium Salts. Part VI. Styryl Derivatives of 9-Methylxanthylum Chloride and 3:6-Dihydroxy-9-methylxanthylum Chloride.

By HAROLD ATKINSON and ISIDOR MORRIS HEILBRON.

THE only styrylxanthylum salt recorded in the literature is 9-styrylxanthylum chloride (I), which Ziegler and Ochs (*Ber.*, 1922, 55, 2257) obtained by the action of  $\beta$ -bromostyrene and

magnesium upon xanthone. A more detailed study of styryl-xanthylum salts has now been made in order to compare them with the members of the styrylbenzopyrylium series. As the method employed by Ziegler and Ochs could not readily be adopted for the preparation of salts containing substituents in either the styryl or the xanthylum residue, other methods of preparation had to be sought. The ease with which the anhydro-base, 6-hydroxy-9-methylfluorone (II), reacts with nitrous acid to form the *iso*-nitroso-derivative (Kehrmann, *Annalen*, 1910, **372**, 287) rendered it probable that a methyl group in position 9 in a xanthylum nucleus would show the same reactivity as an  $\alpha$ - or  $\gamma$ -methyl group does in the benzopyrylium series. In order to test this point, an attempt was made to prepare 9-methylxanthylum chloride which had previously been prepared by Decker (*Ber.*, 1905, **38**, 2493) in the form of its double ferrichloride salt by the action of magnesium methyl iodide upon xanthone. The free chloride can actually be isolated, but it is difficult to obtain in good yield. On the other hand, an ethereal solution of the easily accessible 9-methylxanthenol (III) may be utilised in place of the chloride itself. Thus, on saturation of the solution mixed with benzaldehyde with dry hydrogen chloride, 9-styrylxanthylum chloride, identical in all respects with the compound prepared by Ziegler and Ochs (*loc. cit.*), was readily obtained. Similar condensations have been

effected with *p*-hydroxybenzaldehyde, *p*-methoxybenzaldehyde, piperonal, and vanillin, and in all cases excellent yields obtained.

The styrylxanthylum salts containing substituents in the styryl residue are highly coloured, crystalline compounds, readily soluble in formic acid, giving deep red to purple solutions. In their reaction towards water and alkali, they behave similarly to the unsubstituted 2-styrylbenzopyryliums (Buck and Heilbron, *J.*, 1922, **121**, 1198). Thus, when 4'-hydroxy-9-styrylxanthylum chloride (IV) was dissolved in dilute formic acid, a reddish-violet solution resulted which on dilution with a large excess of water slowly changed to blue. This colour effect we attribute, as in former cases, to formation of the quinonoid anhydro-base (V), for with 4'-methoxy-9-styrylxanthylum chloride, where such isomerisation is precluded, the solution rapidly becomes opalescent and decolorised, followed by deposition of the colourless carbinol base (VI).

3' : 4'-Methylenedioxy-9-styrylxanthylum chloride, which dissolves in formic acid with a blue colour, reacts similarly. The same effect

is noted on treatment of the formic acid solutions with dilute sodium hydroxide. On the other hand, with the 4'-hydroxy-derivatives the quinonoid anhydro-bases are first precipitated and then slowly isomerise to the colourless carbinol bases (compare Dilthey and Taucher, *Ber.*, 1920, **53**, 252). In all cases, the effect of heat on the colourless carbinol solutions produces a reversion in colour, a fact indicating that at higher temperatures the oxonium bases are more stable than the isomeric carbinol compounds. This phenomenon has also been observed by Bunzly and Decker (*Ber.*, 1904, **37**, 2931) in the case of 9-phenylxanthanol.

The behaviour of these styrylxanthylum chlorides towards alcohol is peculiar. Ziegler and Ochs (*loc. cit.*) noted that on trituration of 9-styrylxanthylum chloride with alcohol, 9-styrylxanthyl ethyl ether (VII) was formed, while, on the other hand, boiling with this solvent produced 9-styrylxanthen (VIII). A

preliminary study of the styrylxanthylum chlorides containing substituents in the styryl residue has shown that when these are kept in contact with small quantities of alcohol, they are gradually converted into colourless substances, all of which crystallise from acetone in well-defined crystals with sharp melting point. The compounds thus prepared have been analysed, but in each case the carbon content is too high for formulation either as an ethyl ether, xanthen or allene derivative. The formation of the last type of compound from other styryl derivatives was noted by Meyer and Schuster (*Ber.*, 1922, **55**, 815), and Ziegler and Ochs, by boiling 9-styrylxanthenol with glacial acetic acid, obtained a compound the composition of which would agree with that of an allene derivative. A full investigation of these interesting compounds is at present being undertaken.

Walker and Heilbron (*J.*, 1925, **127**, 685) have shown that in the  $\gamma$ -styrylbenzopyryliums the presence of a free hydroxyl group in the meta-position to pyrylium oxygen inhibits the change to quinonoid anhydro-base on water dilution. In order to ascertain

whether a similar effect holds in this series, styrylxanthylum salts prepared from 3:6-dihydroxy-9-methylxanthylum chloride have been examined. The latter compound, which has been described by Kehrmann (*loc. cit.*), can be isolated directly in good yield by continuously passing dry hydrogen chloride into a molten mixture of resacetophenone and resorcinol until the mass solidifies.

**3:6-Dihydroxy-9-styrylxanthylum Salts.**—The general method employed was to saturate with dry hydrogen chloride a suspension of 3:6-dihydroxy-9-methylxanthylum chloride in alcohol containing a slight excess of the required aldehyde. Condensation usually started in the cold and was completed by boiling under reflux; the suspended chloride then gradually disappeared and the condensation product separated either from the boiling solution or on cooling. These salts differ from those having the unsubstituted xanthylum nucleus in being soluble in alcohol without change, whilst the colour of the solutions both in this solvent and in formic acid is considerably lighter. A notable point is that whereas 3:6-dihydroxy-9-methylxanthylum chloride is characterised by its strong fluorescence in alkaline solution, substitution of the styryl radical for the methyl group caused the complete disappearance of this property. The colour changes observed on dilution with water or treatment with alkali differ essentially from those of the unsubstituted styrylxanthylum members. A neutral alcoholic solution of 3:4':6-trihydroxy-9-styrylxanthylum chloride remains unaltered on dilution, and in presence of alkali the orange-red colour only changes to bright red, due doubtless to salt formation. 3:6-Dihydroxy-4'-methoxy-9-styrylxanthylum chloride reacts similarly, for neither on dilution nor in presence of alkali does isomerisation to the carbinol base occur. The non-formation of this can only be attributed to the presence of the hydroxyl groups, which stabilise the molecule, presumably by formation of the betaine (IX). The same phenomenon must consequently hold for the 4'-hydroxy-analogue, but apart from this no structural change from benzenoid to quinonoid can be assumed.

#### EXPERIMENTAL.

**9-Methylxanthylum chloride** was prepared by a modification of Decker's method (*loc. cit.*). Xanthen (30 g.) was dissolved in

boiling benzene (250 c.c.), and the Grignard reagent (12 g. of magnesium and 66 g. of methyl iodide) gradually added. The solution immediately became orange and a yellow solid separated. This was rapidly reabsorbed, however, and later a colourless, crystalline compound separated from the greyish-green liquid. The whole was boiled under reflux for 1 hour, after which the ether and about half the benzene were removed. The solid was filtered off from the cold solution, washed with dry ether, and decomposed with cold water. The yellow solution so formed was repeatedly extracted with ether until the aqueous layer gave only a pale yellow colour on the addition of concentrated hydrochloric acid. After drying over sodium sulphate, this ethereal solution was employed directly for the preparation of the styryl salts. In order to obtain 9-methylxanthylum chloride, the solution was saturated with dry hydrogen chloride; the colour then changed from pale yellow to green and on standing in the ice-chest, dark red crystals separated. After recrystallisation from a mixture of anhydrous formic acid and ether containing hydrogen chloride, the salt was obtained in golden needles, m. p. 175°, and identified by means of the double ferrichloride, m. p. 204°, and mercurichloride (compare Decker, *loc. cit.*). The melting point of the ferrichloride is given in the literature as 240°, but this is possibly a typographical error.

*9-Styrylxanthylum Chlorides.*—The general method of preparation of these salts consisted in the addition of the aldehyde in slight excess to the dry ethereal solution of 9-methylxanthanol, the mixture being then saturated with dry hydrogen chloride, when condensation readily took place. The actual amount of xanthanol in solution was not ascertained, but the Grignard reaction, by means of which it was prepared, was assumed to have given a quantitative yield.

*9-Styrylxanthylum chloride* rapidly separated from the condensation mixture of 9-methylxanthanol and benzaldehyde either as golden, glistening plates or as red needles with a bright green sheen. The plates melted at 95°, the same melting point as that given by Ziegler and Ochs (*loc. cit.*), but the red needles melted over a range of temperature (66–92°) and probably contained some easily lost addenda. This salt was proved to be identical with that prepared by Ziegler and Ochs by means of the deep red double salt with zinc chloride (m. p. 188°) and its ethyl ether (m. p. 168–169°).

*4'-Hydroxy-9-styrylxanthylum chloride.* On passing dry hydrogen chloride into the well-dried ethereal solution of 9-methylxanthanol and excess of *p*-hydroxybenzaldehyde, the solution gradually passed

through orange to dark red and a violet oil with bronze reflex separated. The mixture having been left in the ice-chest for several hours, the ether was poured off; the oil gradually solidified to a green, amorphous mass. This was taken up in a small amount of warm anhydrous formic acid previously saturated with hydrogen chloride, and dry ether was added to the cold filtered solution in small quantities at a time; the styryl salt then separated in long, bright-green, lustrous needles containing 1 mol.  $\text{HCO}_2\text{H}$ . These were immediately transferred to a large test-tube, which was then evacuated, whereby adherent hydrogen chloride was removed and the crystals were rendered stable. If this was not done, the compound tended to become resinous, a tendency exhibited by all members of this series. The salt was readily soluble in cold formic acid and in hot glacial acetic acid, giving dark violet solutions. It was sparingly soluble in cold chloroform to a blue solution which changed to reddish-brown on warming but reverted to blue on cooling. The same colour change on heating was shown by a solution in nitrobenzene. When a large volume of water was added to a very dilute formic acid solution (wine-red colour), no immediate change of colour occurred, but on standing (6 hours) the solution became pure blue. The addition of water to a more concentrated formic acid solution caused the immediate separation of a violet, amorphous precipitate, presumably the anhydro-base (V) (Found: C, 69.4; H, 4.5; Cl, 9.4.  $\text{C}_{22}\text{H}_{17}\text{O}_4\text{Cl}\cdot\text{HCO}_2\text{H}$  requires C, 69.4; H, 4.5; Cl, 9.3%). In contact with absolute alcohol, the salt was partly converted into a colourless, crystalline substance, but this change was not absolutely complete despite repeated trituration, even after 15 days. The substance crystallises from acetone in long, colourless needles, m. p.  $228^\circ$  (Found: C, 85.0; H, 5.8%).

*4'-Methoxy-9-styrylxanthylum chloride* separated from the condensation liquor in dark green crystals. Considerable difficulty was experienced in obtaining it in a stable crystalline state sufficiently pure for analysis, but this was ultimately accomplished by crystallisation from chloroform containing hydrogen chloride; it then separated in bright green needles, m. p.  $98^\circ$ , which were rendered stable by removal of all addenda in a vacuum. The salt dissolved readily in formic and glacial acetic acids, giving dark violet solutions. When a dilute solution in formic acid was treated with water, a strong opalescence immediately developed, the wine-red colour rapidly faded, and the colourless carbinol base was deposited. As with the 4'-hydroxystyryl salt, long trituration with alcohol gave a colourless compound, m. p.  $194^\circ$ , of undetermined constitution. The *ferrichloride*, prepared by the action of powdered hydrated ferric

chloride on a solution of 4'-methoxy-9-styrylxanthylum chloride in formic acid, separated from glacial acetic acid in long, copper-coloured plates which softened and turned blue at 175° and decomposed with inflation at 212° (Found : C, 51.5; H, 3.2; Cl, 27.7; Fe, 10.5.  $C_{22}H_{17}O_2Cl_4Fe$  requires C, 51.7; H, 3.3; Cl, 27.8; Fe, 10.9%).

4'-Hydroxy-3'-methoxy-9-styrylxanthylum chloride crystallised from formic acid in golden-brown needles which contained a molecule of formic acid (m. p. 135°). The salt was readily soluble in cold formic acid and in hot glacial acetic acid, giving royal-blue solutions. Neutralisation of a dilute formic acid solution with sodium carbonate precipitated the colour base, which was gradually converted into the colourless carbinol base (Found : C, 67.1; H, 4.6; Cl, 8.9.  $C_{22}H_{17}O_3Cl.HCO_2H$  requires C, 67.2; H, 4.6; Cl, 8.7%).

3' : 4'-Methylenedioxy-9-styrylxanthylum chloride could not be obtained pure, for although it separated from the condensation mixture in green crystals, attempts to recrystallise these from either formic acid or glacial acetic acid with or without the addition of hydrogen chloride resulted in the formation of a yellow oil, which gradually solidified to a colourless compound. Recourse was made, therefore, to analysis of the zinc chloride double salt, which was readily prepared by suspending the crude xanthylum chloride in cold formic acid and shaking vigorously with zinc chloride in hydrochloric acid. The salt separated from glacial acetic acid in glistening, green needles (Found : C, 49.6; H, 3.1; Cl, 20.3.  $C_{22}H_{15}O_3Cl_3Zn.H_2O$  requires C, 51.2; H, 3.3; Cl, 20.6%).

3 : 6-Dihydroxy-9-methylxanthylum Chloride.—Dry hydrogen chloride was passed into a molten mixture of resacetophenone (10 g.) and resorcinol (7.2 g.) (oil-bath at 140—150°). The melt gradually turned red and, after several hours, became semi-solid. The stream of hydrogen chloride was continued until the mass became too viscous, the temperature being gradually raised to 170°. The solid mass was dissolved in boiling anhydrous formic acid (80 c.c.); the xanthylum chloride then separated in reddish-yellow needles with a characteristic blue metallic reflex. On several occasions, however, the salt was deposited as a chocolate powder, which was again recrystallised from formic acid containing hydrogen chloride. It is soluble in alcohol, acetone, or formic acid and insoluble in ether or benzene. It dissolves in sodium hydroxide solution to a reddish-brown solution which when dilute shows an intense green fluorescence. With sodium acetate it yields the base in the form of brick-red flocks.

3 : 4' : 6-Trihydroxy-9-styrylxanthylum Chloride.—The parent

chloride (5 g.) was suspended in 70 c.c. of alcohol together with *p*-hydroxybenzaldehyde (2.6 g.), and dry hydrogen chloride was passed into the cold solution; the xanthylum chloride then gradually dissolved. After  $\frac{1}{2}$  hour the styrylxanthylum chloride (4.3 g.) separated from the deep red solution as a red, amorphous solid. On recrystallisation from anhydrous formic acid containing hydrogen chloride, it formed long needles which appeared red by transmitted and green by reflected light. On heating the chloride changed to red and melted with inflation at 273–274°. It is readily soluble in hot formic acid, sparingly soluble in alcohol or acetone to orange-red solutions, whilst in dilute sodium hydroxide it dissolves, giving a permanent bright claret-red solution (Found: C, 65.1; H, 4.2; Cl, 9.0.  $C_{21}H_{15}O_4Cl \cdot H_2O$  requires C, 65.5; H, 4.4; Cl, 9.2%).

3 : 6-Dihydroxy-4'-methoxy-9-styrylxanthylum chloride separated as a dark red, amorphous solid (70% yield) on passing hydrogen chloride into a boiling alcoholic suspension of equimolecular quantities of the parent chloride and anisaldehyde. It was purified by boiling with alcohol, which removed any uncondensed products, and was then crystallised from formic acid containing hydrogen chloride. It forms golden-coloured plates with a metallic sheen which on heating change to green and melt at 282° (decomp.). It is very sparingly soluble in boiling alcohol or acetone, but readily soluble in hot formic acid. It dissolves in warm dilute sodium carbonate to a bright red solution, from which the base separates on cooling (Found: C, 65.9; H, 4.6; Cl, 8.7.  $C_{22}H_{17}O_4Cl \cdot H_2O$  requires C, 66.2; H, 4.8; Cl, 8.9%).

3 : 4' : 6-Trihydroxy-5'-methoxy-9-styrylxanthylum chloride crystallises from formic acid in reddish-violet needles which appear green by reflected light (m. p. 244–245°). It is readily soluble in alcohol, acetone, or hot formic acid and dissolves in dilute sodium hydroxide solution with a deep reddish-violet colour. It is extremely hygroscopic and specimens were dried at 100° immediately prior to analysis (Found: C, 66.6; H, 4.4; Cl, 8.8.  $C_{22}H_{17}O_5Cl$  requires C, 66.6; H, 4.3; Cl, 8.9%).

3 : 6-Dihydroxy-4' : 5'-methylenedioxy-9-styrylxanthylum chloride separates from formic acid containing hydrogen chloride in bronze-coloured needles which, on heating, turn green and decompose at 316°. It is very sparingly soluble in alcohol, but dissolves readily in boiling formic acid to a red solution (Found, in material heated at 80° for several hours: C, 66.8; H, 3.9; Cl, 9.3.  $C_{22}H_{15}O_5Cl$  requires C, 66.9; H, 3.8; Cl, 9.0%).

3 : 6-Dihydroxy-4'-dimethylamino-9-styrylxanthylum Chloride.—A suspension of the parent chloride (5 g.) and *p*-dimethylamino-

benzaldehyde (3.2 g.) in 100 c.c. of alcohol was boiled for 10 minutes under reflux without addition of hydrogen chloride, the condensation product separating as a hard, green solid. On recrystallisation from a large volume of alcohol, it formed microscopic, green needles which on heating changed to red. It is sparingly soluble in alcohol or acetone, giving intense green solutions which change to claret-red on dilution with water. Addition of hydrochloric acid to the alcoholic solution produces a yellow solution of the xanthylum chloride hydrochloride. The salt dissolves in aqueous sodium hydroxide to a bright scarlet solution, which is not altered on further dilution (Found: C, 66.6; H, 5.2; Cl, 8.8.  $C_{23}H_{20}O_3NCl \cdot H_2O$  requires C, 67.1; H, 5.3; Cl, 8.6%).

We wish to record our thanks to the Council of the Department of Scientific and Industrial Research for a grant to one of us (H. A.) which enabled this work to be carried out.

THE UNIVERSITY, LIVERPOOL.

[Received, December 28th, 1925.]

### XCV.—*Arylsulphuric Acids.*

By GEORGE NORMAN BURKHARDT and ARTHUR LAPWORTH.

THE use of dialkylanilines in place of pyridine for the preparation of arylsulphuric acids by Verley's method [*Bull. Soc. chim.*, 1901, 25, 46; compare Durand and Huguenin, Brit. Pat. 186057 (1922), 202630 and 202632 (1923)] has been found to lead to rather better yields and recovery of tertiary base is simplified.

Diethylaniline (100 g.;  $2\frac{1}{2}$  mols.) or the equivalent quantity of dimethylaniline in carbon disulphide (100 c.c.) was stirred mechanically and cooled to  $-10^\circ$ . Chlorosulphonic acid (34 g.; 1.1 mols.) was run in steadily during 15 minutes, the temperature being maintained below  $10^\circ$ . Phenol (25 g.; 1 mol.) in carbon disulphide (50 c.c.) was then added all at once, the mixture stirred for an hour, and the disulphide thereafter removed by distillation on a steam-bath. The cold, viscous residue was run into a solution of sodium hydroxide (22 g.) in water (150 c.c.) containing 10 g. of hydrated barium hydroxide,\* with vigorous shaking, the temperature being kept below  $35^\circ$ . A large proportion of the diethylaniline could

\* For certain purposes, the use of excess of ammonia instead of the hydroxide of an alkali metal is advantageous; but in this case, before removing the tertiary base in a current of steam, it is necessary to add sufficient barium hydroxide to convert all salts present into barium salts, as ammonium phenyl sulphate may suffer hydrolysis in the steam distillation process.

then be separated directly and the remainder removed by steam distillation or by extraction with benzene; the aqueous residue on direct evaporation yielded 90% of the theoretical quantity of sodium phenyl sulphate together with 7% of sodium chloride.

If the base and phenol were mixed before the chlorosulphonic acid was added, the yields never exceeded 60% of the theoretical.

*Use of Sulphuric Anhydride in place of Chlorosulphonic Acid.*—The authors carried out a number of experiments on the use of sulphuric anhydride in place of the chlorosulphonic acid employed by Verley (*loc. cit.*), as the formation of hydrogen chloride in the preparation is often disadvantageous. The experiments were completed before the patents of Durand and Huguenin (Brit. Pat. 202632 of 1923) came to their notice, but some of the observations made were not redundant and appear worthy of record.

As it was evident that the use of sulphuric anhydride as sulphating agent for phenols would render it easy to isolate pure products, trials of a number of organic media as solvents were made. The liquids were cooled and the anhydride was distilled slowly into them. Chloroform and carbon tetrachloride were decomposed rapidly, yielding carbonyl chloride even with most careful cooling, and carbon disulphide evolved carbonyl sulphide. Diethylaniline could not be made to dissolve the anhydride without charring and sulphonation; hexane did not appear to dissolve the anhydride as such, but was rapidly attacked when in contact with it: the nature of the reaction in the latter instance is under investigation. Experiments in which sulphuric anhydride was distilled into a cooled solution containing both phenol and diethylaniline in carbon tetrachloride gave more promising results, but even in presence of the tertiary base about 13% of the anhydride was destroyed by reaction with the tetrachloride, and the mixed salts obtained at the end of the operation contained 8% of inorganic chloride.

The only solvent found to dissolve sulphuric anhydride readily and without decomposition was liquid sulphur dioxide, and the following is an account of one of the experiments in which it was tried as solvent for sulphating phenols.

A solution of sulphuric anhydride (19 g.) in 80 c.c. of liquid sulphur dioxide was slowly added with vigorous stirring to phenol (20 g.) and diethylaniline (60 g.) in a wide-mouthed flask, cooled in a freezing mixture. After remaining over-night to allow most of the solvent to evaporate, it was found that much of the latter was obstinately retained and had to be removed by heating for an hour on a steam-bath. The product, after cooling, was neutralised with aqueous sodium hydroxide and sufficient barium hydroxide to precipitate inorganic sulphate. Nearly pure sodium phenyl

sulphate in 60% yield was isolated on removal of diethylaniline and evaporation of the aqueous residue.

*Use of Pyridine Sulphuro-anhydride in the Preparation of Salts of Phenylsulphuric Acids.* [With FRANK ASHWORTH].—This method is virtually a modification of the process last described, inasmuch as sulphuric anhydride with a tertiary base, in this instance pyridine, is used. The following is an example of its application to a nitrophenol.

Sulphur trioxide (25 g.) is slowly distilled, with stirring and drastic cooling, into pyridine (29 g.; 1.75 mols.). Benzene (200 c.c.) is now added, and the whole heated to boiling\* under a reflux condenser. *p*-Nitrophenol (30 g.; 1 mol.) is next introduced and the whole boiled for 4 hours, during which time the pyridine salt of *p*-nitrophenylsulphuric acid crystallises out. The mixture is cooled, poured into a slight excess of aqueous potassium hydroxide, the benzene distilled off under diminished pressure, the residual solution made just acid with acetic acid, and unchanged nitrophenol (2 g.) extracted with ether. The solution is rendered slightly alkaline once more and the water and pyridine evaporated off under diminished pressure, when potassium *p*-nitrophenyl sulphate is obtained in yields of 90—94% of the theoretical.

Eugenol under similar conditions gave a 70% yield of potassium eugenyl sulphate.

*o*-Nitrophenol proved much more difficult to attack than the para-isomeride. Yields of the sulphate up to 25% were obtained when equivalent proportions of *o*-nitrophenol and pyridine sulphuro-anhydride were used, and 56% yields with twice the theoretical amount of the latter.

*Use of Pyrosulphate and Tertiary Bases in the Preparation of Phenylsulphuric Acids.*—It is somewhat remarkable that there are no published records of attempts to extend or improve upon the results obtained by Baumann (*Ber.*, 1878, **11**, 1907), who succeeded in making potassium phenyl sulphate from phenol by means of potassium pyrosulphate. He worked with aqueous solutions only, however, with potassium hydroxide as condensing agent, and the yields were very poor. The present authors have found that good yields of the phenyl sulphates can be obtained by heating finely powdered potassium pyrosulphate with a solution of the phenol or naphthol in dry dimethylaniline, followed by extraction of the product with aqueous alkali.

A mixture of phenol (1 mol.) and dimethyl- or diethyl-aniline (1 mol.) was heated on a steam-bath and stirred mechanically while

\* Control experiments showed that pyridine sulphuro-anhydride has no appreciable action on boiling benzene.

finely powdered potassium pyrosulphate\* ( $1\frac{1}{2}$  mols.) was added; the suspension was stirred and heated for 8 hours. The reaction mixture was poured into a suspension of excess of baryta in cold water, the base being subsequently removed by steam distillation, the excess of baryta being precipitated by means of carbon dioxide. After filtering and evaporating, potassium phenyl sulphate in 80–85% yield was easily isolated.

Another experiment using phenol (1 mol.), base (3 mols.), and pyrosulphate ( $2\frac{1}{2}$  mols.), heated and stirred for 4 hours, gave a yield of 90%.

The method was also found satisfactory for  $\alpha$ - and  $\beta$ -naphthols, and for eugenol and isoeugenol, except that in all these cases it was impossible to use barium hydroxide on account of the low solubility of the salts of the products. A slight excess of potassium hydroxide was therefore added and the base separated while the solution was hot.

*Notes on the Properties of the Salts of Arylsulphuric Acids.*—Baumann and Verley (*loc. cit.*) recorded (a) that the potassium salts of the arylsulphuric acids are stable to alkalis, but are readily hydrolysed by acids; (b) that they decompose, with some isomerisation to sulphonates, at 150–200°; (c) one or two physical properties in a few instances. Heymann and Koenigs oxidised potassium *o*- and *p*-tolyl sulphates to the corresponding carboxylic acids (*Ber.*, 1886, 19, 704). In the present investigation many of the above observations were confirmed and extended, and a variety of salts of arylsulphuric acids examined in some detail.

The salts show some variations in their ease of hydrolysis. The alkali salts are stable at 100° in neutral aqueous solution and require heating to boiling before rapid hydrolysis sets in in presence of mineral acid. The barium salt is decomposed on heating to 100° in aqueous solution for  $1\frac{1}{2}$  hours, after which the hydrolysis proceeds rapidly to completion in 2 hours. The ammonium and magnesium salts are of intermediate stability. All the salts are stable at 100° in an aqueous solution of sodium acetate even in presence of a considerable concentration of acetic acid. Hydrolysis of the potassium salt is also brought about by heating at 150° with strong alkali or with half-concentrated ammonia at 190–220° for 4 hours. In the latter case, no aniline is produced.

\* Potassium pyrosulphate was made by heating powdered potassium hydrogen sulphate, under 2–3 mm. pressure, in a bolt-head flask on a sand-bath. The reaction proceeded at 270–330° and was stopped when the temperature began to rise rapidly. The mass was then poured on to an iron plate and allowed to cool in a desiccator; it contained 90% of pyrosulphate. The salt was powdered and sieved as rapidly as possible immediately before application in the above reactions, otherwise it deteriorated.

Heating with aniline gave no indication of replacement of the hydroxyl group. Diazo-compounds do not couple to an appreciable extent with salts of phenylsulphuric acid in alkaline solution, and nitrous acid is without action, even after several days. Concentrated nitric acid rapidly decomposes the alkali salts, producing a mixture of nitro-derivatives without tarring or much evolution of heat. The bromination of salts of phenylsulphuric acids is described in another communication. Potassium phenyl sulphate crystallises in anhydrous, rhombohedral or six-sided plates with apex angle  $95^\circ$ . It dissolves to the extent of 0.7% in alcohol and 14% in water at  $17^\circ$ , and is freely soluble in both media when hot (Found: K, 18.3. Calc. for  $C_6H_5O_4SK$ , K, 18.5%).

The sodium salt forms rhombic plates consisting of aggregates of twinned leaflets. It dissolves to the extent of 7% in alcohol and 31% in water at  $17^\circ$ , and is freely soluble in both media when hot (Found: Na, 9.3. Calc. for  $C_6H_5O_4SN_{a,3}H_2O$ , Na, 9.2%). The barium salt forms fine granules and is rather less readily soluble in water than is barium chloride; in hot or cold alcohol, it dissolves to the extent of about 15%; when the moist salt is exposed in a steam-oven it is quantitatively decomposed in a few minutes, phenol being liberated, and the same change occurs at the ordinary temperature in the course of a few days. The ammonium salt is extremely soluble in cold water and crystallises in hydrated, rhombohedra composed of thin plates like the sodium salt. The magnesium salt forms small, nacreous, rectangular or six-sided plates; it is less soluble in cold water than any of the other salts examined.

Salts of the isomeric tolylsulphuric acids are very sparingly soluble in cold alcohol and acetone and only slightly soluble in hot; they can be recrystallised from 85% alcohol, and, in the case of the *p*-tolyl derivative, from acetone containing 2% of water. They are very freely soluble in acetone containing 5% of water. The *o*-salt is soluble to the extent of 22% in water at  $17^\circ$ , the *m*- 9%, and the *p*- 10%.

*p*-Toluidine tolyl sulphates are characteristic. They were prepared as follows: Potassium tolyl sulphate (5.5 g.) was added to a hot solution of *p*-toluidine (2 g.) in 50 c.c. of alcohol, the mixture stirred for a minute with the liquid just below the boiling point, and *p*-toluidine hydrochloride (3.5 g.) added. The solution was boiled and shaken for a few minutes, and the potassium chloride (1.8 g.) which separated was filtered off. On evaporation, the liquor gave an almost theoretical yield of the toluidine tolyl sulphate, which was washed with benzene and recrystallised from benzene containing 5% of alcohol. The salts from *o*- and *p*-cresols are fairly soluble in

water and readily in alcohol and acetone but insoluble in benzene. On recrystallisation, they formed matted, woolly needles which on melting or heating for some time at  $110^{\circ}$  gave *p*-toluidine sulphate and free cresol. The salt from *o*-cresol melted sharply with decomposition at  $125\text{--}127^{\circ}$ , and the *p*-salt at  $149\text{--}151^{\circ}$ .

*Potassium m-carboxyphenyl sulphate* was prepared by oxidation of the *m*-tolylsulphate. The latter (30 g.) was dissolved in water (100 c.c.) containing a little potassium hydroxide. A hot saturated solution of potassium permanganate (60 g.) was added to the solution, and the mixture heated on the steam-bath for 8 hours, after which the excess permanganate was reduced by means of alcohol, and the precipitate removed by filtration. The filtrate after cooling was rendered slightly acid with hydrochloric acid. The flocculent precipitate formed was collected, washed, and recrystallised from 70% alcohol. The yield was 80%. The salt forms plates: 3.2 parts dissolve in 100 parts of water at  $17^{\circ}$ ; it is readily soluble in acetone containing 10% of water (Found: K, 15.3.  $\text{C}_7\text{H}_5\text{O}_6\text{SK}$  requires K, 15.3%). It gave no coloration with ferric chloride. It was hydrolysed, on boiling with mineral acid, yielding *m*-hydroxybenzoic acid and potassium hydrogen sulphate.

*Salts of Naphthylsulphuric Acids.*—These are readily obtained in yields of 80–90% by the methods described on pp. 684 and 686. High purity of the naphthols is important in using the latter method or the products are discoloured.

*Potassium  $\alpha$ -naphthyl sulphate* crystallises from water as a coarse, crystalline powder or in long, soft needles. It dissolves in 40 parts of water at  $17^{\circ}$ , is freely soluble in hot water, and almost insoluble in most of the usual organic media (Found: K, 14.7.  $\text{C}_{10}\text{H}_7\text{O}_4\text{SK}$  requires K, 14.9%).

*Potassium  $\beta$ -naphthyl sulphate* resembles its isomeride in general appearance and characters, but its crystals are hydrated. It dissolves in 70 parts of water at  $17^{\circ}$  (Found: K, 11.9.  $\text{C}_{10}\text{H}_7\text{O}_4\text{SK} \cdot 4\text{H}_2\text{O}$  requires K, 11.7%).

Both these salts are stable to boiling alkalis and to boiling dilute acetic acid in presence of sodium acetate; they are easily hydrolysed, however, by hot dilute mineral acids. They are at once attacked in aqueous solution by bromine, and precipitates soluble in ether are formed together with free sulphuric acid; the elimination of the sulphate residue is not, however, complete after several minutes in presence of excess of bromine.

A considerable amount of time was spent in investigating the oxidation of the isomeric potassium naphthyl sulphates with alkaline permanganate in aqueous solution. It was found that rapid oxidation took place at  $80^{\circ}$ , and from the quantity of free

inorganic sulphate formed, that about 42% of the  $\alpha$ -salt underwent oxidation in the unsubstituted ring, and in the case of the  $\beta$ -isomeric about 62%. Numerous attempts to separate from the resulting mixtures the sulphates of the hydroxyphthalic, hydroxyphthalonic acids, or the corresponding products formed after elimination of the sulphate radicals were not successful, owing mainly to the excessive solubility of these acids and their derivatives.

From potassium  $\alpha$ -naphthyl sulphate, a small amount of the hydroxyphthalic acid (m. p. 150°) and some phthalic acid were obtained (compare Miller, *Annalen*, 1881, 208, 247).

The authors wish to acknowledge a grant from the Research Fund of the Chemical Society towards the expenses of this investigation, and a maintenance grant to one of them (G. N. B.) from the Department of Scientific and Industrial Research which enabled him to take part in the later sections of the work.

XCVI.—*A New Reaction of Certain Diazosulphonates derived from  $\beta$ -Naphthol-1-sulphonic Acid. Part I. Preparation of Phthalazine, Phthalazone, and Phthalimidine Derivatives from 4'-Nitrobenzene-2-naphthol-1-diazosulphonate.*

By FREDERICK MAURICE ROWE, ESTHER LEVIN, ALAN CHAMLEY BURNS, JOHN STANLEY HERBERT DAVIES, and WOLFE TEPPER.

SOME  $\beta$ -naphtholsulphonic acids condense with diazo-compounds in acid solution to form stable diazosulphonates; thus,  $\beta$ -naphthol-1-sulphonic acid or oxy-Tobias acid (Bayer & Co., Brit. Pat. 11757 of 1895) gives diazosulphonates which Grant Hepburn (Brit. Pat. 116360) found to possess interesting properties. For example, Para-red is obtained in substance quantitatively by dissolving one molecular proportion of 4'-nitrobenzene-2-naphthol-1-diazosulphonate in an aqueous solution of sodium carbonate or of one molecular proportion of sodium hydroxide, and then acidifying the cold solution. Diazosulphonates derived from  $\beta$ -naphthol-1-sulphonic acid appear to be the only examples in which the stabilising component can provide subsequently an azo-coupling component. Bucherer (*Ber.*, 1909, 42, 47; "*Lehrbuch der Farbenchemie*," 1914, 125), without giving experimental details, explains this reaction thus:

Wahl and Lantz (*Bull. Soc. chim.*, 1923, **33**, 97) have re-examined the above reaction and agree with Bucherer's conclusion that compound (II) is a diazo-oxide, but were unable to isolate an analogous compound from 1-bromo-(or chloro)- $\beta$ -naphthol, although the latter reacts with diazotised *p*-nitroaniline to form Para-red as shown by Hewitt and Mitchell (*J.*, 1906, **89**, 1169).

As Wahl and Lantz state that they propose to study the diazo-oxides which can be prepared from  $\beta$ -naphthol-1-sulphonic acid and other diazo-compounds, we must mention here that we began our present investigation in 1918 with an examination of these compounds. Diazosulphonates derived from  $\beta$ -naphthol-1-sulphonic acid are stable, whereas the compounds formed from them by the action of one molecular proportion of alkali are unstable and particularly sensitive to acids. If the latter are diazo-oxides, it is not clear why they should be more reactive and unstable than diazosulphonates, and, in view of our other results, we suggest that they are sodium aryl-1-azo- $\beta$ -naphthaquinone-1-sulphonates of the general formula (IIIa). Compounds of this type would be hydrolysed readily by cold dilute acid, forming azo- $\beta$ -naphthol derivatives. It might be anticipated that such compounds would give different reduction products from those obtained from corresponding diazo-oxides, but they are so unstable that the reduction products more probably would be derived from the corresponding azo- $\beta$ -naphthol derivative, owing to the preliminary elimination of the sulphonic group. In support of this, we find that even the more stable diazosulphonates give 1-amino-2-naphthol on reduction.

Grant Hepburn (*loc. cit.*) observed that although Para-red is obtained by acidifying a solution of 4'-nitrobenzene-2-naphthol-1-diazosulphonate in one molecular proportion of aqueous sodium hydroxide, this is not the case if an excess of sodium hydroxide is used, and he handed over the investigation of this interesting reaction to one of us (F. M. R.).

When the orange solution of 4'-nitrobenzene-2-naphthol-1-diazosulphonate in aqueous sodium carbonate is added to an excess of cold aqueous sodium hydroxide, or vice versa, the temperature

risers and a crimson colour is developed immediately, which changes slowly to orange-brown, or more rapidly when warmed on the water-bath. There is no evolution of nitrogen, and no formation of sodium  $\beta$ -naphthol-1-sulphonate or sodium *p*-nitrophenylnitrosoamine. Subsequent acidification gives traces only of Para-red, and, consequently, a reaction has occurred in which the whole of the diazosulphonate has taken part. No organic by-products can be detected and a homogeneous yellow compound can now be isolated in excellent yield.

In order to test the generality of this reaction, various diazosulphonates were prepared, using other diazo-compounds in place of diazotised *p*-nitroaniline. Each diazosulphonate was converted by sodium carbonate into a sodium aryl-1-azo- $\beta$ -naphthaquinone-1-sulphonate, many of which were isolated in a well-crystalline condition, and all of which were converted quantitatively into the corresponding azo-derivative of  $\beta$ -naphthol, with elimination of the sulphonic group, by the action of cold dilute acid. On the other hand, only certain diazosulphonates give rise to the new reaction with sodium hydroxide. For example, the compounds from aniline, *o*- and *p*-toluidine, 2:5-dichloroaniline, tribromoaniline, sulphanilic acid, *p*-aminoacetanilide, anthranilic acid, *p*-aminobenzonitrile,  $\alpha$ - and  $\beta$ -naphthylamine, and benzidine are decomposed by sodium hydroxide with formation of sodium  $\beta$ -naphthol-1-sulphonate and evolution of nitrogen or formation of the nitrosoamine, although the reaction was examined under a variety of conditions. On the other hand, the compounds, for example, from *o*- and *m*-nitroaniline, 2:4-dinitroaniline, 4-nitroaniline-2-sulphonic acid, 4-chloro-2-nitroaniline, 4-nitro-2-chloroaniline, 2:6-dibromo-4-nitroaniline, and 3-nitro-4-aminotoluene give rise to the new reaction with sodium hydroxide, accompanied usually by the development of a transient intense colour, and new compounds are formed with properties similar to those of the compound derived from *p*-nitroaniline. In fact, the only compounds which have yet been found to give rise to the new reaction, and which do not contain a nitro-group, are aminoazo-compounds, such as 4-aminoazobenzene and its sulphonic acid. The suitability of a diazo-compound for participation in the new reaction depends mainly on the formation of a condensation product with  $\beta$ -naphthol-1-sulphonic acid, sufficiently stable to react further with sodium hydroxide without decomposition.

The possibility of using other compounds in place of  $\beta$ -naphthol-1-sulphonic acid was examined next. Diazotised *p*-nitroaniline condenses with  $\beta$ -naphthylamine-1-sulphonic acid, but the product does not react in the new way, nor is there any evidence of the

occurrence of the new reaction with  $\beta$ -naphthol-8-sulphonic acid or phenol-*o*-sulphonic acid. Naphthalene- $\alpha$ -sulphonic acid condenses with diazotised *p*-nitroaniline (Becker, D.R.-P. 89998) and the diazosulphonate dissolves in aqueous sodium carbonate, but the addition of sodium hydroxide to the solution causes decomposition with formation of sodium naphthalene- $\alpha$ -sulphonate and sodium *p*-nitrophenylnitrosoamine. Consequently, the presence of a hydroxyl group in the *o*-position with respect to the sulphonic group in the naphthalene nucleus is an essential feature of the new reaction. 1-Methyl- $\beta$ -naphthol condenses with diazotised *p*-nitroaniline and its *o*-sulphonic acid, probably with formation of diazo-oxides, but these also are decomposed by sodium hydroxide. Finally, there was no evidence of the occurrence of the new reaction when diazotised *p*-nitroaniline and 1-bromo- $\beta$ -naphthol were used, for the halogen atom in the latter compound is so labile that Para-red is produced under all conditions. Consequently,  $\beta$ -naphthol-1-sulphonic acid stands alone in giving rise to the new reaction.

From this point our attention has been confined to a detailed study of the compound formed by the action of an excess of sodium hydroxide on a solution of 4'-nitrobenzene-2-naphthol-1-diazosulphonate in aqueous sodium carbonate.

This compound has the formula  $C_{16}H_{12}O_7N_3SNa$  and is the sodium salt of a sulphonic acid. Aqueous solutions are decolorised by zinc dust and ammonia, and are reoxidised to a deeper colour, indicating, *inter alia*, that a nitro-group has been reduced to an amino-group. Reduction proceeds further with hydrosulphite [hyposulphite] or acid stannous chloride, and, although concordant results were obtained with difficulty in titrations with titanous chloride or sulphate, the figures indicated that 8 atoms of hydrogen were required for complete reduction as compared with 6 for the mere reduction of a nitro- to an amino-group. When an aqueous solution of the compound  $C_{16}H_{12}O_7N_3SNa$  is boiled with aqueous mineral acid, the sulphur is eliminated as sulphur dioxide, thus :

This behaviour is not confined to this compound, but is a common property of all the analogous compounds which we have yet prepared, and gave the first clue to the actual mechanism of the new reaction, for although the sulphonic group in  $\beta$ -naphthol-1-sulphonic acid is hydrolysed by similar treatment,  $\beta$ -naphthol is formed and not 1 : 2-dihydroxynaphthalene. The hydroxy-derivative has the formula  $C_{16}H_{13}O_5N_3$  and with alkaline hydrosulphite a compound  $C_{16}H_{17}O_3N_3$  is formed as the sole reduction product, *i.e.*, not only

has a nitro-group been reduced to an amino-group, but an additional two hydrogen atoms have been introduced. Reduction with acid stannous chloride, alone or in presence of granulated tin, however, gave varying results according to the duration and temperature of the reaction, and two further compounds were obtained. Closer investigation showed that whether alkaline hydrosulphite or acid stannous chloride is used, the initial reduction product is the compound  $C_{16}H_{17}O_3N_3$ . The latter, however, reacts with boiling hydrochloric acid, forming the compound  $C_{14}H_{11}ON_3$ , which is capable of undergoing further change with acid-reducing agents, forming the compound  $C_{14}H_{12}ON_2$ . Thus, although several derivatives and degradation products were obtained, we failed to bring about fission into two aromatic products by these reactions.

We wish to acknowledge here our great indebtedness to Professor Arthur Lapworth, F.R.S., and to Professor Robert Robinson, F.R.S., who first propounded the explanation of the mechanism of the new reaction upon which our constitutional formulæ are based, and to whom our warmest thanks are due for their interest in this investigation.

The course of the reaction in the case of 4'-nitrobenzene-2-naphthol-1-diazosulphonate (I) is outlined in the scheme on p. 695.

Reference has been made already to the compounds formed by the action of aqueous sodium carbonate on diazosulphonates derived from  $\beta$ -naphthol-1-sulphonic acid, and regarded hitherto as diazo-oxides. It would not be anticipated that diazo-oxides would react with alkali hydroxides in the manner outlined on p. 695, and it is upon the occurrence of this new reaction and the properties of the compounds to which it leads, that our opinion is based that the former compounds are really *sodium aryl-1-azo- $\beta$ -naphthaquinone-1-sulphonates*. It is considered that sodium hydroxide opens the ring\* of *sodium 4'-nitrobenzene-1-azo- $\beta$ -naphthaquinone-1-sulphonate* (III) with addition of sodium hydroxide, forming the intermediate carboxylic acid (IV), which is not isolated, and a quinonoid modification of which would account for the transient intense coloration. The next step is a rearrangement and closing of the ring which we believe occurs as shown in (V) with formation of *disodium 3-(4'-nitrophenyl)-1:3-dihydrophthalazine-4-acetate-1-sulphonate*, and when the mixture is rendered faintly acid, the *mono-sodium* salt separates. The replacement of the sodium-1-sulphon-

\* The opening of the naphthalene ring forming a carboxylic acid has also been effected by Werner and Piguet (*Ber.*, 1904, 37, 4310), who prepared *o*-cyanocinnamic acid by the very vigorous reaction which occurs when a pyridine solution of 1-nitroso- $\beta$ -naphthol is treated with benzenesulphonyl chloride or sulphuryl chloride.

ate group by hydroxyl gives 1-hydroxy-3-(4'-nitrophenyl)-1:3-dihydrophthalazine-4-acetic acid (VI). Formula (VI) is in agreement with the behaviour of this compound on reduction, whereby 1-hydroxy-3-(4'-aminophenyl)-tetrahydrophthalazine-4-acetic acid (VII) is formed.

N.B.—Formulae (V) and (VI) above correspond with the familiar formula for nitrobenzene (A), but the formulae may be expressed equally well as containing the semi-polar bond (B), corresponding with the form (C) for nitrobenzene.

Attempts to degrade compound (VI) by oxidation with acid dichromate were unsuccessful and gave an apparently more com-

plex compound, which has been set aside for future investigation, as has also a compound formed by boiling with aqueous sulphuric acid.

The oxidation of compound (VII) with acid dichromate proceeded satisfactorily only if limited, and the compound formed has also been set aside for future investigation.

When compound (VII) is boiled with aqueous mineral acid, it is converted into 4'-amino-3-phenylphthalaz-4-one (VIII), the latter constitution being supported by the fact that oxidation with hot acid dichromate gives phthalic acid and benzoquinone.

When compound (VIII) is reduced with zinc dust and hydrochloric acid, one nitrogen atom is eliminated as ammonia and 4'-amino-*N*-phenylphthalimidine (IX) is produced. Thus, this reaction is similar to that observed by Racine (*Annalen*, 1887, 239, 78) in the preparation of *N*-phenylphthalimidine (XI) from 3-phenylphthalaz-4-one by reduction with tin and hydrochloric acid. The constitution of compound (IX) was confirmed by the preparation from it of *N*-phenylphthalimidine (XI), and also by oxidation with cold acid dichromate, when phthalimide and benzoquinone were obtained. The fact that phthalimide was obtained in this case suggests that it was also the primary oxidation product of compound (VIII), but that hydrolysis then occurred at the temperature necessary for satisfactory oxidation in the latter case.

At an early stage in our investigation it appeared possible that the rearrangement and closing of the ring in passing from compound (IV) might occur with the formation of *N*-arylimino-derivatives of isoquinoline thus :

In order to determine which of the two schemes for the final stage in the reaction is correct, the compound (VI) or (VIa) was studied closely. It might be argued that a compound such as (VIa) would give *p*-phenylenediamine as one of its reduction products, whereas we failed to obtain any trace of *p*-phenylenediamine by the reduc-

tion of this compound. As the literature appeared to contain no reference to *N*-arylimino-derivatives of isoquinoline, for purposes of comparison with compound (VI) or (VIa), a related compound undoubtedly of the type of the latter was synthesised thus :

$\beta$ -Naphthaquinone was oxidised by calcium hypochlorite (Zincke and Scharfenberg, *Ber.*, 1892, 25, 399; compare Zincke, *ibid.*, 1168, 1493; Bamberger and Kitschelt, *ibid.*, 888) to the  $\delta$ -lactone of *o*-carboxyphenylglyceric acid (XII), and this was converted into isocoumarin-3-carboxylic acid (XIII) by heating with hydrochloric acid at 160—165°. It was anticipated that the latter would condense with *p*-nitrophenylhydrazine in alcoholic solution with elimination of water, forming *N*-4'-nitrophenyliminoisocarbostyryl-3-carboxylic acid (XV), as Bamberger and Frew (*Ber.*, 1894, 27, 198) prepared *N*-phenylisocarbostyryl-3-carboxylic acid in this way, using aniline. Actually, this condensation gave in our case the *hydrazone* (XIV), and the final stage of the synthesis was completed only by boiling a suspension of the latter in toluene in presence of phosphorus trichloride.

Compound (VI) or (VIa) dissolves in alkalis with a deep wine-red colour, and is reduced by hydrosulphite to compound (VII) in almost theoretical yield. Compound (XV) dissolves in alkalis with a deep red colour, but when reduced with hydrosulphite under exactly the same conditions, although no *p*-phenylenediamine could be detected and the sole reduction product was an *amino-acid*, the yield of the latter was much inferior to that obtained in the former case. This is probably due to the fact that compound (XV) is much more sensitive to alkalis than compound (VI) or (VIa). Other noteworthy differences between the properties of the two compounds were observed. Thus, whereas compound (VI) or (VIa) is esterified readily by passing hydrogen chloride through a solution in the requisite alcohol, or by means of the alcohol and sulphuric acid, or by the action of alkyl halides on the silver salt, we failed to esterify the carboxyl group in compound (XV). Further, compound (VI) or (VIa) forms an *anilide* when boiled with aniline in toluene solution in presence of phosphorus trichloride, but

compound (XV) is unaffected by this treatment. These differences in the properties of the two carboxylic acids are probably due to the proximity of the imino- and carboxyl-groups in compound (XV), and indicate the improbability of formula (VI<sub>A</sub>), particularly as we failed to prepare a nitroso-derivative of the compound, or to detect an imino-group in it by alkylation. In order to arrive at a definite conclusion on this point, the behaviour of compound (VI) or (VI<sub>A</sub>), when heated with an excess of zinc dust, was examined next, as Bamberger and Frew (*loc. cit.*) found that *N*-phenylisocarbostyryl-3-carboxylic acid gives isoquinoline when treated in this manner. In our case, however, we failed to obtain any trace of isoquinoline, a fact which appeared definitely to exclude formula (VI<sub>A</sub>). This is supported also by the fact that one of our later degradation products (VIII) undoubtedly contains two nitrogen atoms in the ring, and it is difficult to conceive how such a compound could be formed from an isoquinoline derivative. Further support of formula (VI) is afforded by the fact that when this compound is heated carefully above its melting point, nitrobenzene is formed, together with a basic residue which has not yet been examined closely; this behaviour is analogous to that of *p*-nitroazoxybenzene, which also gives nitrobenzene and a basic residue under similar conditions.

Consequently, formulæ (V<sub>A</sub>) and (VI<sub>A</sub>) have been discarded and it appears that formulæ (V) and (VI) are correct, although the possibility of tautomeric forms of these, such, for example, as (VI<sub>B</sub>),

must not be overlooked. This is virtually an isoamide of a carboxylic acid, however, and it is improbable that such a compound would be reduced by alkaline hydrosulphite in the manner shown in (VII).

In the present state of our investigation, formulæ (V) and (VI) appear the most probable and agree best with the formulæ assigned to their derivatives and degradation products which we have yet prepared, although it is possible that the former may require slight modification in the light of future work. The closing of the ring which occurs in passing from (IV) to (V) is a condensation of a type closely allied to the condensation of nitrosobenzene and ethyl methylenemalonate recently described by Burkhardt and Lapworth (*J.* 1925, 127, 1749).

Noteworthy features of the new reaction described in this communication are the simplicity and neatness with which certain naphthalene derivatives are converted into complex phthalazine derivatives. The latter by simple means are capable of almost

quantitative conversion into many other interesting compounds, which are now rendered readily accessible for further study.

Further work on this subject is in progress and the investigation will be extended in the various directions indicated.

#### EXPERIMENTAL.

*Monosodium 3-(4'-Nitrophenyl)-1:3-dihydrophthalazine-4-acetic acid-1-sulphonate* (compare V).—A filtered solution of 48 g. of commercial sodium  $\beta$ -naphthol-1-sulphonate in 220 c.c. of water was stirred into a cold solution of diazotised *p*-nitroaniline, obtained by adding a concentrated solution of 14 g. of sodium nitrite to a solution of 24 g. of *p*-nitroaniline in 60 c.c. of concentrated hydrochloric acid and 240 c.c. of water. The 4'-nitrobenzene-2-naphthol-1-diazosulphonate (I) separated immediately as an orange precipitate in theoretical yield (calculated on the *p*-nitroaniline). This was filtered, washed free from acid with brine, made into a paste with 150 c.c. of cold water, and stirred into a cold solution of 48 g. of anhydrous sodium carbonate in 120 c.c. of water. A solution was produced but, if kept, crystals of *sodium 4'-nitrobenzene-1-azo- $\beta$ -naphthoquinone-1-sulphonate* (III) separated. The cold orange solution was added immediately to a cold solution of 40 g. of sodium hydroxide in 80 c.c. of water, the temperature rose about 15°, and the deep crimson mixture was left overnight until the colour had changed completely to yellowish-brown. It was rendered faintly acid with hydrochloric acid, then made alkaline with sodium carbonate, and a trace of Para-red filtered off. The filtrate was rendered faintly acid with hydrochloric acid and, under these conditions, the product separated completely as a yellow, semi-crystalline precipitate. (N.B.—Many experiments were carried out to determine the best conditions for the preparation of this compound, and although the yield was not affected materially, variations of temperature, excess of sodium hydroxide, and duration of the reaction, gave a resinous product which coagulated slowly.) After drying, sodium chloride was removed by extraction with absolute alcohol, from which solvent the product crystallised in orange, prismatic needles (yield 66 g.; 91.5% of the theoretical) (Found: C, 46.3; H, 2.9; N, 10.4; S, 7.5; Na, 5.2.  $C_{16}H_{12}O_7N_3SNa$  requires C, 46.5; H, 2.9; N, 10.2; S, 7.7; Na, 5.5%). It is readily soluble in water, but less soluble in alcohol, forming yellow solutions, which are deepened by the addition of alkalis. The aqueous solution is decolorised by zinc dust and ammonia, and on exposure to air a deeper colour returns. It is a level-dyeing, pure greenish-yellow acid dye of good tinctorial power and of good fastness to other influences, but fugitive to light, even when dyed

in admixture with a fast blue. When heated with concentrated nitric acid at  $105^{\circ}$  in a sealed tube for 8 hours, decomposition occurs and picric acid was isolated in yellow needles, m. p.  $122^{\circ}$ .

*1-Hydroxy-3-(4'-nitrophenyl)-1 : 3-dihydrophthalazine-4-acetic Acid* (VI).—A solution of 32 g. of monosodium 3-(4'-nitrophenyl)-1 : 3-dihydrophthalazine-4-acetic acid 1-sulphonate in 120 c.c. of water was boiled with 64 c.c. of concentrated hydrochloric acid (aqueous sulphuric acid also can be used) until evolution of sulphur dioxide had ceased, and the product, which separated first as an oil, had formed yellowish-brown crystals. The latter were washed with boiling water and crystallised from ethyl acetate in pale yellow, vitreous, irregular prisms, m. p.  $241^{\circ}$  (yield 24 g.; 94%). Sulphur dioxide evolved during the reaction was determined quantitatively in the usual manner and was equivalent to one molecular proportion (Found: C, 58.9; H, 4.2; N, 12.8.  $C_{16}H_{13}O_5N_3$  requires C, 58.7; H, 4.0; N, 12.8%). When the substance was heated carefully above its melting point, nitrobenzene (confirmed by conversion into aniline) was obtained, together with a basic residue which has not yet been examined closely. This behaviour is analogous to that of *p*-nitroazoxybenzene, which also gives nitrobenzene under similar conditions. The substance is readily soluble in alcohol, acetone, or glacial acetic acid, but less soluble in benzene or ether. It is sparingly soluble in water, forming a solution acid to litmus, but dissolves readily in sodium carbonate or hydroxide with a deep wine-red colour, and prolonged boiling of the alkaline solution causes decomposition. It forms a reddish-brown *silver* salt and a yellowish-brown *barium* salt, and decolorises bromine water. It dissolves in cold concentrated sulphuric acid with an orange colour and is reprecipitated unaltered on dilution, but when 5 g. were dissolved in 50 c.c. of sulphuric acid, then diluted with 60 c.c. of water, and the solution boiled under reflux for 1 hour, there was no precipitate on further dilution. A substance (4 g.) was isolated and crystallised from alcohol in fine yellow needles, m. p.  $331^{\circ}$ , but this has not yet been examined closely.

*Derivatives of 1-Hydroxy-3-(4'-nitrophenyl)-1 : 3-dihydrophthalazine-4-acetic Acid.*—*Methyl ester.* A solution of 5 g. in 50 c.c. of dry methyl alcohol was saturated with dry hydrogen chloride at  $0^{\circ}$ , left over-night, and then boiled under reflux for 2 hours. The *ester* crystallised from methyl alcohol in yellow prisms, m. p.  $153^{\circ}$  (Found: C, 59.8; H, 4.6; N, 12.5.  $C_{17}H_{15}O_5N_3$  requires C, 59.8; H, 4.4; N, 12.3%). *Ethyl ester.* (a) A solution of 3 g. in 30 c.c. of dry ethyl alcohol was boiled with 1.5 g. of concentrated sulphuric acid under reflux for 4 hours. (b) The dry, reddish-brown, amorph-

ous silver salt, precipitated by the addition of silver nitrate to a neutral solution of 5 g. in sodium hydroxide, was boiled with 2 g. of ethyl iodide and 50 c.c. of dry ethyl alcohol under reflux for 1 hour. (c) As described above for the methyl ester, except that 60 c.c. of dry ethyl alcohol were used. The three products were identical in all respects and crystallised from ethyl alcohol in yellow crystals, tabular in character and with hexagonal outline; m. p.  $180^{\circ}$ . We have been furnished with the following crystallographic description of the substance by Mr. H. E. Buckley of the Department of Crystallography, University of Manchester, to whom we express our grateful thanks:

"The symmetry is anorthic (triclinic) pinacoidal, with  $a : b : c = 1.387 : 1.0626$  and  $\alpha = 78^{\circ} 15'$ ,  $\beta = 40^{\circ} 10'$ ,  $\gamma = 117^{\circ} 6'$ .

The forms usually developed are  $a(100)$ ,  $b(010)$ ,  $c(001)$ , tabular,  $n(011)$  and  $r(\bar{1}01)$  (Fig. 1).

Angles measured:  $a : b = 118^{\circ} 11'$ ,  $a : c = 39^{\circ} 42'$ ,  $a : m = 54^{\circ} 53'$ ,  $c : m = 56^{\circ} 42'$ ,  $c : n = 57^{\circ} 53'$ ,  $c : b = 103^{\circ} 19'$ ,  $n : r = 68^{\circ} 19'$ ,  $m : n = 35^{\circ} 45'$ , and  $c : r = 89^{\circ} 10'$ " (Found: C, 61.1; H, 4.7; N, 12.1.  $C_{18}H_{17}O_5N_3$  requires C, 60.8; H, 4.8; N, 11.8%). It dissolves

in sodium carbonate with an orange-brown colour, and is hydrolysed to the original acid by boiling with alcoholic potassium hydroxide. Attempts to acetylate the ester gave a yellow, resinous product which could not be crystallised. *Acetyl derivative*. A solution of 5 g. of the acid in 10 c.c. of glacial acetic acid was boiled with 5 c.c. of acetic anhydride under reflux for 8 hours, and then poured on to ice. The *acetyl* derivative crystallised from ethyl alcohol in greenish-yellow, vitreous prisms, m. p.  $212^{\circ}$  (Found: C, 58.8; H, 4.2; N, 11.7.  $C_{18}H_{15}O_6N_3$  requires C, 58.5; H, 4.1; N, 11.4%). It dissolves in sodium carbonate with an orange-brown colour or in sodium hydroxide with a wine-red colour, and attempts to esterify it gave resinous products which could not be crystallised. *Anilide*. A fine suspension of 4 g. of the acid in 400 c.c. of toluene was boiled with 2.3 g. of aniline and 1 g. of

phosphorus trichloride under reflux for 5 hours with stirring. When cold, the residue was washed with a little sodium carbonate and, after several crystallisations from ethyl acetate, formed yellow needles, m. p. 190—192° (decomp.) (Found : C, 65.4; H, 4.6; N, 13.9.  $C_{22}H_{18}O_4N_4$  requires C, 65.7; H, 4.5; N, 13.9%). The anilide dissolves in sodium hydroxide with a red colour and is hydrolysed to the original acid by boiling concentrated hydrochloric acid. *Oxidation of (VI)*. A fine suspension, obtained by dissolving 20 g. in 200 c.c. of cold concentrated sulphuric acid and pouring on to 800 g. of ice, was oxidised by adding gradually 10 g. of powdered sodium dichromate. Next day the product was precipitated completely by nearly neutralising with sodium hydroxide and, after several crystallisations from ethyl alcohol and ethyl acetate, yellow leaflets (11.5 g.), m. p. 247°, were obtained, but this substance requires further investigation.

*1-Hydroxy-3-(4'-aminophenyl)-tetrahydrophthalazine-4-acetic Acid (VII)*.—Hydrosulphite was added to a solution of 12 g. of 1-hydroxy-3-(4'-nitrophenyl)-1 : 3-dihydrophthalazine-4-acetic acid in 150 c.c. of water and 10 g. of sodium hydroxide at about 90° until the deep wine-red colour had disappeared, the mixture being kept alkaline throughout by the addition of sodium hydroxide. The yellow solution was filtered and, if the filtrate was cooled, fine yellow needles of the *sodium* salt separated incompletely. The product was best isolated, therefore, by the addition of hydrochloric acid until a white precipitate had separated completely. The end-point is readily determined, because too much acid redissolves the precipitate with a brown colour. It was washed with cold water and crystallised from a large volume of boiling water in colourless prisms, m. p. 239° (yield 10.7 g.; 97.5%) (Found : C, 64.3; H, 5.7; N, 14.2.  $C_{16}H_{17}O_3N_3$  requires C, 64.2; H, 5.7; N, 14.0%). This compound can also be obtained by rapid reduction with acid stannous chloride, but the yield is not so good owing to the subsequent action of acid upon it. It is soluble in alcohol, insoluble in benzene, and gives a transient wine-red colour with ferric chloride. It dissolves readily in dilute alkalis or dilute acids and can be diazotised. The esters could not be obtained by the reduction of the esters of 1-hydroxy-3-(4'-nitrophenyl)-1 : 3-dihydrophthalazine-4-acetic acid with alkaline hydrosulphite, for hydrolysis also occurred, nor did direct esterification prove satisfactory. The fact that the compound is affected by acids interfered with the preparation of a pure *acetyl* derivative, for, after crystallisation from dilute acetic acid, colourless plates, softening at 145—165° and melting sharply at 266°, were obtained (Found : C, 64.3; H, 5.2; N, 12.3.  $C_{18}H_{19}O_4N_3$  requires C, 63.3; H, 5.6;

N, 12.3%). *Oxidation of (VII).* Powdered sodium dichromate (7 g.) was added in small portions during 3 hours to a solution of 20 g. in 400 c.c. of water and 100 c.c. of concentrated sulphuric acid at the air temperature. A transient wine-red colour was produced after each addition, but any further addition did not produce this colour. The mixture was rendered just alkaline with sodium hydroxide, diluted with water to 2 litres, boiled, filtered, the filtrate neutralised, and concentrated. After crystallisation from alcohol and then from water, yellow, prismatic needles (15 g.), m. p.  $276^{\circ}$ , were obtained, but this substance requires further investigation.

*4'-Amino-3-phenylphthalaz-4-one (VIII).*—A solution of 12 g. of 1-hydroxy-3-(4'-aminophenyl)-tetrahydrophthalazine-4-acetic acid in 300 c.c. of concentrated hydrochloric acid (25–30% aqueous sulphuric acid also can be used) was boiled under reflux. A less soluble *hydrochloride* separated progressively in colourless needles after 1 hour and the reaction was completed by boiling for 18 hours. After cooling, the hydrochloride was filtered off and converted into the base, which crystallised from alcohol in deep straw-coloured, prismatic needles, m. p.  $259^{\circ}$  (yield 8.8 g.; 92.5%) (Found: C, 71.0; H, 4.7; N, 17.8.  $C_{14}H_{11}ON_3$  requires C, 70.9; H, 4.6; N, 17.7%). It is soluble in hot water, insoluble in alkalis, but soluble in dilute acids and can be diazotised, although we have not yet succeeded in removing the amino-group or replacing it by a hydroxyl group without the compound undergoing further change. *Acetyl derivative.* A solution of 1 g. in 10 c.c. of glacial acetic acid was boiled with 0.5 c.c. of acetic anhydride. After a few minutes the colourless acetyl derivative separated completely; it crystallised from a large volume of boiling water in almost colourless plates, m. p.  $348^{\circ}$  (Found: C, 68.9; H, 4.8; N, 14.9.  $C_{18}H_{13}O_2N_3$  requires C, 68.8; H, 4.7; N, 15.0%). *Oxidation of (VIII).* A solution of 5 g. in 400 c.c. of water and 80 c.c. of concentrated sulphuric acid was oxidised at the air temperature by adding gradually 16 g. of powdered sodium dichromate. A brown precipitate separated and next day benzoquinone, yellow needles, m. p.  $115^{\circ}$ , was isolated by extraction with ether. The other oxidation product could not be obtained satisfactorily under these conditions, but was obtained in a second oxidation in which a further 14 g. of dichromate were added and the mixture heated. In this case extraction with ether gave phthalic acid, colourless needles, m. p.  $197^{\circ}$  (confirmed by conversion into phthalic anhydride, colourless needles, m. p.  $129^{\circ}$ , and by the formation of fluorescein).

*4'-Amino-N-phenylphthalimidine (IX).*—A solution of 20 g. of 4'-amino-3-phenylphthalaz-4-one in 1 litre of water and 100 c.c. of

concentrated hydrochloric acid was boiled, and 300 c.c. of concentrated hydrochloric acid were added, followed by 30 g. of zinc dust in small portions during  $2\frac{1}{2}$  hours with vigorous boiling so that the volume was reduced to 700 c.c. After cooling, the product separated completely as colourless plates of the *hydrochloride*, together with a small proportion of colourless needles of the *zinc double chloride*. Completion of the reaction was indicated by the pink colour of the filtrate, and the latter contained ammonia. The crystals were dissolved in a little hot water and hydrochloric acid, the solution was rendered alkaline, and the dry precipitate extracted with alcohol. The base crystallised in almost colourless, prismatic needles, m. p.  $198^{\circ}$  (yield 16.5 g.; 87%) (Found: C, 75.1; H, 5.5; N, 12.4.  $C_{14}H_{12}ON_2$  requires C, 75.0; H, 5.4; N, 12.5%). *Acetyl derivative*. A solution of 1 g. in 10 c.c. of glacial acetic acid was boiled with 0.5 c.c. of acetic anhydride and poured into water; the product crystallised from dilute acetic acid in fine, colourless needles, m. p.  $196^{\circ}$  (Found: C, 72.0; H, 5.5; N, 10.7.  $C_{16}H_{14}O_2N_2$  requires C, 72.2; H, 5.4; N, 10.5%). *Oxidation of (IX)*. This was effected as described in the first example under oxidation of (VIII), except that a fine suspension of the *sulphate* was used, and dark green needles separated at first and disappeared subsequently. Ether extraction gave benzoquinone, yellow needles, m. p.  $115^{\circ}$ . The other oxidation product was obtained best in a second oxidation in which a further 16 g. of dichromate were added at the air temperature. In this case extraction with ether gave phthalimide, flat, colourless needles, m. p.  $234^{\circ}$  (confirmed by conversion into phthalamide, colourless crystals, m. p.  $222^{\circ}$  with evolution of ammonia and reformation of the imide).

*N-Phenylphthalimidine (XI)*.—A fine suspension of the sulphate, obtained by grinding 10 g. of the amino-derivative with sulphuric acid, was diazotised with a concentrated solution of 3.6 g. of sodium nitrite. The sparingly soluble *diazo-sulphate*, almost colourless needles, was boiled with 1 litre of alcohol until the evolution of nitrogen had ceased; the *N*-phenylphthalimidine crystallised in almost colourless plates, m. p.  $160^{\circ}$  as given by Racine (*loc. cit.*)

*4'-Hydroxy-N-phenylphthalimidine (X)*.—A fine suspension of the hydrochloride, obtained by grinding 20 g. of the amino-derivative with 36 c.c. of concentrated hydrochloric acid and 800 c.c. of water, was diazotised with a concentrated solution of 7.2 g. of sodium nitrite. Carbamide was added to remove excess nitrous acid, the solution poured into 640 c.c. of dilute sulphuric acid (1:3) at  $90^{\circ}$ , and the mixture boiled for 2 hours until the stable diazo-compound had decomposed completely. The hydroxy-

derivative crystallised from alcohol in colourless needles, m. p. 228° (yield 18.2 g.; 90.5%) (Found: C, 74.8; H, 5.1; N, 6.1.  $C_{14}H_{11}O_2N$  requires C, 74.7; H, 4.9; N, 6.2%). *Methyl ether*. A solution of 2 g. in 50 c.c. of dry methyl alcohol was boiled with methyl iodide and sodium. The ether crystallised from methyl alcohol in colourless plates, m. p. 134° (Found: C, 75.2; H, 5.5; N, 6.0.  $C_{15}H_{13}O_2N$  requires C, 75.3; H, 5.4; N, 5.9%). The *ethyl ether* crystallised from ethyl alcohol in colourless needles, m. p. 148° (Found: C, 75.7; H, 5.9; N, 5.6.  $C_{16}H_{15}O_2N$  requires C, 75.9; H, 5.9; N, 5.5%).

*N-4'-Nitrophenyliminoisocarbostyryl-3-carboxylic Acid* (XV).— $\beta$ -Naphthaquinone (3 g.) was oxidised by calcium hypochlorite to the  $\delta$ -lactone of *o*-carboxyphenylglyceric acid (2 g.) (XII), colourless leaflets, m. p. 202—203°, as described by Zincke and Scharfberg (*loc. cit.*), who give m. p. 202°, whereas Bamberger and Kitschelt (*loc. cit.*) give m. p. 204.5°. This acid (12 g.) was heated with concentrated hydrochloric acid (60 c.c.) at 160—165° and gave *isocoumarin-3-carboxylic acid* (8.2 g.) (XIII), colourless, quadrilateral plates, m. p. 238—239° (Zincke, *Ber.*, 1892, 25, 1493 gives m. p. 235°, whereas Bamberger and Kitschelt give m. p. 237°). An alcoholic solution of *isocoumarin-3-carboxylic acid* (5 g.) and *p*-nitrophenylhydrazine (4.05 g.) was boiled under reflux for  $\frac{1}{2}$  hour, and gave *o*-carboxy- $\alpha$ -hydroxycinnamic acid *p*-nitrophenylhydrazide (8.5 g.) (XIV), which crystallised from alcohol in fibrous, yellow needles, m. p. 189—190° (decomp.) (Found: C, 55.9; H, 4.0; N, 12.5.  $C_{16}H_{13}O_6N_3$  requires C, 56.0; H, 3.8; N, 12.2%). The hydrazide is hydrolysed into its constituents by heating with dilute mineral acids. The elements of water were removed by boiling the finely divided hydrazide (4 g.) suspended in toluene (800 c.c.) with phosphorus trichloride (1 g.) under reflux for 5 hours. *N-4'-Nitrophenyliminoisocarbostyryl-3-carboxylic acid* (2.24 g.) crystallised from ethyl acetate in small, pale yellow needles, m. p. 287° (decomp.). This compound is formed also by condensing *isocoumarin-3-carboxylic acid* with *p*-nitrophenylhydrazine in presence of phosphorus trichloride and boiling toluene, but the yield is much inferior (Found: C, 58.8; H, 3.6; N, 13.0.  $C_{18}H_{11}O_5N_3$  requires C, 59.1; H, 3.4; N, 12.9%). It is readily soluble in acetone or glacial acetic acid, but less soluble in alcohol or ether, and dissolves in alkalis with a deep red colour, the alkaline solution decomposing when heated. It is unaltered by boiling with dilute mineral acids, and is neither esterified nor converted into an anilide when treated under the conditions described for the preparation of these derivatives of 1-hydroxy-3-(4'-nitrophenyl)-1:3-dihydrophthalazine-4-acetic acid (VI). Reduction of the acid (4 g.) with alkaline hydro-

sulphite gave an *amino-acid* (2 g.), almost colourless, crystalline powder, m. p.  $265^{\circ}$ , which was not examined closely, and no trace of *p*-phenylenediamine could be detected in the reduction mixture.

We desire to thank (1) the Society of Dyers and Colourists for a grant which enabled one of us (A. C. B.) to take part in this investigation, and also for permission to publish the detailed results elsewhere than in the Journal of that Society, (2) Professor F. L. Pyman, F.R.S., for his kindly interest during the progress of the investigation, and (3) Alliance Colour and Chemical Co., British Dyestuffs Corporation, and the Gas Light and Coke Co., for gifts of sodium  $\beta$ -naphthol-1-sulphonate.

MUNICIPAL COLLEGE OF TECHNOLOGY,  
MANCHESTER.

[Received, December 1st, 1925.]

## XCVII.—*Absorption Spectra and Tautomerism. Part I.* *Keto-enol Tautomerism. Ethyl Acetoacetate, Acetyl- acetone, and $\alpha$ -Benzoylcamphor.*

By RICHARD ALAN MORTON and WILLIAM CHARLES VICTOR  
ROSNEY.

ALTHOUGH the absorption spectra of ethyl acetoacetate and its derivatives have been studied repeatedly (Baly and Desch, J., 1904, 85, 1029; Stewart and Baly, J., 1906, 89, 489; Hantzsch, Ber., 1911, 44, 1771; Hantzsch and Voigt, Ber., 1912, 45, 85; Baly and Rice, J., 1913, 103, 91; Morgan and Reilly, J., 1913, 103, 1494; Bielecki and Henri, *Compt. rend.*, 1913, 156, 1332; 1914, 158, 866; Ber., 1913, 46, 3627; Hantzsch, Ber., 1912, 43, 3029), a reconsideration of the problem of the origin of their absorption bands is called for in view of the improved experimental methods which are now available (compare Grossmann, *Z. physikal. Chem.*, 1914, 109, 305).

The vapour from ethyl acetoacetate, cooled to  $-80^{\circ}$  in order to reduce the vapour pressure, shows an absorption band, without fine structure, at  $\lambda_{(\max.)} = 2381 \text{ \AA.}$ ,  $e_{(\max.)} = 1000$  (approx.). Thin layers of the liquid ester show a band at  $\lambda_{(\max.)} = 2430$ ,  $e_{(\max.)} = 367$ , and the same band appears in solutions in ether, alcohol ( $e = 2000$ ), and hexane ( $e = 9100$ ). Since the ratio  $e_{\text{alcohol}}$  to  $e_{\text{hexane}}$  agrees excellently with the relative content of enol in the solutions as measured by the addition of bromine, the band at  $2430 \text{ \AA.}$  may be ascribed to the enol. This band is shifted to  $2550 \text{ \AA.}$  in ethyl ethylacetoacetate,  $\text{CH}_3\text{-C(OH):C(OC}_2\text{H}_5\text{)-CO}_2\text{Et}$ , and to  $2348 \text{ \AA.}$  in ethyl  $\beta$ -ethoxycrotonate,  $\text{CH}_3\text{-C(OEt):CH-CO}_2\text{Et}$ .

Aqueous solutions of ethyl acetoacetate, which appear to be mainly ketonic since they do not absorb bromine appreciably, give a band at 2550 Å., which is nearer to the enolic band than to the undoubtedly ketonic band of acetone at 2747 Å. Its absorptive power,  $e = 81$ , is intermediate between those of acetone (17.2) and liquid ethyl acetoacetate (367). Since a displacement of 100 Å. is often produced by a change of solvent, there is as much

*Ethyl acetoacetate (a) in hexane, (b) in alcohol, (c) in dilute hydrochloric acid, (d) in water, (e) liquid.*

reason to ascribe the band at 2550 Å. to a trace of enol as to a large amount of ketone. There is, however, an inflexion in the curves for the liquid ester and for its solution in hexane, which may be due to an incipient ketonic band at 2700–2800 Å. This conclusion is confirmed by the fact that the liquid dialkylacetoacetic esters exhibit well-defined bands near 2900 Å., which are weakened on the addition of alcohol, but reappear when alkali is

added. Moreover, analogy with other ketones would lead us to predict a band in ethyl acetoacetate at about 2750 Å. and  $e_{(\max.)}$  about 100. Since in hexane, where 80% of the ester is enolic,  $e_{(\max.)}$  is 9100, the value for the pure enol must then be about 100 times greater than for the pure ketone. We therefore conclude that the band at 2430 Å. can be attributed to the enolic form and

FIG. 2.

Ketonic  $\alpha$ -benzoylcamphor in (a) piperidine, (b) chloroform, and (c) alcohol.

that the ketonic form possesses a weak band near 2700 Å., which is usually masked by the stronger absorption of the enol.

Acetylacetone, which is too absorbent to be examined in the liquid state, gives a strong band at 2750 Å. in aqueous and alcoholic solutions. The ratio of the molecular extinction coefficients,  $8920/2200 = 4.05$ , agrees with the ratio 4.2 of the enol content of these solutions as measured by K. H. Meyer. The band appears, therefore, to be due to the enol, although its wave-length corresponds with that of the acetone band at 2747 Å. Since hexa-

methylacetone shows the usual ketonic band, even when very carefully purified (Rice, *Proc. Roy. Soc.*, 1914, *A*, **91**, 76), and the weak bands of the dimethyl- and diethyl-acetoacetic esters could not have been detected in presence of strongly absorbing enolic impurities, it is clear that the ketonic band cannot be attributed to the presence of a trace of enol in all ketones. It is therefore necessary to conclude that the enolic form of acetylacetone gives a band at the same wave-length as the ketonic form. This conclusion is confirmed by the facts that addition of alkali to acetone (which presumably gives rise to a trace of an enolic salt) increases the intensity of the band but does not produce a new band, and

FIG. 3.

that the two isomeric forms of benzoylcamphor give bands at the same wave-length but of unequal intensity.

Formation of a new compound from acetone by addition of alkali must result in a redistribution of selective absorption. If the compound exhibits a new absorption band, the number of acetone molecules absorbing at 2747  $\text{\AA}$ ., and therefore  $e_{(\text{max.})}$ , should decrease. The reverse is observed, so that whatever the nature of the new absorbing entity its position of maximum absorption must coincide with that of acetone itself. The data on acetone are thus in agreement with the view that enolic and ketonic modifications possess the same wave-length of maximum absorption. Since the enolic sodium salt can be present only in minute amount,

the enolic form must have a high molecular extinction, as otherwise no increase would have been observed.

The effect of alkali on ethyl acetoacetate and acetylacetone is more complicated, new bands being developed, with high extinction coefficients varying directly as the ratio of alkali to ester up to a molecular ratio of 100 : 1.

Alkaline solutions of ethyl acetoacetate were rapidly neutralised and the bromine addition was measured immediately. Although the nature of the experiments precluded reproducible quantitative data, the concurrent increases of the alkali/ester ratio and of  $\epsilon_{(\max)}$  were accompanied by an increased capacity for bromine addition. Hence the bands at 2430 and 2725 Å. for ethyl acetoacetate, and the bands at 2750 and 2913 Å. for acetylacetone, all correspond with enolic substances.

The substitution of potassium, lithium or other metals for sodium causes a small shift in the position of maximum absorption which is roughly proportional to the atomic weight of the substituent. We can therefore infer  $\lambda_{(\max)}$  when hydrogen replaces sodium. The position of such a band for ethyl acetoacetate would be nearer 2700 Å. in alcoholic solution, *i.e.*, the enolic ester corresponding with the enolic sodium salt would display the same position of maximum absorption as the ketonic tautomeride. In acetylacetone, the normal ketonic substance has already been shown to absorb at the same wave-length as the ordinary enolic form. The hypothetical enolic form of acetylacetone would, however, show a band different from that of the ketonic form.

Much valuable work has been done in recent years leading to a ringed, chelate, co-ordinated or polar structure for the metallic derivatives of acetylacetone. From the present work, it is evident that the free enolic tautomerides are different from the metallic derivatives in a very distinct way. The free enol does not give the same band as the metallic salts. It therefore seems erroneous to picture the free enol as co-ordinated or ringed in structure (compare Lowry, *Trans. Faraday Soc.*, 1924, 18, 495, 537).

The views advanced may be subjected to a fairly rigorous test by the isolation and examination of pure ketonic and enolic tautomerides. The isolation of such forms of ethyl acetoacetate can be accomplished by aseptically distilling from evacuated quartz vessels. Unfortunately, it proved quite impossible to retain the purity of thin films of the liquids between quartz plates for the period of time necessary to secure absorption spectra photographs.

The tautomeric forms of benzoylcamphor exhibit the same frequency of maximum absorption, but differ widely in absorptive power. The molecular extinction coefficients of the ketonic form

and of camphor are of the same order (34—100), and the extinctions of the enolic modification and of dibenzoylcamphene are of the order 10,000—14,000. Addition of alkali causes the appearance of a new band, which confirms the view advanced by Lowry that the metallic salts of  $\alpha$ -benzoylcamphor are co-ordinated compounds.

### Summary of Results.

Substance.	$\lambda$ (max.).	$\epsilon$ (max.).	Remarks.
Ethyl acetoacetate, vapour .	2381	ca. 1000	No fine structure.

The following maxima have been measured for metallic derivatives of acetylacetone :

Metal.	Solvent.	$\lambda$ (max.).	Metal.	Solvent.	$\lambda$ (max.).
Cu	Alcohol	2435 and 2965	Th	Alcohol	2840
"	Heptane	2445 2970	"	Heptane	2735
Be	Alcohol	2930	"	Ammonia +	2960
Fe <sup>III</sup>	Alcohol	2730 3525 4350	"	alcohol	2960
"	Heptane	2720 3527 4340	Al	Alcohol	2893
Mg	Alcohol	2837	"	Heptane	2875

Some of the results are recorded as supplementing the work of Lowry and Desch (J., 1909, **95**, 807), Morgan and Moss (J., 1914, **105**, 189), and French (*Proc. Roy. Soc.*, 1924, **A**, **106**, 489).

The present investigation was completed before the appearance of Grossmann's work (*loc. cit.*). Whilst our experimental data are on the whole in excellent agreement with those of this investigator, some important differences may be noted. Grossmann does not record the fact that thin films of ethyl acetoacetate exhibit a band at 2430 Å., and the existence of a band in the dialkylacetoacetic esters appears to have escaped his notice.

We wish to express our thanks to the Advisory Council of the Department of Scientific and Industrial Research for maintenance grants during a part of the time occupied by the work, and to Professor E. C. C. Baly, C.B.E., F.R.S., for much guidance and encouragement.

THE UNIVERSITY, LIVERPOOL.

[Received, December 16th, 1925.]

### XCVIII. — *Absorption Spectra and Tautomerism.* *Part II. Ethyl Mesityloxidoxalate, Formylphenyl-* *acetate, and Diacetylsuccinate.*

By RICHARD ALAN MORTON and EDWARD ROGERS.

#### *Ethyl Mesityloxidoxalate.*

THREE modifications of ethyl mesityloxidoxalate have been isolated: (i)  $\alpha$ , m. p. 21°; (ii)  $\beta$ , m. p. 59—60°; (iii) a dimeric form, m. p. 175° (Federlin, *Annalen*, 1907, **356**, 261). These can be converted into one another as follows :

$\beta \rightleftharpoons \alpha$  in the dark, equilibrium being reached after about 12 weeks.

$\alpha \rightarrow \beta \rightarrow$  dimeride in diffuse daylight, with precipitation of the dimeride from most solvents.

The  $\alpha$ -form develops a red colour with ferric chloride and is undoubtedly the enolic form (I). Claisen at first regarded the

$\beta$ -form as a dihydropyrone derivative (III) (*Ber.*, 1891, 24, 116), but later he formulated it as the ketone (II).

Dieckmann (*Ber.*, 1920, 53, 1772) regards the  $\alpha$ -form as enolic, but rejects the ketonic formula for the  $\beta$ -form, on the ground that the small percentage of enol in the equilibrium mixture is not in accordance with Claisen's rule that the velocity of enolisation and the enol content of the equilibrium mixture increase with increasing acidity of the acyl groups: moreover, the  $\alpha$ -ester when distilled passes mainly into the  $\beta$ -ester. Dieckmann and von Auwers (*Ber.*, 1923, 56, 1527) regard the refractometric data for the fused material as confirming the structure (III), and Borsche and Thiele (*Ber.*, 1923, 56, 2132) find further confirmation in the fact that the catalytic hydrogenation of the  $\alpha$ -ester is more rapid than that of the  $\beta$ -ester.

This example of tautomerism is interesting in several respects.

(1) The equilibrium can be studied either as a reversible or as an irreversible one.

(2) The  $\beta$ -form can be examined under conditions such that the enolic tautomeride is excluded.

(3) The relatively slow rate of change renders the course of the reactions amenable to spectrographic investigation.

In the preceding paper definite conclusions have been drawn concerning the absorption spectra of keto-enol tautomerides. The results of an examination of ring-chain tautomerides are now recorded. We are greatly indebted to Dr. A. McGookin of this University, who suggested and synthesised the compounds of this nature.

Spectrographic evidence shows that keto-enol tautomerides exhibit absorption maxima at the same wave-length but with differing absorptive power. In the cases of pure ring-chain tautomerism without elimination of water, *e.g.*,

(IV) shows two bands at 3600 Å. and 2545 Å. and (V) shows one band at 2790 Å. Ring-chain tautomerides thus differ markedly from keto-enol tautomerides in absorption spectra.

The dimeric modification of ethyl mesityloxidoxalate shows no selective absorption and the continuous absorption is relatively feeble, so that the presence of this form does not seriously interfere with the absorption of the  $\beta$ -form in various solvents.

The  $\beta$ -form in alcohol, hexane, or chloroform shows a well-defined band of high extinction coefficient, with  $\lambda$  (max.) varying a little for the different solvents. The enolic modification shows another band of high extinction coefficient, and a less noticeable shift due to the solvent. When a solution of the  $\alpha$ -form in any of the three solvents used was kept, the position of maximum absorption shifted towards the ultra-violet and the measured absorption curve was the sum of the curves due to the  $\alpha$ - and  $\beta$ -forms.

The  $\beta$ -form in presence of alkali shows three bands at  $\lambda$  (max.) 3512, 2867, and 2450–2500 Å. The first and the third are developed when alkali is added to the  $\alpha$ -(enolic) modification and are also shown by the pure sodium derivative. If alkali is added to the  $\beta$ -form, the system will contain unchanged  $\beta$ -ester and the sodium salt of the  $\alpha$ -ester. Hence the observed curve is a summation of two curves, one with a maximum at 2825 Å. due to the  $\beta$ -ester and the other with maxima at 3510 and 2457 Å., due to the sodium derivative of the  $\alpha$ -ester.

An alcoholic solution of the  $\beta$ -compound to which a large excess of sodium ethoxide had been added was left on ice. Later it was saturated with dry hydrogen chloride, and the sodium chloride filtered off. The solution then showed only one band, namely, the 3120 band due to the enolic ester.

The spectrographic data show that the reversible  $\alpha \rightleftharpoons \beta$  isomerism of ethyl mesityloxidoxalate resembles ring-chain tautomerism rather than keto-enol tautomerism. This conclusion is in agreement with the most recent chemical evidence. The metallic derivatives are probably co-ordinated compounds.

*Ethyl Formylphenylacetate.*

Four forms of this substance have been recorded :

- (1) Liquid, b. p.  $135^{\circ}/15$  mm.; enolic.
- (2) Solid, m. p.  $70^{\circ}$ ; regarded as an aldo-form or as a geometrical isomeride of (3).
- (3) Solid, m. p.  $100-110^{\circ}$ .
- (4) Solid, m. p.  $50^{\circ}$  (Michael's modification).

Doubtless these forms are not all isomerides. Wolf (*J. Physical Chem.*, 1900, 4, 123) has shown that by keeping the ester at different temperatures for long periods it can be made to melt at any temperature between  $50^{\circ}$  and  $100^{\circ}$ , the former temperature being a stable triple point in the phase diagram. The difference in m. p. and refractivity of the various forms is due to one or more of the alternatives: (1) keto-enol tautomerism, (2) stereoisomerism, (3) unequal degrees of association. Michael and Fuller (*Annalen*, 1912, 391, 275) have adduced evidence that all the forms are unimolecular. The conclusion is drawn that only three forms exist having b. p.  $125^{\circ}/9$  mm., m. p.  $40^{\circ}$ , and m. p.  $100-103^{\circ}$ , respectively, all of which are enolic, since they react with aliphatic tertiary amines.

Wislicenus, however, after studying the isomerism of ethyl formylphenylacetate over a period of 30 years, draws the conclusion that the only two forms possessing real existence are ( $\alpha$ ), b. p.  $125-126^{\circ}/9$  mm., and ( $\beta$ ), m. p.  $103-105^{\circ}$ . All other "forms" he regards as mixtures of the  $\alpha$ - and the  $\beta$ -form. These he considers, after reviewing all the available evidence, to be *cis*- and *trans*-isomerides.

Together with his pupils he has studied the methyl formylphenylacetates and has found two modifications: ( $\alpha$ ), m. p.  $40-41^{\circ}$ , and ( $\beta$ ), m. p.  $91-93^{\circ}$ . No mixtures occur.

The  $\alpha$ -modification is undoubtedly enolic, but the  $\beta$ -form presents difficulties, since it is doubtful whether it exists as an aldo-form or as a geometrical isomeride of the  $\alpha$ -form. The two modifications react differently with copper acetate, and the  $\beta$ -form will under no conditions develop a coloration with ferric chloride. The anilides and piperidides of formylphenylacetic acid give two modifications, both of which are enolic. Michael considers that the aldo-modification has never been isolated and that much of the earlier work was misinterpreted owing to the fact that the  $\beta$ -form can add on a molecule of alcohol. For example, methyl formylphenylacetate-

methyl alcoholate is a crystalline substance, m. p. 89—92°, which does not develop a colour with ferric chloride.

Dieckmann (*Ber.*, 1917, 50, 1375) concludes that the ethyl ester exists in the pure state only as a liquid enol,  $\alpha$ , and a solid, m. p. 110°, which also is enolic.

Preparations of ethyl formylphenylacetate were examined having b. p. 127°/10 mm., m. p. 70°, and m. p. 100°, respectively. No maxima were found in the absorption curves, which were similar in extinction coefficient (order 7500 at 2600 Å.) and inflexions (2600—2100). With alkali, a definite band was obtained with a maximum at 2740 ( $e$  max. 19,200, 22,200, 16,800).

The interpretation of these results is somewhat difficult. Although ketones show well-defined maxima, in this substance the carbonyl group is a part of the formyl radical, so that the absence of the ketonic band does not prove the non-existence of an aldo-form. The data do not show the very large variations of  $e$  which are observed in keto-enol tautomerism. The absorptive powers of *cis*- and *trans*-isomerides (Errara and Henri, *Compt. rend.*, 1925, 181, 549) for a given wave-length are in the ratio 1 : 1—2, generally near 1.0—1.2. This is precisely the kind of variation observed in ethyl formylphenylacetate. Hence the spectrographic data strongly support the conclusion that the isomerism of this substance is of the *cis*- and *trans*-variety.

### *Ethyl Diacetylsuccinate.*

The isomerism of this ester has been the subject of much controversy. Two definite modifications were isolated and examined spectrographically :

Isomeride, m.p. 92°;  $\lambda$  (max.) = 2490,  $e$  (max.) 7600.

Isomeride, m. p. 31°;  $\lambda$  (max.) = 2490,  $e$  (max.) 6250.

With alkali both forms exhibit a band at  $\lambda = 2750$  ( $e$  max. varying with the alkali/ester ratio).

The two substances provide an interesting comparison with ethyl acetoacetate :

	Acetoacetate.	Diacetylsuccinate.
Enol band .....	2430Å.; $e$ , 10,000	2490Å.; $e$ , 7600 6250
Keto band .....	2700Å. app.; $e$ order 100.	unknown.
Co-ordinated sodium salt	$\lambda$ (max.) 2725.	$\lambda$ (max.) 2750.
Ratio of extinctions .....	enol/keto = 100 : 1 (order)	m.p. 92°/m.p. 31° = 1.22.

The following results are from Henri and Errara's work. The

figures denote the ratio of  $\epsilon$  for the *trans*-isomeride to  $\epsilon$  for the *cis*-isomeride at the wave-lengths cited.

(a) Ethyl  $\alpha$ -mesityloxidoxalate in alcohol. (b) Ethyl  $\beta$ -mesityloxidoxalate in alcohol. (c) Ethyl diacetylsuccinate, *m. p.* 92°, in alcohol. (d) Ethyl diacetylsuccinate, *m. p.* 31°, in alcohol.

Substances.	$\lambda$ 2520Å.	$\lambda$ 2410Å.
CHCl:CHCl	1.4	2
CH <sub>2</sub> Et:CHBr	1.15	1.2
CHMe:CHBr	1.5	1.5
CHI:CHCl	1.3	1.25

Hence the data provide strong support for the view that the isomerism of ethyl diacetylsuccinate is of the *cis-trans* type.

One of us (E. R.) wishes to express his gratitude to the Advisory Council of the Department of Scientific and Industrial Research for a maintenance grant. We are very grateful to Professor E. C. C. Baly, C.B.E., F.R.S., whose advice and encouragement have been of great value to us.

THE UNIVERSITY, LIVERPOOL.

XCIX.—*Absorption Spectra of Mesityl Oxide.*

By RICHARD ALAN MORTON.

HARRIES (*Ber.*, 1899, **32**, 1329; *Annalen*, 1904, **330**, 189) has stated that when mesityl oxide was shaken for 36 hours with a 40% solution of sodium bisulphite, 30% of the material remained unchanged. The residue obtained after shaking five times with fresh solutions of sodium bisulphite showed a refractive index and a density differing in the third decimal place from those of the original ketone. It appeared, nevertheless, to be mesityl oxide, since it yielded the same *cis*- and *trans*-oximes. Since the mesityl oxide regenerated from the bisulphite compound reacted completely with fresh sodium bisulphite, Harries concluded that the phenomena were not due to tautomeric equilibrium but to a new type of isomerism. Experiments were therefore made in order to determine whether the absorption spectrum of the inactive form differs from that of ordinary mesityl oxide.

Mesityl oxide synthesised from acetone by means of hydrogen chloride proved to be spectroscopically identical with the redistilled commercial material, b. p. 128°, which was used in an attempt to repeat the work of Harries. The results were as follow :

- (1) The whole of the mesityl oxide reacted with sodium bisulphite.
- (2) The yield of double compound was practically quantitative.
- (3) The ketone regenerated from the bisulphite compound was identical with the original product in respect of (a) boiling point, (b) absorption spectrum in the liquid state, (c) absorption spectrum in alcoholic solution.

(4) Earlier results (Henri and Bielecki, *Compt. rend.*, 1914, **158**, 567, 866, 1022; Purvis and McClelland, *J.*, 1913, **103**, 433) were confirmed.

(5) Four distinct absorption bands were found. Shifts due to solvent occurred, but none due to vapour-liquid, the pure liquid ketone showing the same frequency of maximum absorption as the vapour.

*Summary of Data.*

	$\lambda$ max. Å.	Present work.	Other work.
		$\epsilon$ max.	
Vapour .....	3239	low	Purvis and McClelland found $\lambda$ max. = 3238.
Liquid .....	3240	58	—
Alcoholic solution .....	3130	55	Henri and Bielecki found max. = 2380.
	2380	14,000	
Aqueous solution .....	2440	11,000	—
Hexane solution .....	3272	56	—
	2348	14,000	2335
Heptane solution .....	3275	50	—
	2330	14,000	—

It must be concluded that some unrecorded factor entered into the work of Harries.

I wish to express my thanks to Professor E. C. C. Baly, C.B.E., F.R.S., for his interest and advice.

THE UNIVERSITY, LIVERPOOL.

[Received, December 16th, 1925.]

C.—*Studies of Dynamic Isomerism. Part XXI. The Velocity of Mutarotation of Tetramethylglucose and of Tetra-acetylglucose in Aqueous Acetone.*

By GRIFFITH GLYN JONES and THOMAS MARTIN LOWRY.

ALTHOUGH it has long been known that water is an effective catalyst for the mutarotation of the sugars, even apart from the presence of basic or acidic impurities (see Part I, J., 1903, **83**, 1314), there was until recently no clear picture available as to the way in which the water intervenes in order to determine the changes of structure which give rise to the observed changes of rotatory power. In particular, although it was known that the formation of a hydrate does not bring about any marked alteration of the rotatory power of  $\alpha$ -glucose, and cannot therefore be a direct cause of the mutarotation of this sugar (Part III, J., 1904, **85**, 1551), there were no experimental data to show how the subsequent molecular rearrangement of the hydrate was effected. It was suggested, however, in a recent paper (Part XVIII, J., 1925, **127**, 1371) that there is a marked analogy between the conditions under which mutarotation occurs and those which are used to promote the hydrolysis of an ester, and that, since mixtures of acids and bases with water are even more efficient catalysts than water itself, the action of the water probably depends on its amphoteric properties. If this view were correct, any solvent which can accept a proton from the sugar, and return it to the sugar residue, might act as a complete catalyst for the mutarotation. This conclusion has been verified (Part XX, J., 1925, **127**, 2883) by the discovery that an anhydrous mixture of pyridine and cresol is an excellent catalyst for the mutarotation of tetramethylglucose.

The experiments now described were undertaken in order to secure information in reference to solvents which appear to diminish the catalytic activity of water instead of increasing it. The choice of acetone as a diluent was dictated by the fact that Irvine (J., 1913, **103**, 584) has found it to be a particularly easy solvent in which to effect an arrest of mutarotation in a methylated sugar. It was thought that this might be due to some restraining action of the

acetone upon the water or upon the other impurities which give rise to mutarotation in inert solvents. We therefore anticipated that, when mixed with water in various proportions, acetone would reduce the catalytic activity of the water more rapidly than its total concentration. The results recorded in Tables I and II show that this anticipation was amply fulfilled. Thus in a 50% mixture of acetone and water the velocity of mutarotation of tetramethylglucose is only about 20% of that in pure water. The water in this solution has therefore less than one-half of its normal activity in the free state.

We have also compared the velocity coefficients in Tables I and II with the partial vapour pressures of aqueous acetone at 30° as recorded by Makovetzki (*J. Russ. Phys. Chem. Soc.*, 1908, 40, 226),

FIG. 1.

but can find no indication of any parallelism between them. In particular, the velocities shown in the figure appear to rise progressively from the origin at 0%  $\text{H}_2\text{O}$ , where the curves are perhaps tangential to the horizontal axis, whilst the dotted curve which shows the partial vapour pressure of water is inflected in the normal fashion for mixtures showing strong positive deviations from Raoult's law of lowering of vapour pressure. We therefore conclude that the catalytic activity of the water, which is obviously not proportional to its total concentration, is also not a simple linear function of its activity as measured by its partial vapour pressure above the solution.

#### EXPERIMENTAL.

The physical constants of the tetramethylglucose used in these experiments have already been given (*J.*, 1925, 127, 1387, footnote);

they are in close agreement with those recorded by Irvine. The purity of the sample is, however, guaranteed even more effectively by the arrest of mutarotation observed in several inert solvents; moreover, the mutarotation constants of the sugar were not altered appreciably by three further crystallisations from ether and from petrol:

	Initial.	Specific rotation, $[\alpha]_{5461}$ .		Vel. coeff.
		Final.	Ratio.

After                    " .....	115	94	1.23	0.0124

The tetra-acetylglucose was prepared for us by Messrs. Boots Pure Drug Co., Nottingham, to whom we wish to express our thanks for their generous gift. The substantial purity of the specimen was established by analysis, but we have not been able to find any trustworthy figures for the physical constants of the compound. The melting point, 118°, given by Fischer and Delbrück (*Ber.*, 1909, 42, 2779) has no clear significance, since prototropic compounds have two different melting points, according as time is allowed for isomeric change to take place or not. In the case of tetra-acetylglucose we find that the true melting point, at which the compound melts in about 10 seconds when plunged into a bath heated to a known temperature, is 123°, as recorded by a standardised Anschütz thermometer graduated to 0.2°; and that the "equilibrium temperature" (Lowry, J., 1899, 75, 233), at which the compound melts or re-melts when heated slowly, is 110°. Since a small specimen of tetra-acetylglucose given to us by Professor Haworth melted at the same temperatures, within less than a degree in each case, we feel justified in putting forward these temperatures as provisional standards, which can be verified by comparison with values recorded in the future for other specimens of the purified sugar. The rotatory powers given by Fischer and Delbrück,  $[\alpha]_D^{20} = +2.19^\circ$  to  $+82.7^\circ$ , were apparently determined at room temperature, with unpurified sodium light, and in alcohol of unspecified water content. We have not attempted to make any exact comparison with these uncertain data, but in our opinion the value  $[\alpha]_{5461} = +6^\circ$  for a 5% solution of tetra-acetylglucose in pure anhydrous acetone at 20° can be accepted provisionally as a characteristic constant of the unchanged sugar, since this value is permanent over a period of several hours. As in the case of tetramethylglucose, the purity of the sample used in our experiments was established most satisfactorily by the complete arrest of mutarotation which we have observed repeatedly in solutions of the sugar in an inert solvent. Since the suggestion has been made that the mutarotation of tetra-acetylglucose in aqueous acetone may be due in part to hydrolysis instead of to isomeric change, we have made direct experiments to test this point, but could

not detect any hydrolysis after a week at a temperature of about  $18^{\circ}$ ; after 10 days, the proportion of sugar hydrolysed was only of the order of 0.5%. After 7 months, the residues from the original experiments were hydrolysed to the extent of only 5%. The hydrolysis of the sugar can therefore have had no perceptible influence on the velocity of mutarotation, a conclusion which we had already anticipated from the steadiness of the observed end-points, since it was incredible that hydrolysis (as well as isomeric change) could be complete in the course of a few hours or days.

The acetone had been purified through the compound with sodium iodide (J., 1913, 103, 1255). The solutions were prepared by dissolving about 1 g. of tetramethylglucose, or 0.5 g. of tetra-acetylglucose, in 20 c.c. of an aqueous acetone made up by weighing. Tetramethylglucose was examined over the whole range of concentrations from 0 to 95% of acetone, but tetra-acetylglucose is almost insoluble in water and only slightly soluble in water containing 5% of acetone. A solution of the latter concentration was prepared by dissolving the sugar in acetone and adding the necessary quantity of water; but the constants of the mutarotation curve were unsatisfactory, and the values for this solution have not been included in the table. The very slow mutarotations in acetone containing only traces of water were not included in the present research. In order to economise space, all the individual readings have been omitted, but the unimolecular velocity coefficients for the various solutions are set out in Tables I and II, and are shown graphically in the figure.

## CI.—*Absorption Spectra of Condensed Nuclear Hydrocarbons.*

By NORMAN STEWART CAPPER and JOSEPH KENNETH MARSH.

It was shown recently that visible absorption bands attributed to anthracene were due to an impurity, chrysogen (*J. Amer. Chem. Soc.*, 1925, 47, 2847). It has now been found that other coal-tar hydrocarbons have been insufficiently purified for spectroscopic examination. Thus the four chief hydrocarbons boiling between 275° and 360° cannot be separated by crystallisation, as they appear to form mixed crystals. In particular, fluorene and phenanthrene retain traces of anthracene, which can be detected by its intense ultra-violet absorption. The absorption bands of the purified substances exhibit constant frequency differences, which have been attributed to the double carbon bond in the aromatic series (Marsh, *Phil. Mag.*, 1925, 49, 971, 1206). Other synthetic hydrocarbons also have been examined.

*Purification of Phenanthrene and Fluorene from Anthracene.*—A good commercial phenanthrene showed anthracene bands of an intensity corresponding with a content of about 16%, and this was not greatly reduced by fractional crystallisation. The melting point gives no trustworthy information as to the purity. In the fluorene used, the anthracene content was not more than 1 or 2%.

Purification of both substances was effected by refluxing a strong xylene solution by the heat from a silica mercury vapour lamp. The light caused the anthracene present to polymerise, even in glass vessels. Owing to its very slight solubility, the dianthracene produced was readily separated, but since anthracene and dianthracene attain to an equilibrium repeated light treatments and separations were necessary. About 1% of anthracene was thus eliminated from Kahlbaum's "purest reagent" phenanthrene. The spectra of the purified products examined in concentrated chloroform solutions indicated an anthracene content of about 0.01% in the phenanthrene and 0.001% in the fluorene. The melting point of the fluorene was 114–114.5°, a value higher than that commonly accepted. The phenanthrene melted at 98°. The higher values usually quoted probably result from the eutectic mixture with anthracene containing very nearly 100% of phenanthrene. The purified material in both cases lost its visible fluorescence, even in strong actinic light, or in the case of phenanthrene at most only a slight trace remained.

The absorption spectra were studied with a Hilger spectrophotometer and condensed copper spark. Little description will be

necessary if the absorption curves, the photographic reproductions, and the table of band positions are examined.

*Phenanthrene*.—Previous spectroscopists have used specimens containing from 0.3% (Baly and Tuck, J., 1908, 93, 1902) to upwards of 10% of anthracene, masking completely the true spectrum, which in the region above 3000 Å. is some 25 times weaker than that of anthracene. Probably the small narrow band recorded at about  $1/\lambda 4000$  is due to the remaining trace of anthracene, and a very faint band at  $1/\lambda 3120$  to acenaphthene.

*Fluorene*.—A band found at  $1/\lambda 3117$  may be ascribable to the presence of 1% of acenaphthene.

*Anthracene, 9-phenylanthracene, and 1:2-benzanthracene* have very similar spectra. Relatively to those of anthracene, 9-phenylanthracene has its bands shifted about 60 units towards the visible spectrum, and they are not so distinct. In 1:2-benzanthracene, the weaker member of each pair appears on the red side of the strong band, but the first pair is very weak. In the middle ultra-violet, bands corresponding to those found in phenanthrene are seen. The structure may be regarded as 2:3-benzphenanthrene.

On examining anthracene vapour (20 cm.) at 50° to 120°, both of the strongest bands were seen to have a weak neighbour on each side, and there was also a faint band midway between the two strong ones. The bands were shifted almost 100 units with respect to their solution positions.

*Octahydroanthracene* lacks entirely the set of bands above  $\lambda 3000$  found in anthracene, but has several at about  $1/\lambda 3500$  to 3700, i.e., in the same region as those in other alkyl derivatives of benzene.

*Bisdiphenylene-ethylene*,  $(C_6H_4)_2C:C(C_6H_4)_2$ , showed only a broad band in the blue region, an undeveloped one at about  $1/\lambda 3600$ , and another at about 4100.

*Chrysogen*.—This substance of unknown structure occurring in small quantities—probably less than 0.1%—in most samples of anthracene has an anthracene nucleus, since it is capable of polymerising similarly to anthracene itself. Its spectrum is distinctly of the polynuclear hydrocarbon type. In fused anthracene the band positions are 60–80 Å. nearer the red end of the spectrum.

*Other Polynuclear Hydrocarbons*.—In the substances examined, except fluorene and octahydroanthracene, every carbon atom has an unsatisfied valency, and except for bisdiphenylene-ethylene the unsaturation is entirely aromatic in character. Leaving aside these three, the chief feature of the spectra is a series of rather narrow bands between  $\lambda 3000$  and 4000, which show a constant frequency difference of about 142 waves/mm. Previous workers have examined other hydrocarbons which come into the same

category. These substances also exhibit narrow bands, although the interval may vary. The absorption bands of benzene vapour are spaced 92.4 units apart (Henri, *J. Phys. Radium*, 1922, 3, 181) and the emission bands at 98.7 unit intervals (J., 1923, 123, 642). Naphthalene vapour shows a long series of bands, both absorption (Henri and László, *Proc. Roy. Soc.*, 1924, A, 105, 662) and emission (Dickson, *Z. wiss. Photochem.*, 1912, 10, 166), at 47.4 unit intervals. The emission spectrum shows every third band stronger than its neighbours, making an interval of 142 as in anthracene, etc. Baly and Tuck found in chrysene (J., 1908, 93, 1902) four bands as nearly as can be determined at 140 unit intervals. A partial examination of picene, 2:3:6:7-dibenzanthracene, and  $\beta\beta$ -dinaphthyl was made by Homer and Purvis (J., 1908, 93, 1319).

## TABLE OF BANDS.

The figures are oscillation frequencies, and in italics are the frequency intervals. Small bands detected but difficult to locate accurately have been omitted.

Bisdiphenylene-ethylene.	2190	3610	4130	(All broad and indefinite)			

Benzene and the other eight condensed nuclear hydrocarbons all have the same type of multiple narrow-banded spectra, the main intervals being generally 142 units in the heavier molecules, 142 or 142/3 in naphthalene, and  $142 \times \frac{2}{3}$  in benzene. The simple methyl and other derivatives may also give spectra consisting of

Phenanthrene. 1 cm.  $M/200$ .

Anthracene. 1 cm.  $M/5000$ .

1:2-Benzanthracene.  
1 cm.  $M/5000$ .

9-Phenylanthracene.  
1 cm.  $M/5000$ .

Chrysogen in 4 cm. of  
 $M/10$ -anthracene.

Naphthalene. 1 cm.  $M/5000$ .

Benzene. 1 cm.  $M/200$ .

a number of narrow bands, but the regularity and sharpness are usually less marked, *e.g.*, László (*Z. physikal. Chem.*, 1925, **118**, 369) finds band series at the intervals 154, 142.5, 147, and 138, for 1-methyl-, 2-methyl-, 2:7-dimethyl-, and 2:6-dimethylnaphthalene, respectively. In phenanthrene alternate bands are similar and show the interval 142, the intermediate ones being not quite centrally situated.

FIG. 1.

Besides the series of five or six bands already mentioned, most of the substances give other bands farther in the ultra-violet and of greater intensity. There is usually one well marked, with, on the more refrangible side, other less distinct bands, again at intervals of 142 units. Phenanthrene and 2:3-benzphenanthrene (1:2-benzanthracene) have also a third intermediate region.

#### Discussion of Results.

By removing all anthracene from phenanthrene and fluorene, entirely new absorption curves for these two substances have been found. Fluorene now gives a spectrum similar to that of *o*-xylene or other simple substituted benzene derivative. Phen-

anthrene presents a spectrum differing from that of anthracene in strength, band position, and arrangement. Hyatt (*Physical Rev.*, 1922, 19, 391), employing the same methods as ours, measured 16 bands for anthracene. Three of these not now observed were possibly due to phenanthrene. We do not find that the remainder can be divided into a series at intervals of 147 and another at 142. Both our series run at intervals of 142. The spectral type of bisdiphenylene-ethylene differs completely from that of the other polynuclear hydrocarbons. The strong red colour is associated with the ethylenic bond, disappearing on its reduction, and it constitutes with its neighbours the characteristic system of the visibly coloured fulvenes, .

The spectrum of stilbene, the simplest example of a substance containing an ethylenic bond between benzene nuclei, consists of a single broad band at about  $\lambda 3300$ : in phenanthrene this double bond becomes aromatic, and half-a-dozen narrow bands occupy the same region. Thus the effect of an ethylenic bond is to cause the fusion of the aromatic bands. Another substance having an absorption curve very similar to those of bisdiphenylene-ethylene and stilbene and in a position intermediate between them was examined by Purvis and Homer (J., 1909, 97, 1155). It was a product of the reaction between tetrabromoethane and naphthalene. They concluded, largely on spectroscopic evidence, that it was 1:2:7:8-dibenzanthracene. Its spectrum, however, is entirely different from what we have found for 1:2-benzanthracene and would be the only deviation from the type characteristic of the class of substances to which their formula would relegate it. Ethylene dibromide and naphthalene were considered to give rise to *s*-di- $\alpha$ -naphthylethane (I), which then broke down to picene. Tetrabromoethane and naphthalene might therefore give rise to the substance (II), and this would be much more likely to give a spectrum with broad bands than would a substance having the suggested formula (III).

*Relationship to Infra-red Spectra.*—It does not seem possible to offer any detailed explanation of the differences which make all these closely related spectra individually characteristic, but the cause of the similarity constituting the spectral type found in this

group of hydrocarbons must be some common factor, and therefore one or more of the following: (a) a benzene ring, (b) a  $C \equiv C$  linking, (c) a  $CH$  group. These possibilities will be considered with reference to the known features of the infra-red spectra of these or similar substances. Coblenz (*Carnegie Inst. Publication*, No. 35, 1905), from a study of some thirty hydrocarbons, concluded that characteristic absorption maxima due to methyl and methylene groups are found at 3.43, 6.86, 13.6—13.8, and 14  $\mu$ . Weniger (*Physical Rev.*, 1910, **31**, 388) gives also a band at 7.3  $\mu$ . In the aromatic series, Coblenz gives the following bands as characteristic of benzene: 3.25, 6.75, 8.68, 9.8, 11.8, and 12.95  $\mu$ . The first two and the last are identifiable with bands in hydrocarbons of the aliphatic series, but, owing to the unsaturation of the carbon atom of the  $CH$  group, their frequency is increased somewhat. Thus the 3  $\mu$  band has the value 3.08 for acetylene, 3.25 for benzene, 3.28 for ethylene, and 3.39 for ethane.

The strongest bands of ethylene are:

$\lambda$ .....	(21)	10.5	6.98	5.3	3.28
$1/\lambda$ .....	(47.6)	95.24	143.3	188.9	304.9
Diff. ....		47.6	48.1	45.6	—

Except the last, these are evidently multiples of a band which should occur at  $1/\lambda 47.6$ , and may be considered as due to  $C:C$ . In benzene vapour, is a series of bands at intervals of 15.9, *i.e.*, 47.6/3; in naphthalene, the series interval is 47.4 and in the heavier hydrocarbons 142, *i.e.*,  $47.4 \times 3$ . The ethylene band 6.98  $\mu$  occupies also the position of a  $CH$ -band. The fifteen aliphatic hydrocarbons examined by Coblenz show, as consistently the most prominent in their spectrum, two bands at about 6.86 and 7.33  $\mu$ . The frequencies (145.8—136.4 waves/mm.) are just what are found to be the intervals between the ultra-violet bands of the polynuclear hydrocarbons. Experimental difficulties have prevented thorough investigation of the infra-red spectra of the solid aromatic hydrocarbons. Stang (*Physical Rev.*, 1917, **9**, 342), however, has examined naphthalene and several of its derivatives and finds a band at 7.19  $\mu$  ( $1/\lambda 139.1$ ) to be among the strongest in the spectrum. It remains therefore an open question as to whether this common frequency difference is due to  $CH$  or  $C:C$ , but probably it is a frequency to which both can resonate and for this cause it dominates the infra-red and ultra-violet spectra. Indeed, if any sort of harmonic motion is to be preserved in the molecule, it is necessary that different oscillations should be in tune with one another, and that the relative frequencies must be expressible as whole numbers.

We are much indebted to Mr. E. de B. Barnett for supplying very pure samples of the three anthracene derivatives examined.

THE SIR DONALD CURRIE LABORATORIES, QUEEN'S UNIVERSITY,  
BELFAST, NORTHERN IRELAND. [Received, December 5th, 1925.]

## CII.—*The Interaction of Nitric Oxide and Hydrogen and the Molecular Statistics of Termolecular Gaseous Reactions.*

By CYRIL NORMAN HINSHELWOOD and THOMAS EDWARD GREEN.

THE only known termolecular gaseous reactions are :

We have succeeded in measuring a homogeneous change between nitric oxide and hydrogen in the region of 1100° Abs., which proceeds in accordance with the equation

$$-d[\text{NO}]/dt = k[\text{NO}]^2[\text{H}_2] \quad . \quad . \quad . \quad (1)$$

and is thus termolecular.

The ultimate result of the interaction being expressed by the equation

it must be supposed that the action takes place in stages thus,

the second stage in either of the alternatives being a rapid reaction subsequent to the main change of which the speed is measured.

There are reasons why this new reaction possesses considerable interest. These may be briefly outlined as follows.

The majority of known gaseous reactions are bimolecular. The application of the kinetic theory of gases leads to a simple explanation of these. The molecules which react are those which collide while they possess the "energy of activation," which can be found from the temperature coefficient of the reaction velocity. When the total number of collisions taking place in unit time is multiplied by  $e^{-E/RT}$ , a fraction representing the chance that the energy of the colliding molecules shall exceed the energy of activation,  $E$ , a number is obtained which is very nearly equal to the number of

molecules which actually undergo chemical transformation. Thus the possession of the energy of activation seems to be the only important factor in bimolecular reactions. Since the number of collisions depends on the molecular diameter, and since all molecular diameters are of the same order,  $10^{-8}$  cm., the rate of a bimolecular change is chiefly determined by the value of  $e^{-E/RT}$ . We find, therefore, that different bimolecular reactions attain approximately equal rates at temperatures which make  $E/RT$  respectively the same for each (Hinshelwood and Hughes, J., 1924, 125, 1841; Hinshelwood and Thornton, *Phil. Mag.*, 1925, 50, 1135).

A bimolecular gaseous reaction which takes place with conveniently measurable velocity in the neighbourhood of  $350^{\circ}$  Abs. will have a heat of activation of about 20,000 calories, at  $700^{\circ}$  Abs. about 40,000 calories, and one which attains an equal speed at  $1000^{\circ}$  Abs. will have a value of about 60,000 calories. No exception is known to this rule, so that if we know the rate of a bimolecular reaction at a given temperature we can form a fairly accurate estimate of the heat of activation.

From the point of view of the molecular statistics of chemical change termolecular reactions are of special interest, since they depend on the rather rare event of a collision between three molecules. Bodenstein estimates the frequency of termolecular collisions to bear about the same proportion to the frequency of bimolecular collisions as the molecular diameter bears to the mean free path. At atmospheric pressure, the mean free path is of the order  $10^{-5}$  cm., and since the molecular diameter is of the order  $10^{-8}$ , ternary collisions should be about 1000 times less frequent than binary collisions. Thus if we have a bimolecular reaction and a termolecular reaction with equal heats of activation, the rate of the termolecular reaction should be at least 1000 times smaller than that of the bimolecular reaction at the same temperature. It will probably be more than 1000 times slower, since a considerable number of the ternary collisions are likely to be ineffective simply on account of unfavourable orientation of the molecules during impact. Taking this into consideration, it appears that the factor may be nearer 10,000.

Conversely, if a termolecular reaction and a bimolecular reaction were to take place at equal rates at the same temperature, then the heat of activation of the termolecular reaction would need to be the smaller by an amount  $\Delta E$ , such that  $e^{\Delta E/RT} = 1000$  to 10,000. Thus, other things being equal, the heats of activation of termolecular reactions ought to be about 5000 calories less at the ordinary temperature and about 15,000 calories less at  $1000^{\circ}$  Abs. than those of bimolecular reactions.

A bimolecular reaction which would take place at a rapid but measurable rate at the ordinary temperature would have a heat of activation of 12,000 to 15,000 calories, a termolecular reaction might therefore be expected to have one of 5000 to 10,000 calories. This would mean a very small temperature coefficient. Another factor enters, however, in this case, for Bodenstein found that the reaction  $2\text{NO} + \text{O}_2 = 2\text{NO}_2$ , instead of having a small positive temperature coefficient, had actually a very small negative temperature coefficient. This he attributed to the diminished "duration of collisions" at higher temperatures, which decreases the chance that two molecules shall still be within molecular distance of each other when a third approaches to complete a ternary collision. This factor is enough just to invert the small positive temperature coefficient which would otherwise be found. The other two termolecular reactions have in fact very small positive temperature coefficients. This new factor, therefore, is equivalent to the reduction of the apparent heat of activation by 5000 calories or so.

Trautz has an alternative explanation of Bodenstein's result. The reaction is supposed to be a bimolecular one between  $\text{N}_2\text{O}_2$  and  $\text{O}_2$ . But since  $[\text{N}_2\text{O}_2]$  is proportional to  $[\text{NO}]^2$ , the reaction is kinetically termolecular. The negative temperature coefficient is due to the increasing dissociation of  $\text{N}_2\text{O}_2$  at higher temperatures. The apparent heat of activation would thus be equal to the difference between that of the bimolecular reaction between  $\text{N}_2\text{O}_2$  and  $\text{O}_2$  and the heat of dissociation of  $\text{N}_2\text{O}_2$ ; and actually this difference comes out to be a small negative quantity.

Whichever way of regarding the matter is preferred—and there is not really much difference between the transitory existence of  $\text{N}_2\text{O}_2$  and a collision of finite duration between two molecules of NO—it is clearly of interest to examine the behaviour of a termolecular reaction which takes place at a much higher temperature, say in the neighbourhood of  $1000^\circ \text{Abs}$ . A bimolecular reaction which proceeded at a conveniently measurable speed at this temperature would have a heat of activation of approximately 60,000 calories. A termolecular reaction should therefore have one about 20,000 calories less.

The predicted heat of activation is thus about 40,000 calories. We find actually the heat of activation of the termolecular reaction between nitric oxide and hydrogen to be 44,000 calories. This result seems to show that termolecular reactions can be interpreted satisfactorily in terms of the simple kinetic theory, and to provide further evidence that the energy of activation is a quantity with a real physical meaning.

It is perhaps significant that the four termolecular reactions now

known all involve the participation of two molecules of nitric oxide. It may be simply coincidence, or it may be that the "duration of collision" is greater in encounters between molecules of nitric oxide than in encounters between other molecules, so that there is more chance of the third molecule arriving in time. Some may prefer to call this phenomenon, assuming it to be a real one, formation of  $N_2O_2$ .

*Preparation of the Gases.*—The hydrogen used was electrolytic and was purified from oxygen by passage over a hot platinum wire; it was then dried with phosphoric oxide. The nitric oxide was prepared in a state of purity by the "nitrometer" reaction and stored in contact with concentrated sulphuric acid in the vessel in which it was made.

*Apparatus and Method of Measurement.*—Since the reaction is attended by a decrease in pressure, a simple manometric method can be employed. It is necessary, however, to prevent the condensation of the steam which is produced. This was done in the following way. The reaction vessels were of clear fused silica, 260 c.c. and 155 c.c. in capacity, respectively. The bulb was sealed to a long T-piece of fine silica capillary tube, which communicated with the manometer. The whole of this T-piece was heated to about  $140^\circ$ . Under these conditions, when the reaction took place in the heated bulb, no water vapour diffused through the length of capillary tube and condensed in the cooler part of the apparatus such as the capillary of the manometer itself. The silica capillary tube was joined to the glass parts of the apparatus by means of stout rubber joints. It was arranged that the silica and the glass made good contact beneath the joints, and careful observation showed that no disturbance of any kind arose from the presence of these. They were quite cold. The escape of hydrogen through the walls of the silica bulb at the temperature of the experiments was known from independent experiments to be negligible.

The arrangement of the apparatus is obvious from Fig. 1. *A* is the reaction bulb, heated in an electric furnace, the temperature of which was controlled by a thermo-couple and kept constant to about a degree by hand regulation of the heating current. The thermo-couple was standardised as described in previous papers (J., 1924, 125, 393). *B* is a reservoir in which the gases could be mixed before being allowed to stream into the reaction vessel. In some of the experiments it was omitted.

It was ascertained by direct experiment that the reaction tended asymptotically to the theoretical "end-point" and that diffusion of water vapour from the heated region did not occur during the time of an ordinary experiment.

*Kinetics of the Reaction.*—The main series of experiments were made at  $826^{\circ}\text{C}$ . This approaches the highest temperature at which experiments can be made accurately. The conclusions drawn about the nature of the reaction are as follows. It is almost entirely homogeneous at higher pressures, and is of the third order, its rate being proportional to the square of the pressure of the nitric oxide and to the first power of that of the hydrogen. At lower pressures, where the reaction is slower, it is less exactly of the third order, and, moreover, the straight line obtained by plotting the initial rate of reaction against the pressure of hydrogen does not pass exactly through the origin. These facts indicate that a certain amount of heterogeneous reaction takes place concurrently with

FIG. 1.

the homogeneous reaction. The heterogeneous change, as would be expected from the strong adsorption of hydrogen by silica, is probably almost independent of the hydrogen pressure. This assumption would explain also the failure of the reaction to follow the equation of a third-order reaction exactly at the lower pressures. These conclusions are confirmed by the addition of powdered silica to the reaction vessel to test for the existence of a surface reaction. There was found to be some, but it accounted for a small fraction only of the total change.

The results were very satisfactorily reproducible. For example, experiments 4, 5, and 31 of the whole series, which were made with the same pressures of nitric oxide and hydrogen, respectively, gave almost exactly superposable curves. This is in pleasing contrast with what is found when the reaction is one which takes place on the surface of the silica. A typical experiment is recorded below and others are shown in the curves of Fig. 2.

Temp. 826°. Initial pressure of NO = 406 mm. Initial pressure of  $H_2$  = 289 mm.,  $t$  is the time in seconds, and  $x$  the change of pressure in mm.

$t$ .....	8	13	19	26	33	43	54	69	87	110	140	204	310	$\infty$
$x$ .....	10	20	30	40	50	60	70	80	90	100	110	120	127	144.5

*The Order of the Reaction.*—The following experiments were made with equimolecular amounts of nitric oxide and hydrogen.  $\tau$  is the time in seconds required for half the reaction to complete itself,

FIG. 2.

Interaction of nitric oxide and hydrogen at 826° C.

Since the rate of reaction depends upon the square of the NO concentration but the first power only of the  $H_2$  concentration, a high pressure of nitric oxide has much more effect than a high pressure of hydrogen.

$a$  is the initial pressure in mm. of each gas, and  $n$  is the reaction order calculated from the equation  $(a_1/a_2)^{n-1} = \tau_2/\tau_1$ .

$a_1$ .	$\tau_1$ .	$a_2$ .	$\tau_2$ .	$n$ .
354	81	202	224	2.81
340.5	102	288	140	2.89
340.5	102	243	176	2.62
375	95	251	180	2.60

The reason why  $n$  falls a little under 3.0 will be discussed below.

*Influence of the Pressure of the Separate Gases.*—(a) *Nitric oxide.* Experiments were made in which a fixed initial pressure of hydrogen was used and various initial pressures of nitric oxide. Curves were plotted on a large scale and the initial rate of reaction was found by drawing tangents. The following figures show that the rate is

proportional to the square of the nitric oxide concentration. The initial pressure of hydrogen was 400 mm. in each instance.

[NO]. (mm.).	[NO]. Relative.	[NO] <sup>2</sup> . Relative.	Rate of reaction. (mm./100 sec.).	Rate of reaction. Relative.
359	2.38	5.57	150	6.00
300	1.98	4.12	103	3.92
152	1.00	1.00	25	1.00

A corresponding series of experiments made with a fixed initial pressure of hydrogen equal to 300 mm. gave the results

[NO]. (mm.).	[NO]. Relative.	[NO] <sup>2</sup> . Relative.	Rate of reaction. (mm./100 sec.).	Rate of reaction. Relative.
400	1.73	3.00	174	3.86
310	1.34	1.80	92	2.05
232	1.00	1.00	45	1.00

(b) *Hydrogen*. In one series of experiments the initial pressure of nitric oxide was 400 mm.

[H <sub>2</sub> ]. (mm.).	[H <sub>2</sub> ]. Relative.	Rate of reaction (mm./100 sec.).	Rate of reaction. Relative.
289	1.97	160	2.02
205	1.39	110	1.39
147	1.00	79	1.00

In the second series, the pressure of nitric oxide was 300 mm. [The reaction is slower in the ratio  $(300/400)^2$  for equal hydrogen pressures.]

[H <sub>2</sub> ] .....	404	302	244	147	117	104
Rate of reaction .....	103	85	72	59	52	45

These figures give a straight line when plotted, but the line does not pass exactly through the origin. The explanation of this lies in the fact that there is a small amount of surface reaction nearly independent of the pressure of hydrogen. This is what makes the experimentally determined order of reaction slightly less than 3.0. The effect is scarcely noticeable when there is a high pressure of nitric oxide, so that the speed of the gas reaction is great.

*Influence of the Reaction Products.*—We propose to investigate further the influence of inert gases on the rate of reaction. A preliminary investigation of the effect of the reaction products, steam and nitrogen, was made in the following way. Pairs of experiments were selected in which the nitric oxide and hydrogen were present in equimolecular proportions. A curve showing the amount of change at different times was first plotted from the results of the experiment in which the initial pressure was the greater. A point on this curve could be found at which the pressures of unchanged nitric oxide and hydrogen were the same as the initial pressures in the experiment with smaller initial pressures. This point was

used as the origin in plotting the results of the second experiment. The two curves proceeding from the new origin corresponded to reactions taking place under exactly the same conditions except that in one known amounts of the reaction products were present initially. In general, the curves nearly coincided; if anything, the products had a very slight accelerating influence, but it cannot be described as a first-order effect.

*The Termolecular Velocity Coefficients.*—The reaction follows the equation (1). If  $a$  is the initial pressure of nitric oxide and  $b$  that of hydrogen, this becomes

$$dx/dt = k(a-x)^2(b-x),$$

whence

$$kt = \frac{1}{(a-b)^2} \log \frac{b(a-x)}{a(b-x)} + \frac{1}{(a-b)} \left\{ \frac{1}{a} - \frac{1}{a-x} \right\}$$

It is convenient to record results in terms of the period of half-change,  $\tau$ . If hydrogen is in excess, half-change corresponds to  $x = a/2$ . Thus

$$k = \frac{1}{\tau} \left\{ \frac{1}{(b-a)^2} \log \left( \frac{b}{2b-a} \right) + \frac{1}{a(b-a)} \right\}$$

When nitric oxide is in excess, half-change corresponds to  $x = b/2$ . Then

$$k = \frac{1}{\tau} \left\{ \frac{1}{(a-b)^2} \log \left( \frac{2a-b}{a} \right) + \frac{1}{(b-a)} \left( \frac{b}{a(2a-b)} \right) \right\}.$$

Finally, when the two gases are in equimolecular proportions,  $k = 3/(2\tau a^2)$ .

The following table shows the constancy of  $k$  when  $[\text{NO}]$  and  $[\text{H}_2]$  are varied considerably. The temperature was  $826^\circ \text{C}$ .

$[\text{NO}]$ .	$[\text{H}_2]$ .	$\tau$ (secs.).	$k \times 10^7$ .	$[\text{NO}]$ .	$[\text{H}_2]$ .	$\tau$ (secs.).	$k \times 10^7$ .
299	244	112	1.24	110	316	270	1.19
310	302	129	1.19	152	404	204	0.91
300	404	100	1.09	359	400	89	1.12
293	402	100	1.11	144	323.5	227	1.10
406	289	57	1.21	298	280	125	1.35
402	201	46	1.23	181	209.5	264	1.39
405	147	50	1.06	378	376	98	1.08
404	209	49	1.21	370	376	92	1.17
299	147	66	1.60	253	250	180	1.31
175.5	208.5	254	1.50	340.5	340.5	102	1.27
178	220	238	1.45	243	243	176	1.44
232	313	152	1.19	288	288	140	1.29

The increase in  $k$  at lower pressures is due to the existence of the small amount of heterogeneous reaction.

*Influence of Surface.*—The results already described lead us to suspect that a certain amount of surface reaction goes on concurrently with the gaseous change. A series of experiments was

made in a smaller silica bulb containing some powdered silica. A summary of these is given below. The temperature was  $826^{\circ}$  as before.

Av. value of $k$ for expts. in which $[\text{NO}]$ and $[\text{H}_2]$ were both greater than 300 mm. ....	$1.18 \times 10^{-7}$
Compare av. value for larger, empty bulb .....	$1.17 \times 10^{-7}$
Av. value of $k$ for expts. in which $[\text{NO}]$ and $[\text{H}_2]$ were both greater than 200 mm. but not greater than 300 mm. ...	$1.66 \times 10^{-7}$
Compare av. value for corresponding expts. with the empty bulb .....	$1.30 \times 10^{-7}$

This confirms our conclusions, and indicates that at pressures above 300 mm. of each gas the reaction is almost entirely homogeneous.

The smaller bulb was now packed nearly half full with powdered silica. Its catalytic activity towards the decomposition of ammonia—a typical heterogeneous reaction—was about twenty to thirty times greater than that of the larger, empty bulb used in the main series of experiments. At a pressure of 270 mm. of nitric oxide and of hydrogen, the value of  $k$  was now found to be  $2.5 \times 10^{-7}$ , or about doubled, as compared with the twenty- to thirty-fold increase produced in the rate of decomposition of ammonia. The heterogeneous reaction must therefore be a small part of the whole change. These results can only be regarded as qualitative, since the catalysis of the ammonia decomposition is very erratic and cannot be taken as a strictly quantitative measure of the surface area. At temperatures about  $100^{\circ}$  lower, the surface reaction was relatively slightly more in evidence, but not very markedly so.

*Influence of Temperature.*—Three series of experiments were made, two series with the empty bulb, of which the second is the better, since the pressures were higher in all the experiments (greater than 300 mm.), and a third series in the smaller bulb packed with powdered silica. The object of the last series was to find how the proportion of surface reaction varied with temperature, and thus discover what error, if any, would be introduced into the value for the heat of activation determined from the experiments made in the empty bulb.

The first series extended over a range of seven temperatures from  $652^{\circ}$  to  $834^{\circ}$  C. The value of  $E$  was found to be 42,000 calories. The Arrhenius equation was used in the usual manner.

The results of the second series are given below.

$t^{\circ}$ C. ....	$826^{\circ}$	$788^{\circ}$	$751^{\circ}$	$711^{\circ}$	$683^{\circ}$	$631^{\circ}$
$k'$ (av.) .....	476	275	130	59	25.3	5.3

$k'$  is the velocity coefficient expressed, not as before with the concentrations in mm., but with these converted into gram-molecules per litre. The time is in seconds. By plotting  $\log k$  against the reciprocal of  $(t + 273)$  a value of  $E$  is found equal to 44,000

calories. This second value is the better. We adopt it rather than the average value 43,000.

The third series gave the results

$t$ .....	827°	785°	745°	718°	684°
$k'$ .....	1446	692	415	280	90

From these the value found for  $E$  is 39,000 calories. In these last experiments rather more than half the reaction was probably heterogeneous, yet the value of  $E$  was only changed from 44,000 to 39,000 calories. Hence we may conclude that the correction to be applied to the value 44,000 for the small fraction of surface reaction is negligible.

*Conclusion.*—We may therefore conclude that the reaction which takes place at 826° C. between nitric oxide and hydrogen is almost entirely in the gaseous phase, and that the velocity coefficient of the homogeneous reaction is within 10% of  $1.0 \times 10^{-7}$  when the concentrations are expressed in millimetres of mercury and the time in seconds. The heat of activation of the gaseous reaction is 44,000 calories. We consider that it is justifiable to use these values in considerations of the molecular statistics of the reaction. From this point of view the reaction possesses much interest. But the presence of some surface reaction makes it rather unsuitable for studies much more detailed than the general one we have described. We are now investigating the catalytic reaction at the surface of platinum.

### *Summary.*

The interaction of nitric oxide and hydrogen in the region 1000° to 1100° Abs. is a termolecular reaction proceeding in accordance with the equation —  $d[\text{NO}]/dt = k[\text{NO}]^2[\text{H}_2]$ . At pressures above 300 mm. of each of the gases, it is almost entirely homogeneous, but there is a small amount of surface reaction which becomes relatively more important at lower pressures. The heat of activation of the gaseous reaction is 44,000 calories. The molecular statistics of termolecular gaseous reactions are discussed from the point of view of the theory of activation.

It is pointed out that all the termolecular gaseous reactions now known involve the participation of two molecules of nitric oxide.

CIII.—*Synthetical Work on the isoQuinoline Alkaloids.*  
*Part I. Substituted o-Carboxyphenylethylamines.*

By GEORGE ALFRED EDWARDS.

THIS communication is concerned with the preparation and properties of substances obtained in a preliminary investigation of possible methods of preparing  $\beta$ -(4 : 5-dimethoxy-2-carboxyphenyl)ethyl-methylamine (I), and of similar substances required in connexion with proposed syntheses of alkaloids of the cryptopine type.

Laudanosine appeared to be a possible source of this amino-acid, since Pyman (J., 1909, 95, 1272) had shown that the lactam, 6 : 7-dimethoxy-2-methyldihydroisoquinolone (II), was obtained by its oxidation. He further showed that on more gentle oxidation

1-hydroxy-6 : 7-dimethoxy-2-methyltetrahydroisoquinoline (III) was produced, and that it reacted in many respects like hydrastinine, which differs from it structurally only in containing the methylenedioxy-group in place of the two methoxy-groups. Freund (Ber., 1889, 22, 1156) found that hydrastinine gave a benzoyl derivative in which the tetrahydropyridine ring had presumably been opened, and on oxidation gave what was probably *N*-benzoyl- $\beta$ -(4 : 5-methylenedioxy-2-carboxyphenyl)ethylmethylamine (IV). Attempts to benzoylate substance (III), however, resulted in the conversion of the benzoyl chloride into benzoic anhydride, the  $\psi$ -base acting merely as a catalyst.

In the proposed synthesis of cryptopine, the substance (I) was to have been esterified and condensed, in presence of sodium ethoxide, with homopiperonylnitrile,  $(\text{CH}_2\text{O}_2)\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{CN}$ , or a derivative of it with a substituent in the ortho-position to the  $-\text{CH}_2\cdot\text{CN}$  group. Attempts to prepare this nitrile from homopiperonal by Semmler and Bartelt's method (Ber., 1908, 41, 2751) gave minute yields, valueless for synthetic purposes. Interaction of piperonyl bromide

and alcoholic potassium cyanide led to *piperonyl ethyl ether*,  $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\text{:CH}_2\text{:O:C}_2\text{H}_5$ . The nitrile was most conveniently prepared by condensing piperonal with hippuric acid, hydrolysing the resulting so-called azlactone to piperonylpyruvic acid (Kropp and Decker, *Ber.*, 1909, **42**, 1188; compare Buck and Perkin, *J.*, 1924, **125**, 1680), and treating the *oxime* of this with acetic anhydride, whereby the nitrile was produced by loss of carbon dioxide and water.

Homopiperonylonitrile condenses with the  $\psi$ -base (III) in warm alcohol. The product, 6:7-dimethoxy-1(3':4'-methylenedioxy- $\omega$ -cyanobenzyl)-2-methyltetrahydroisoquinoline (V) does not give a benzoyl derivative under any of the normal conditions of benzoylation, and after several unsuccessful attempts to open the ring between the 1-carbon atom and the nitrogen, this line of attack was abandoned.

The direct synthesis of the required amino-acid (I) from *m*-opianic acid was next tried. The only suitable method for preparing *m*-opianic acid in the quantities required for synthetic work is that of Fargher and Perkin (*J.*, 1921, **119**, 1724), which makes use of creosole. Only a small quantity of this being available, a preliminary investigation was made with the more readily accessible opianic acid (Edwards, Perkin, and Stoyale, *J.*, 1925, **127**, 197), three methods of converting it into the required type of substance being examined.

Opianic acid condensed with nitromethane to give a substance (VI) which on reduction yielded the lactone of  $\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylamine hydrochloride (VIII). The base

corresponding to this was formed on treatment with one molecular proportion of cold alkali, whilst hot alkali gave the amino-acid itself (VII). The latter, on being heated alone or in tetralin, lost water and ammonia, leaving a nitrogen-free, resinous substance, and treatment with reagents which attack the amino-group resulted in the formation of derivatives of the amino-lactone (VIII). The poor yields obtained by this method are probably due to the decomposition of the condensation product by the acid reducing agents.

Opianic acid condensed with malonic acid to give meconine-acetic acid (IX) (Liebermann, *Ber.*, 1886, **19**, 2290), the amide of

which in the Hofmann reaction, when carried out under the conditions used by Decker (*Annalen*, 1913, **395**, 291) in the preparation of substituted phenylethylamines from phenylpropionamides, gave about a 30% yield of the amino-acid (VII). The alternative Curtius reaction proceeded quite smoothly as far as the carbamate (X), which proved unexpectedly stable towards acid hydrolysing reagents, boiling concentrated hydrochloric acid leaving it unchanged. When the hydrolysis mixture was heated in a sealed tube at 140–150°, hydrolysis of the carbamate was accompanied by that of the two methoxy-groups, the product being  $\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dihydroxyphenyl)ethylamine (XI). This is a typical catechol derivative, giving an intense green coloration with ferric chloride and oxidising rapidly in air. It is similar in properties to the amino-acid already described. In the cold, sodium hydroxide

merely opened the lactone ring of the carbamate (X), but a boiling solution removed the carbethoxy-group as well. The resulting solution on careful neutralisation slowly deposited the amino-acid (VII).

Of the three methods discussed above, the Curtius reaction gives the best yield, *viz.*, 40% of the theoretical, calculated on the quantity of opianic acid taken.

The amino-acid (VII) was converted into the benzylidene compound (XII), the methiodide of which, on hydrolysis, yielded the lactone of  $\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylmethylamine hydriodide (XIII). On opening the lactone ring, the corresponding amino-acid was formed; it at once passed into its lactone on treatment with mineral acids or with reagents which attack the amino-group.

Benzenesulphonyl derivatives of the amino-acids may be prepared by treating the sodium salts with benzenesulphonyl chloride and caustic soda. The dimethylation of the product and the condensation of the ester group with the reactive methylene group in

such substances as phenylacetonitrile and phenylacetic ester will be dealt with in a later paper.

*m*-Opianic acid condensed best with malonic acid when dissolved in pyridine containing a trace of piperidine. The product, *m*-meconineacetic acid (XIV), was converted by the modification of the Curtius reaction already described into  $\beta$ -hydroxy- $\beta$ -(4:5-dimethoxy-2-carboxyphenyl)ethylamine (XV). This was methylated

in the form of its benzylidene derivative, and the final product (derived from its lactone XVI) was precisely similar in properties to the amino-acids already described.

The quantity of creosole available proved sufficient for the production of only about 5 grams of the amino-acid. The production of this substance in quantity from *m*-meconine by another method is being investigated.

# EXPERIMENTAL.

*r*-Laudanosine (*N*-methyltetrahydropapaverine) was obtained in almost quantitative yield by reducing papaverine methosulphate with zinc and alcoholic sulphuric acid. The yield obtained in Pictet and Finkelstein's process (*Ber.*, 1900, 332, 346), *viz.*, reduction of the methiodide with tin and concentrated hydrochloric acid, is about 50%.

The solid obtained by heating papaverine (50 g.) and methyl sulphate (16 c.c.) on the water-bath for 30 minutes was dissolved in boiling water (200 c.c.), mixed with alcoholic sulphuric acid (25 c.c. of 30% solution), and the whole heated on the water-bath while zinc dust and alcoholic sulphuric acid were added alternately so that hydrogen was gently evolved. After 2½ hours, the boiling solution was filtered, the zinc washed thoroughly with boiling alcohol, and the hot solution added slowly to ammonia (350 c.c.; *d* 0.880) mixed with powdered ice. The product separated slowly as a voluminous mass of needles, and after one recrystallisation from dilute alcohol was pure, *m. p.* 115°.

*Piperonyl Ethyl Ether*.—An alcoholic solution of piperonyl bromide (Orr, Robinson, and Williams, *J.*, 1917, 111, 950; Robinson and Robinson, *J.*, 1914, 105, 1463) and excess of sodium ethoxide was warmed on the water-bath for 10 minutes and poured

into water. The *ether*, which was extracted with ether, was a pleasant-smelling oil, b. p. 130—133°/13 mm. (Found: C, 66.4; H, 6.4.  $C_{12}H_{10}O_3$  requires C, 66.7; H, 6.7%).

*Oxime of Piperonylpyruvic Acid*.—A solution of piperonylpyruvic acid and hydroxylamine hydrochloride ( $1\frac{1}{2}$  equivs.) in 8% aqueous sodium hydroxide (3 equivs.) was heated on the water-bath for 1 hour. According as it was acidified with acetic acid or hydrochloric acid the solution deposited the insoluble sodium salt of the oxime or the *oxime* itself. The white, flocculent precipitate of the latter was separated after 12 hours; it crystallised from alcohol in colourless needles, m. p. 174—175° (Found: N, 6.1.  $C_{10}H_9O_5N$  requires N, 6.3%).

*Homopiperonylonitrile*.—The preceding oxime was gently warmed with acetic anhydride (4 parts); the reaction, at first slow, ultimately became very violent, and water-cooling was usually necessary. The product was distilled in a vacuum; the nitrile then passed over as a golden-yellow liquid, b. p. 160°/10 mm. It quickly solidified on treatment with absolute alcohol, and on recrystallisation from dilute alcohol separated in nearly colourless needles, m. p. 49° (Medinger, *Monatsh.*, 1906, 27, 237, gives m. p. 42°) (Found: C, 67.2; H, 4.4; N, 8.5. Calc., C, 67.1; H, 4.3; N, 8.7%).

6 : 7-Dimethoxy-1-(3' : 4'-methylenedioxy- $\omega$ -cyanobenzyl)-2-methyl-tetrahydroisoquinoline (V).—1-Hydroxy-6 : 7-dimethoxy-2-methyl-tetrahydroisoquinoline (III) (Pyman, *loc. cit.*) was dissolved together with homopiperonylonitrile (1 mol.) in hot alcohol. The condensation product separated from the cooled solution in needles, which melted at 171° to a dark red liquid (Found: C, 68.8; H, 6.0.  $C_{21}H_{22}O_4N_2$  requires C, 68.8; H, 6.0%). It is completely decomposed when boiled with caustic soda, and is a moderately strong base. On treatment with formaldehyde, methylal or methylene oxide, high-melting bases are formed. Since these substances were obviously not of the tetrahydroepi~~ber~~berine type, they were not further investigated.

*Synthesis of  $\beta$ -Hydroxy- $\beta$ -(2-carboxy-3 : 4-dimethoxyphenyl)ethyl-methylamine.*

*Reduction of Meconine-nitromethane*.—Meconine-nitromethane (15 g.) was dissolved with cooling in concentrated hydrochloric acid (200 c.c.) containing stannous chloride (42 g.); much heat was generated, and the liquid soon began to deposit a yellow tin salt. After an hour, this was filtered off, washed with hydrochloric acid, dissolved in boiling water, the tin removed with hydrogen sulphide, and the filtrate evaporated to small bulk. The hydrochloride thus obtained crystallised from dilute alcohol in colourless needles, m. p.

248°, and was the lactone of  $\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylamine hydrochloride (VIII) (Found: C, 51.4; H, 5.3.  $C_{11}H_{13}O_4N \cdot HCl$  requires C, 51.0; H, 5.4%).

The *picrate* of the base separated slowly in golden-yellow needles, m. p. 202—204° (decomp.), when a hot solution of the hydrochloride and picric acid in water was cooled.

*Meconineacetamide*.—Meconineacetic acid (Liebermann, *loc. cit.*) (40 g.) was boiled for  $\frac{1}{2}$  hour with thionyl chloride (130 c.c.), the acid chloride crystallising in fine needles. The excess of thionyl chloride was distilled off on a water-bath; the crystalline residue, after being washed with dry ether and dried in a steam-oven, melted at 158—159° and was sufficiently pure for immediate use.

The finely-powdered acid chloride was added slowly to aqueous ammonia (*d* 0.880; 250 c.c.) containing ice. After 1 hour, the white, amorphous product was washed with cold alkali and ether and crystallised from glacial acetic acid; it then separated in colourless masses of prisms, m. p. 223—224°. It was quite insoluble in cold alkalis, but dissolved readily, on warming, with evolution of ammonia. The latter treatment also opened the lactone ring, but all attempts to effect this change without attacking the amino-group were unsuccessful (Found: C, 57.5; H, 5.2; N, 5.6.  $C_{12}H_{13}O_5N$  requires C, 57.3; H, 5.1; N, 5.6%).

The esters of meconineacetic acid may be prepared by cooling a solution of the acid chloride in the minimum amount of the hot alcohol. The methyl ester was thus obtained in colourless hexahedra, m. p. 124°, identical with that obtained by Liebermann (*loc. cit.*) by direct esterification.

*Action of Sodium Hypochlorite upon the Acid Amide*.—The finely-powdered acid amide, suspended in water at 60°, was shaken with exactly 1.2 mols. of sodium hypochlorite. When the solid had dissolved, the liquid was made very strongly alkaline with caustic soda, the temperature allowed to rise slowly to 85°, and, after  $\frac{1}{2}$  hour, the solution was cooled and made just perceptibly acid to litmus by addition of acetic acid.  $\beta$ -Hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylamine (VII) separated slowly as a microcrystalline powder, m. p. 224°. It was insoluble in all non-hydroxylic organic solvents, and very sparingly soluble in boiling alcohol or water. A solution of the crude substance in hot ammonia was filtered from insoluble impurities and boiled; as the ammonia evaporated, the amino-acid slowly separated in colourless needles, m. p. 225°. The substance is more soluble in hot solutions of such inorganic salts as copper sulphate and silver nitrate than in water, but separates from them unchanged (Found: C, 54.5; H, 6.1.  $C_{11}H_{14}O_5$  requires C, 54.8; H, 6.2%).

Treatment of the amino-acid with hydrochloric acid at once converted it into the hydrochloride of the lactone (VIII), identical with the substance obtained from meconine-nitromethane. When the solid hydrochloride was treated with the theoretical quantity of 30% ice-cold caustic soda solution, it was converted into the lactone base, which is a colourless, fishy-smelling oil, very soluble in water but insoluble in non-hydroxylic solvents. The lactone ring was opened by warming with caustic soda solution for a few minutes, and the amino-acid was precipitated on making the solution just perceptibly acid to litmus with acetic acid.

The amino-acid was boiled with acetic anhydride (3 parts) for 10 minutes and the solution was then refluxed for  $\frac{1}{2}$  hour with its own bulk of absolute alcohol, evaporated to one-fourth its volume, and diluted with dry ether. The *acetyl* derivative of the lactone base separated in colourless needles, which crystallised from xylene in star-shaped clusters, m. p.  $155^{\circ}$  (Found: C, 58.6; H, 5.7.  $C_{13}H_{15}O_5N$  requires C, 58.8; H, 5.7%).

*Preparation of the Amino-acid (VII) by means of the Curtius Reaction.*—Meconineacetyl chloride (20 g.) was added slowly to hydrazine hydrate (20 g.) cooled in ice. The resulting thick paste of meconineacetylhydrazide was thoroughly ground and, after 12 hours, dissolved in 8% hydrochloric acid (200 c.c.). A bulky, amorphous precipitate slowly separated. This was filtered off, and the filtrate cooled in ice and treated slowly with sodium nitrite (34 g. in the minimum of water). *Meconineacetyl azide* separated as a white solid (14 g.) and was washed with dry ether and dried in a vacuum desiccator. A small portion recrystallised from dry chloroform separated in colourless needles. It was comparatively stable, losing nitrogen only when heated at its melting point,  $94^{\circ}$ , for a short time (Found: N, 14.7.  $C_{12}H_{11}O_5N_8$  requires N, 15.1%).

When the crude azide was boiled for  $\frac{1}{2}$  hour with absolute alcohol (2 parts), a violent evolution of nitrogen took place; the solution on cooling deposited crystals of the lactone of *ethyl  $\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylcarbamate* (X). It crystallised from methyl alcohol in colourless cubes, m. p.  $131^{\circ}$  (Found: C, 56.9; H, 5.8; N, 4.7.  $C_{14}H_{17}O_6N$  requires C, 56.9; H, 5.8; N, 4.7%).

This carbamate was heated with concentrated hydrochloric acid (6 parts) in a sealed tube at  $150^{\circ}$  for 3 hours. The insoluble liquid thus produced was mainly methyl chloride. The aqueous liquid in the tube was boiled, filtered hot, and allowed to cool,  *$\beta$ -hydroxy- $\beta$ -(2-carboxy-3:4-dihydroxyphenyl)ethylamine hydrochloride* being thus obtained in colourless needles, m. p.  $262-265^{\circ}$ . On treating

this salt with ammonium carbonate, the *amino-acid* (XI) was obtained in colourless needles, m. p. 138–140° (Found: C, 50.3; H, 5.3.  $C_{19}H_{12}O_4N$  requires C, 50.7; H, 4.8%). The amino-acid dissolved readily in warm dilute acids or alkalis, but not in alkali carbonates. It did not form a lactone under the conditions obtaining in the case of the dimethoxy-compound.

The carbamate (12 g.) was dissolved in 15% sodium hydroxide solution (50 c.c.) by heating on the water-bath for  $\frac{1}{2}$  hour. After boiling for 5 minutes, the solution was cooled, filtered, and faintly acidified (litmus) with acetic acid. After 12 hours, the amino-acid (VII) separated as a microcrystalline powder, m. p. 224°. The yield was 7 g. from 20 g. of meconineacetic acid, *i.e.*, 40%.

From the solution obtained by boiling the amino-acid (30 g.) and benzaldehyde (60 c.c.) for 20 minutes the greater part of the excess of benzaldehyde was removed in a vacuum. The residue was mixed with boiling methyl alcohol (220 c.c.); from the filtered cooled solution the *benzylidene* derivative of the lactone base (XII) separated in slightly cream-tinged plates, m. p. 125° (Found: C, 69.2; H, 5.5.  $C_{18}H_{17}O_4N$  requires C, 69.4; H, 5.5%).

The benzylidene compound was heated for 2 hours with its own weight of methyl iodide in a sealed tube at 100°. The orange liquid thus formed set, on cooling, to a mass of yellow needles, which was at once washed with carefully dried benzene and dried in a vacuum desiccator. The *methiodide* thus obtained melted at 180°. It decomposed rapidly in the air with liberation of benzaldehyde. Hydrolysis was best carried out by boiling for a short time with four parts of 95% ethyl alcohol; the filtered solution, on cooling, deposited the *lactone* of  $\beta$ -*hydroxy*- $\beta$ -(2-*carboxy*-3 : 4-*dimethoxyphenyl*) *ethylmethylamine hydriodide* (XIII) in colourless prisms, m. p. 220–222°. The *hydrochloride*, prepared by boiling the hydriodide in chloroform solution with phosphorus pentachloride for 10 minutes, separated from alcohol in felted needles, m. p. 233°. The *nitroso*-compound separated in colourless needles, m. p. 108°, when a warm aqueous solution of the hydrochloride was dropped slowly into an ice-cold solution of excess of sodium nitrite (Found: C, 54.0; H, 5.2; N, 10.7.  $C_{12}H_{14}O_5N_2$  requires C, 54.1; H, 5.2; N, 10.5%). From the solution obtained by shaking the hydrochloride and benzoyl chloride (1 mol.) with aqueous sodium hydroxide (2 mols.) the *benzoyl* derivative separated slowly; the large amount remaining in solution was extracted with ether. The product crystallised from a little methyl alcohol in rhombs, m. p. 106°. This substance is insoluble in cold caustic soda solution, but dissolves readily on warming (Found: C, 67.2; H, 5.7.  $C_{19}H_{19}O_5N$  requires C, 66.9; H, 5.5).

$\beta$ -Hydroxy- $\beta$ -(2-carboxy-3:4-dimethoxyphenyl)ethylmethylamine (VII with NHMe in place of  $\text{NH}_2$ ) was obtained by heating a salt of the amino-lactone on the water-bath with a slight excess of caustic soda solution for  $\frac{1}{2}$  hour and just acidifying the cooled solution with acetic acid. It crystallised slowly from water in colourless plates, m. p. 190—192° (Found: C, 56.2; H, 6.8.  $\text{C}_{12}\text{H}_{17}\text{O}_5\text{N}$  requires C, 56.5; H, 6.6%).

$\beta$ -Hydroxy- $\beta$ -(2-carboxy-4:5-dimethoxyphenyl)ethylmethylamine (XV with NHMe in place of  $\text{NH}_2$ ).

*m*-Meconineacetic Acid.—*m*-Opianic acid (28 g.), malonic acid (35 g.), piperidine (30 drops), and pyridine (100 c.c.) were heated on a water-bath for 6 hours. After boiling for a few minutes, the mixture was cooled and poured into 16% hydrochloric acid (300 c.c.); the product, which separated slowly in clusters of needles, crystallised well from a little glacial acetic acid in colourless needles, m. p. 230—231° (Found: C, 56.8; H, 5.0.  $\text{C}_{12}\text{H}_{12}\text{O}_6$  requires C, 57.1; H, 4.8%).

*m*-Meconineacetyl Chloride.—*m*-Meconineacetic acid was boiled for  $\frac{1}{2}$  hour with twice its weight of thionyl chloride, the excess of solvent was removed in a vacuum, and the yellow, syrupy product was made to crystallise by treatment with dry ether. It separated from dry xylene in colourless prisms, m. p. 103—104°.

*m*-Meconineacetamide was prepared in exactly the same way as meconineacetamide. It separated from much alcohol in clusters of needles, m. p. 240—241° (Found: N, 5.6.  $\text{C}_{12}\text{H}_{13}\text{O}_5\text{N}$  requires N, 5.6%).

Ethyl *m*-meconineacetate was produced when the acid chloride was dissolved in a little hot ethyl alcohol, and the product allowed to cool. It separated in fine needles, m. p. 133°. The same substance was obtained by direct esterification (Found: C, 59.8; H, 5.8.  $\text{C}_{14}\text{H}_{16}\text{O}_6$  requires C, 60.0; H, 5.8%). The methyl ester separated from methyl alcohol in colourless plates, m. p. 129°.

*m*-Meconineacetic acid was converted by the method already described into *m*-meconineacetyl azide. This separated as a gummy substance which crystallised from chloroform in clusters of needles, m. p. 100° with evolution of nitrogen (Found: N, 14.8.  $\text{C}_{12}\text{H}_{11}\text{O}_5\text{N}_3$  requires N, 15.1%). Treatment with alcohol converted this into the lactone of ethyl  $\beta$ -hydroxy- $\beta$ -(2-carboxy-4:5-dimethoxyphenyl)ethyl-carbamate, which separated in glistening plates with a pale brown tinge, m. p. 177—178° (Found: C, 56.9; H, 5.8; N, 4.7.  $\text{C}_{14}\text{H}_{17}\text{O}_6\text{N}$  requires C, 56.8; H, 5.6; N, 5.0%). Hydrolysis of this with four times its weight of 12% aqueous caustic soda gave a clear solution which, on being cooled and just acidified with acetic acid, deposited  $\beta$ -hydroxy- $\beta$ -(2-carboxy-4:5-dimethoxyphenyl)ethylamine

(XV) in fine, hexagonal prisms, m. p. 204—205° (Found : C, 54.5; H, 6.0.  $C_{11}H_{14}O_5N$  requires C, 54.8; H, 6.2%). The acid readily formed a *benzylidene* compound in the manner described above, which crystallised from methyl alcohol in colourless needles, m. p. 146° (Found : C, 69.1; H, 5.7.  $C_{18}H_{17}O_4$  requires C, 69.4; H, 5.5%). When quite dry, the latter added on methyl iodide in the manner already described, and the *methiodide* was hydrolysed on treatment with hot dilute alcohol to the lactone of  $\beta$ -hydroxy- $\beta$ -(2-carboxy-4 : 5-dimethoxyphenyl)ethylmethylamine (XVI), which crystallised from ethyl alcohol in colourless prisms, m. p. 230—231°. Treatment of this with caustic soda solution opened the lactone ring and produced the amino-acid, which was purified by boiling its solution in ammonia until no more crystals separated. It was thus obtained in needles, m. p. 199—204° (decomp.) (Found : C, 56.9; H, 6.8.  $C_{12}H_{17}O_5N$  requires C, 56.5; H, 6.6%).

The author wishes to thank Professor W. H. Perkin, F.R.S., for many helpful suggestions, and the Advisory Council of the Department of Scientific and Industrial Research for a grant which enabled him to carry out the greater part of this investigation.

#### CIV.—The Electrometric Titration of Halides.

By WALTER CLARK.

THE object of the experiments to be described was to examine the possibility of applying electrometric methods to the analysis of mixtures of soluble halides and of mixed silver halides, in particular where one halide is present in small proportion—less than 1%—in the other.

The estimation of a single soluble halide by titration with silver nitrate, or conversely of silver ions by titration with a halide solution, can be accurately and simply carried out electrometrically (compare Behrend, *Z. physikal. Chem.*, 1893, **11**, 466; Dutoit and von Weise, *J. Chim. Phys.*, 1911, **9**, 578, 608, 630). For this purpose several different methods have been devised. Certain of these have been summarised by Kolthoff (*Chem. Weekblad*, 1920, **17**, 659), Willard and Fenwick (*J. Amer. Chem. Soc.*, 1922, **44**, 2504), and Müller ("Elektrometrische Massanalyse," 2nd edn, 1923).

The most exact method of titration is that in which the titration beaker containing the halide solution and a silver electrode is

connected with a normal electrode, and the *E.M.F.* of the combination is measured after each addition of silver nitrate, the end-point of the titration being taken as the point of maximum rate of change of *E.M.F.* with silver ion added.

In an arrangement due to Pinkhof (*Diss.*, Amsterdam, 1919; *Chem. Weekblad*, 1919, 16, 1163; *Pharm. Weekblad*, 1919, 56, 1218) the normal electrode is replaced by a compensation electrode whose potential is equal to that of the titration system at the end-point. With this method a different compensation electrode would be required for each halide titrated, and in the titration of mixed halides the electrode would have to be changed during the course of the titration.

A variation of Pinkhof's method has been used extensively by Treadwell (*Helv. Chim. Acta*, 1919, 2, 672, 680), and a modification for use with 5 c.c. of solution to be titrated, has been described by Garner and Waters (*J. Soc. Chem. Ind.*, 1922, 41, 337t).

A further method of titration consists in the use of "bimetallic electrode systems," introduced by Willard and Fenwick (*J. Amer. Chem. Soc.*, 1922, 44, 2504, 2516; 1923, 45, 623), and suggested also by Müller (*Z. Elektrochem.*, 1924, 30, 420) and Hostetter and Roberts (*J. Amer. Chem. Soc.*, 1919, 41, 1343). This method has been applied also to acid-alkali titrations by van der Meulen and Wilcoxon (*Ind. Eng. Chem.*, 1923, 15, 62) and by Brännich (*ibid.*, 1925, 17, 631).

Another method of titrating soluble halides has recently been described and is worthy of note. In the "differential titration" method of Cox (*J. Amer. Chem. Soc.*, 1925, 47, 2138) the halide solution is divided equally between two beakers joined by an ammonium nitrate bridge and each containing a silver electrode connected with the potentiometer. Both solutions are titrated simultaneously with silver nitrate, one being kept slightly in advance of the other, and the potential is read after each addition of silver. The titration curve obtained is the first derivative of the normal titration curve, and its maximum is the end-point.

In the investigation to be described the first method of titration was used, *i.e.*, that in which the solution to be titrated contained a silver electrode and was united with a calomel cell, the *E.M.F.* of the combination being measured by means of a potentiometer after each addition of silver nitrate. This method was used because it is quite straightforward and can be used for the titration of mixed halides without changing the electrode or the constant half-cell. It was examined first with a view to its utility for the accurate yet simple estimation of mixtures of two or three alkali halides by direct titration with silver nitrate solution, and then for estimating

mixtures of silver halides. In a few instances, other methods of titration were tested.

### EXPERIMENTAL.

The calomel cell employed was of the saturated potassium chloride type. This was united with the halogen solution to be titrated by a saturated ammonium nitrate bridge in such a way as to prevent diffusion of chloride from the cell into the titration beaker, and to prevent loss of halide from the solution to be titrated by displacement with the specifically heavier ammonium nitrate solution. The arrangement is shown in Fig. 1.

A is a continuation of the side arm of the calomel cell. In the cell itself a wad of glass wool is placed over the surface of the calomel to prevent its disturbance when flushing out with fresh potassium chloride solution. At B is a side tube with clip to allow of the easy removal of air or old potassium chloride from the tube A D when filling it or when renewing the potassium chloride solution. An ordinary separating funnel is used as a reservoir for the saturated ammonium nitrate.

The end of its stem, C, is bent at right angles and a T-piece, D E, is joined on so that D E is parallel to the stem of the funnel. At the upper end, D, the T-piece is constricted, leaving an orifice about 1 mm. in diameter. This partially closed end D is packed tightly to a depth of 1 cm. with filter-paper, previously moistened with ammonium nitrate solution. The lower end, E, of the T-piece is joined by rubber tubing to a drawn-out tube, F, which is immersed in the solution to be titrated. The tapered end of F is also packed tightly to a depth of 1 cm. with a wad of filter-paper moistened with ammonium nitrate solution. The calomel cell is connected with the ammonium nitrate bridge at D by a short piece of rubber tubing.

By means of the side tube and clip at B it is possible to flush out the calomel cell with fresh potassium chloride solution without disturbing the ammonium nitrate bridge. By removing the tube F the nitrate bridge can be flushed out from the reservoir above without disturbing the calomel cell. It is not necessary to change the wad of filter-paper at D often, but the tube F should be changed frequently.

Observations showed that in the course of several hours no chloride reached the titration solution from the calomel cell, and no loss of chloride from the titration solution into the bridge could be detected.

The solution to be titrated was stirred by a motor-driven stirrer at 200 revolutions per minute.

For the silver electrode, No. 20 gauge fine silver wire, provided by Messrs. Johnson Matthey, was used. For the best results it has to be specially treated, as described later. A Cambridge and Paul potentiometer, giving readings to 0.5 millivolt, was used for measuring electromotive forces.

The method of titration was to run standard silver nitrate solution *drop by drop* into the stirred solution of halide, the *E.M.F.* being read after each addition of 1 c.c. When the *E.M.F.* began to rise more rapidly, only 0.1 c.c. of silver nitrate solution was added. When great accuracy was desired, or when only small amounts of halide were being titrated, silver nitrate was added from a micro-burette, or more generally, a *N*/100- or *N*/1000-solution was used, in the neighbourhood of the end-point.

In most cases, a certain time was necessary for establishment of equilibrium of *E.M.F.* in the immediate neighbourhood of the end-point. This will be considered in the course of the description of the titration. The end-point of the titration was obtained either by plotting the titration curve of c.c. of silver nitrate added against *E.M.F.*, and determining its point of inflexion or the mid-point of the maximum slope, or, more readily, by plotting the first derivative of the titration curve, *i.e.*,  $dE/dV$ , against *V*, where *E* is the *E.M.F.* corresponding to a volume *V* of silver nitrate added (compare, for example, Hostetter and Roberts, *J. Amer. Chem. Soc.*, 1919, **41**, 1341). Each of these methods of determining the end-point was used as occasion demanded, for in certain forms of titration curve one method is preferable to another.

#### *Titration of Solutions of Soluble Halides.*

*Preparation of Pure Materials.*—Silver nitrate solutions of *N*/10, *N*/100 and *N*/1000 strength were made up from Johnson's "pure

triple crystallised silver nitrate," which is specially prepared for the manufacture of photographic emulsions.

Potassium chloride, free from other halides, was available as a commercial product, and approximately *N*/10-solutions were prepared.

No commercial sample of bromide or iodide free from chloride was available. Many samples of ammonium and potassium bromide, and of ammonium, barium, cadmium, and potassium iodide were examined quantitatively for chlorides. The proportion present varied with different samples from 0.2% to about 5%, and with a number of samples of any one salt from any one manufacturer, wide variations were found. Potassium bromide was the worst offender in this respect.

*Preparation of Pure Bromide.*—A sample of potassium bromide, free from chloride and bromate, was prepared by heating once-recrystallised potassium bromate in a silica basin, extracting the fused salt with water, and evaporating the solution to dryness.

Ammonium bromide free from chloride was prepared from purified ammonia and bromine. A sample of commercial ammonia solution, labelled "sp. gr. 0.880, extra pure," contained a trace of chloride which was removed by boiling off the ammonia gas and reabsorbing it in distilled water.\*

For the preparation of pure bromine, the purest commercial bromine, which contained some chlorine, was used. 100 G. were shaken with 50 c.c. of concentrated potassium bromide solution, and then distilled off on a water-bath at 70–90°. The distilling apparatus was made entirely of glass, and the receiver was cooled in ice.

The yield of 70 g. of bromine was well shaken with 5 c.c. of *N*-caustic soda solution and distilled again in the same apparatus (compare Scott, J., 1913, 103, 847; Baxter, *Proc. Amer. Acad. Arts Sci.*, 1906, 42, 201).

Ammonium bromide was made by adding the bromine drop by drop, shaking after each addition, to freshly-distilled ammonia contained in an ice-cooled flask until there was only a slight excess of ammonia. This excess was boiled off and the solution evaporated to dryness. The product was free from chloride and bromate.

*Preparation of Pure Iodide.*—Baxter (*Proc. Amer. Acad. Arts Sci.*, 1903, 39, 249; 1904, 40, 419; 1906, 42, 201) has described the conditions for the preparation of pure bromine and iodine. The method he adopted in the case of iodine did not give successful results in the author's hands. Also attempts were made to prepare

\* Addition of a few drops of silver nitrate solution to the ammonia before distillation ensures the freedom of the final product from chloride.

pure ammonium iodide somewhat on the lines described by Baxter, but without success. It was found impossible to remove the last traces of chloride; under the conditions employed, between 0.1% and 0.2% chloride remained.

Some of the earlier experiments on electrometric titrations, to be described later, suggested a method for the preparation of iodide free from chloride which was very satisfactory and simple. It is briefly as follows :

Ordinary commercial potassium iodide is dissolved in a 5% solution of chloride-free barium nitrate (sodium nitrate, ammonium nitrate or sodium acetate may also be used) and silver nitrate solution is run in slowly drop by drop, with vigorous stirring, a marked excess of soluble halide, however, being left finally. This excess must be larger than the equivalent of chloride present. Silver equivalent to 90% of the iodide was used in the actual preparations. Under these conditions, the precipitate consists entirely of silver iodide and all the chloride remains in solution. The silver iodide precipitate is removed and washed several times with water. It is then suspended in water, stirred vigorously, and reduced with hydroxylamine sulphate\* and chloride-free caustic soda prepared from metallic sodium by the action of water vapour. This gives a precipitate of spongy silver, and a solution of sodium iodide, hydroxylamine, sodium hydroxide, and sodium sulphate. The liquid is filtered, evaporated to dryness, the residue is heated at about 200° to destroy the excess of hydroxylamine,† and extracted with water, and the solution neutralised with sulphuric acid. The solution of sodium iodide and sodium sulphate obtained in this way was suitable for the purpose of electrometric titration; in fact, the presence of sodium sulphate was found to be beneficial to the titration. The solutions obtained were absolutely free from chloride.

If it is desired to have pure iodide, free from sodium sulphate, the solution can be treated with permanganate, and the iodine distilled off and converted into hydriodic acid with hydrogen sulphide gas according to the method of Baxter (*loc. cit.*).

If the product still contains chloride, the iodide-sulphate solution can be again partly precipitated as silver iodide, followed by reduction as described, but in no case has more than one precipitation and reduction been found necessary.

Stock solutions of bromide and iodide of practically *N*/10-strength were prepared, and standardised against the stock *N*/10-silver nitrate solution, by the dye-indicator method of Fajans

\* This can be obtained commercially quite free from chloride.

† Alternatively, an excess of silver iodide is used so that there is no excess of hydroxylamine.

and Hassel (*Z. Elektrochem.*, 1923, 29, 495; *Kolloid Z.*, 1924, 34, 304), fluorescein being used as indicator. The stock chloride solution was standardised by the normal titration method, with chromate as indicator.

In the titration of silver ions with halide ions, with fluorescein as indicator, it is essential to define the conditions rather closely, otherwise the true end-point is difficult to determine. It is necessary to titrate in very dilute solution, with a low concentration of dye. For example, in the titration of *N*/10-silver nitrate with *N*/10-potassium bromide it was found best to dilute 10 c.c. of the silver nitrate to about 200 c.c. with water, and use 5 drops of a 1 : 2000 solution of fluorescein as indicator. In these conditions, the silver halide does not coagulate in the neighbourhood of the end-point, and the change from rose colour to yellowish-green is sharp and readily located.

#### *Electrometric Titration of Halides.*

The solutions of soluble halides were titrated electrometrically with a standard silver nitrate solution, and the results agreed identically with those obtained by the ordinary titrations. For any further stock solutions prepared, standardisation was therefore carried out by the electrometric method.

In the titration of the single halide solutions with silver nitrate, the magnitude of the potential jumps about the end-point was roughly : for chloride, 180 mv. ; for bromide, 350 mv. ; for iodide, 500 mv., being bigger the lower the solubility of the corresponding silver salt.

The procedure in titration was to dilute the volume of halide taken to 50 c.c. in some cases, or to 150 c.c. in other cases, with water or any required solution, and then to titrate with the *N*/10-silver nitrate.

In the titration of bromide or iodide, no anomalies were observed which could be ascribed to the nature of the silver electrode employed. In the case of chlorides, however, certain peculiarities were observed which were shown to be dependent on the electrode surface.

#### *Effects Due to the Electrode.*

The first electrodes used were cleaned by scraping with emery cloth or a knife blade. In the titration of chlorides, the addition of the first drop of silver nitrate resulted in a sudden rise in potential. This jump was by no means constant, being about 40–50 mv. in certain cases, and less than 10 mv. in others. With a higher concentration of chloride, a bigger jump was sometimes observed, and its magnitude was dependent to some extent on the presence of

neutral salts. Carrying out the titration in red light did not improve matters. The jump was not due to the presence of a trace of bromide or iodide in the chloride, since its magnitude was variable for the same amount of chloride used, but was due to some peculiarity of the silver electrode, since it varied with the nature of the silver surface.

To avoid any confusion in the event of the possibility of the presence of a trace of iodide or bromide in the chloride, the conditions for obtaining an electrode which did not give the initial jump were studied. A long series of experiments showed that plating the electrode from a potassium argentocyanide solution does not give a reproducible electrode which comes into equilibrium with the chloride immediately. Various other methods of treatment showed that if the electrode was first cleaned with emery cloth and then immersed, until gassing freely, in a solution of nitric acid (1 : 1) to which a little sodium nitrite had been added, it assumed equilibrium immediately on being immersed in the chloride solution, and the potential alteration on addition of the first drop of silver nitrate was very small—never more than about 8 millivolts. Electrodes treated in this way are quite trustworthy, and were used for all the electrometric titrations.

The effect of amalgamating the electrode was next tried. Amalgamation was effected by cleaning the electrode with emery cloth and then rubbing it with mercury by means of a wad of cotton wool on a glass rod, under dilute nitric acid. With such an electrode equilibrium was established in a very short time, but the first addition of silver nitrate produced a big jump in potential, equal to 70 mv. After this, the titration curve proceeded in a normal manner, giving the same end-point as the plain silver electrode. The whole curve, however, was shifted in the direction of a higher *E.M.F.* compared with the plain silver electrode curve; *i.e.*, it was more "noble." This is shown in Fig. 2. Similar results were obtained in the titration of bromides and iodides.

This suggested a new method of titrating halides with silver nitrate by means of a bimetallic electrode system, the use of a calomel cell thus being eliminated. If two electrodes, one of amalgamated silver and the other of plain silver, are immersed in a chloride solution to be titrated, the resulting titration curve should be the difference between curves A and B in Fig. 2. This difference is practically constant until, in the neighbourhood of the end-point, a deviation occurs, giving a sharp break in the curve, after which it becomes constant again. Measurements showed that this method affords a means of determining a halide as accurately as the other methods used. The breaks at the end-point are very sharp and the magnitude

of the jumps in the case of chloride, bromide, and iodide are about 30–40 mv. Fig. 3 shows titration curves for chloride, bromide, and iodide. In the neighbourhood of the end-point, it is necessary to allow a minute or so for equilibrium to be attained after each addition of silver ions.

FIG. 2.

The dotted curve in Fig. 3 (a) is the curve calculated by subtracting the two curves A and B of Fig. 2. It agrees well with the curve obtained by direct titration with the bimetallic system. In the case of chloride only, a drop in the curve is observed in many cases,

FIG. 3.

before the final jump, although in some chloride titrations this drop is absent. The end-point of curves which exhibit this drop is at the point of maximum slope of the final jump. All curves obtained by this bimetallic method exhibit an initial jump on the first addition of silver ions, owing to the amalgamated electrode always

showing such a rise. The method has not yet been applied to mixtures of halides. In the titration of iodides, the curves with plain silver and with amalgamated silver were actually coincident for some distance at the end-point, and yet the bimetallic titration showed a marked jump at the end-point. Müller (*Z. Elektrochem.*, 1924, 30, 420) appears to think that if the curves are tangential the potential should drop to zero at the end-point; but this is not necessarily so.

In many cases of normal titration with a silver wire and calomel cell, some time, often  $\frac{1}{2}$  hour, is required for the attainment of equilibrium of *E.M.F.* in the immediate neighbourhood of an end-point, especially in titrations with very dilute silver nitrate. During this time, the potential rises, rapidly at first, then more slowly, and finally reaches a steady value. This change corresponds with what is equivalent to a slow increase in silver-ion concentration, and obviously is not due, therefore, to the silver ions taking a long time to react with the halide ions remaining. It appears to be due to the time taken for the silver electrode to assume equilibrium with the changed concentration of silver ion.

If an electrode which has been used for one titration of halide is not scraped clean and treated with nitric acid before being used again, the *E.M.F.* found for the new system before the addition of any silver ions is somewhat higher than when a freshly-cleaned electrode is used, and the initial potential jump is very small. The electrode seems to be "formed" in some way, during the first titration.

Good titration curves giving correct end-points are obtained if a bright platinum wire instead of a silver wire is used in conjunction with a calomel cell (compare Müller, *Z. Elektrochem.*, 1924, 30, 420). The curve shows an initial jump of about 40 mv., and lies above the curve for the silver electrode, as shown in Fig. 2. Attempts to use a bimetallic electrode system of platinum and silver gave very poor results, which were useless in practice.

#### *Titration of Mixed Halides.*

The solubility products of the silver halides are of the order : silver chloride,  $10^{-10}$ ; silver bromide,  $10^{-12}$ ; silver iodide,  $10^{-16}$ . Theoretically, then, if silver nitrate is added slowly to a mixture of, say, bromide and chloride in solution, precipitation of the bromide should be complete before that of the chloride begins. In practice, this does not occur; some chloride is precipitated along with the bromide before all the bromide is thrown down, and if a mixture of bromide and chloride in water is titrated electrometrically with silver nitrate, an error in the values is found.

That the individual halides cannot be separated quantitatively from a mixture of halides by addition of silver nitrate has long been known. It has been commented on by many workers, including Foerster ("Elektrochemie Wässrige Lösungen," 3rd edn, 1922, p. 165), Mellor ("Treatise on Inorganic Chemistry," Vol. III, pp. 418—419), Sheppard and Trivelli ("Silver Bromide Grain of Photographic Emulsions," 1921, pp. 42 *et seq.*), Küster (*Z. anorg. Chem.*, 1898, **19**, 81), Küster and Thiel (*ibid.*, 1900, **23**, 25), Thiel (*ibid.*, 1900, **24**, 1), and Müller ("Elektrometrische Massanalyse," 2nd edn, 1923).

The electrometric titration curve of a mixture of two or three soluble halides with silver nitrate shows a sudden break in the neighbourhood of the end-point of each halide, the iodide break occurring before the bromide break, which comes before the final chloride break. The arguments which apply to any pair of halides are obviously applicable to titration of a mixture of all three, so only pairs of halides will be considered at first. If a mixture of chloride and bromide in water, with no other additions, is titrated with silver nitrate, the bromide end-point appears too late, whilst the final break appears in its true position. This results in a correct estimate of the total halide, but a too high value for bromide and a too low value for chloride. The same applies in the case of bromide-iodide mixtures. With chloride-iodide mixtures the error is practically non-existent. It seems to be the general opinion that the end-point error is due to the formation of solid solutions as described by Küster and Thiel (*loc. cit.*), adsorption phenomena playing a preliminary rôle.

According to Dutoit and von Weisse (*J. Chim. Phys.*, 1911, **9**, 630) iodide can be accurately titrated in presence of a large excess (600 times or more) of chloride or bromide. This is true for iodide in chloride, but certainly not for iodide in bromide.

The end-point error increases in the series: chloride-iodide < bromide-iodide < chloride-bromide, being larger the less the solubility difference between the silver salts corresponding with a pair of halides. The magnitude of the error in the case of bromide-chloride and bromide-iodide mixtures is indicated by the following figures :

C.c. of halide solutions in terms of *N*/10-silver nitrate.

Theoretical.		Found.	
Chloride.	Bromide.	Chloride.	Bromide.
{ 5.05	5.05	4.5	5.6
{ 5.05	5.05	4.6	5.5
Bromide.	Iodide.	Bromide.	Iodide.
{ 5.15	5.05	5.0	5.2
{ 5.15	5.05	5.0	5.2

Two methods were tried for eliminating this error, namely : ( 1 ) working in very dilute solution, and ( 2 ) adding certain neutral substances to the titration solution.

The effect of dilution was examined on the titration of a bromide-iodide mixture. Diluting to 330 c.c. instead of the 50 c.c. normally employed in the titrations resulted in an increase in the error.

The correction of the end-point error by adding ions which are strongly adsorbed by silver halides has been studied in detail by Müller (*op. cit.*), who titrated in the presence of 5% barium nitrate solution and found that this salt prevents, or at any rate limits, the formation of solid solutions, so that the end-point error is practically eliminated. Müller writes : "The accuracy of estimation of iodide in the presence of bromide and of iodide in the presence of chloride is good in all cases in presence of 5% barium nitrate. Even the estimation of small amounts of one halide in presence of excess of the other is not affected. . . . In the estimation of bromide and chloride in the presence of one another, we must, unfortunately, reckon on an error of 1% too much bromide and correspondingly too little chloride, if equal molar concentrations of both are taken. This error increases with increasing excess of chloride, and falls off with increasing bromide excess . . . until it can be neglected when the molar concentration of bromide exceeds that of chloride by five times." Müller also mentions potassium alum in the same connexion as barium nitrate, but gives no data concerning its action. According to Foerster (*op. cit.*), in presence of barium nitrate, iodide in a ratio of iodide : bromide  $> 1 : 3600$  can be estimated accurately, but bromide in chloride only when bromide : chloride = 1 : 10.

It appears that adsorption effects of some type are responsible for the end-point error. The exact nature of this adsorption is not quite clear, although it is probable that in the case of iodide-bromide mixtures, for example, it is adsorption of silver bromide to silver iodide which is concerned. It cannot be mere adsorption of bromide ions, because a certain amount of silver ions is involved ; also it is improbable that it is adsorption of silver ions alone. It is most likely adsorption of silver bromide itself (probably colloidal), rather than the formation of a solid solution in the usually accepted sense.

Numerous measurements substantiated Müller's observations that correct end-points are obtained in presence of 5% barium nitrate solution. Lottermoser used ammonium nitrate to remove adsorbed silver from silver halides, and Fajans and his co-workers (Fajans and Hassel, *Z. Elektrochem.*, 1923, 29, 495; Hassel, *Kolloid-Z.*, 1924, 34, 304) studied the adsorption of dyes, and

adsorption replacement by dyes, on silver halides, with particular reference to a titration method for halogen and silver using fluorescein and its halogen-substitution products as indicators. These and other substances, including some which are known to be strongly adsorbed by silver halides, were investigated by the author. Since the end-point error is most marked in the case of bromide-chloride mixtures, in some cases only this mixture was investigated; in others, iodide-bromide mixtures were studied as well. The method of examination in most instances was to titrate with  $N/10$ -silver nitrate a mixture of 5.0 c.c. of a  $N/10$ -solution of each of the halides in the presence of 50 c.c. of the solution of the substance investigated.

FIG. 4.

**Dyestuffs.**—Erythrosin (1 in 2000), fluorescein (1 in 2000), and rose Bengal 3 (1 in 2000) gave correct end-points with the bromide-iodide mixtures. In the case of the chloride-bromide mixture, fluorescein (1 in 2000) gave a partial correction, as shown in curve C, Fig. 4. With erythrosin (1 in 2000), the final end-point for the mixture was accurate and was marked by a definite jump in potential, but the first break, representing the bromide end-point, was flattened out. In Fig. 4, curve D is a titration curve obtained in presence of erythrosin (1 in 2000). Similar results were obtained in presence of safranin (Bayer, 1 in 1000). Curve A (Fig. 4) shows the curve in presence of water alone, and curve B the correct curve, in presence of 5% barium nitrate.

Correct end-points for both chloride-bromide and bromide-iodide mixtures were obtained with 5% solutions, not only of

CO\*

barium nitrate, but also of ammonium nitrate, sodium nitrate, and sodium acetate. The results with sodium acetate show that the effect is not due to the nitrate ion, and this was confirmed when it was found that *N*-sulphuric acid also gave practically complete correction.
